In the population of Belgium there were 91.14 males to 100 females in the cities, and 99.42 males to 100 females in the country districts. Among the deaths there were 101.45 males to 100 females in cities, 99.20 males to 100 females in country districts. There is, therefore, an excess of more than 5 per cent. in the deaths of males over females in cities, while the proportion of the sexes among the deaths in the country is scarcely different from that in the living, in the general population.

In the State of Rhode Island (1871) [City of Providence excluded], the average age of female decedents was 32.35 years, while the average age of this sex in the largest city (Providence) was 37.92 years.

I have stated, in another place, that the number of still-births and the proportion of males in such cases, was greater in the country (the excess amounting to 9.3 per cent. in Belgium) than in the city. This is in some degree due to the greater fecundity and larger number of male conceptions in the country districts over cities, but there are other causes to which the death of a larger proportion of the difference between the mortality from this cause in cities over the country is due: and principal among these I would suggest the delay and lessened facilities for calling in a practitioner, and less skilful obstetrical aid, afforded to the parturient woman and her issue. Seeing that still-births are more frequent in the country, and as this condition of the child is usually attended with greater danger to the mother, we are not surprised to find greater mortality among child-bearing women in the country than in the city. Whether the greater mortality of females of all ages in the country than in the city is principally due to this cause, I am not prepared to state, but am persuaded it is not.

In the State of Michigan (1870) there were 10,766 deaths, 150 or 1.3 per cent. of which were recorded as occurring among women in childbirth. In Philadelphia, for the 11 years ending 1870, there were but 93 deaths registered from this cause, or .053 per cent. of total mortality; of these, 1 was from 15 to 20 years of age; 43 were from 20 to 30; 41 were from 30 to 40; 8 were from 40 to 50; average age of all at death, 31.05 years. In Rhode Island, 1871, there were 27 deaths in childbirth, or .808 per cent. of whole mortality; in Providence, the principal city in the State, only .567 per cent. of total mortality was from childbirth. According to the U. S. census for 1870, the deaths from childbirth, abortion, and puerperal convulsions numbered 4,810, or .977 per cent. of total mortality. In 1860, 4,066 women died from these causes, or 1.033 per cent. of total mortality. In 1850, 3,117, or .965 per cent. of mortality. Quetelet has shown, in the following table on the influence of the sexes on the deaths at different ages, that from the 14th to the 50th year of age, or during the child-bearing period, in cities 1,025 females die for every 1,000 males, while in the country, 1,215 females die to every 1,000 males, during the same period. In this same table, which we give below, in cities, from 50 to 100 years of age, 1,185 females die for every 1,000 males.

* *Quetelet*, Sur la Reproduct., Mortal., etc., 1832, p. 68.

† 101.45 males to 100 female decedents in cities; 99.20 to 100 in country.

while in the country there are only 972 females to every 1,000 males attaining these ages. In Belgium, where these calculations were made, there are in the population, of all ages, 1,098 females to 1,000 males in cities, and 1,006 females to 1,000 males in the country.

There is scarcely a single city of any magnitude in which the female population is not in excess of the male, though there be an excess of from 2 to 6 per cent. of males in the births. The proportion of females in the population of cities, as well as in the births, is nearly always greater than in the surrounding country.

EFFECT OF RACE.

I have shown in my previous article * that race had some influence on longevity, but neglected to mention that the colored population of Philadelphia had a much lower degree of viability than the white,—the whites, during the period from 1820 to 1830,† lost 1 person by death to every 42.3 inhabitants, while the colored population lost 1 in every 21.7, or about twice as many proportionally; but what is most curious, is the fact that the black males lost 1 to every 14 colored inhabitants, while the black females only lost 1 to every 22 inhabitants; and this great difference is much increased when we state that the female portion of the colored population exceeded the male in numbers by 32 per cent., and yet they had an excess of male deaths amounting to 13 per cent., exclusive of still-births.

Thus it appears that the race which has a lesser degree of viability declines most in the male line. This statement is further illustrated and corroborated by the Rhode Island report for 1871,‡ which gives the average age of colored male decedents 23.13 years, while the females reached an average of 36.85 years.

In New Orleans (1872) about one-fourth of the whole population are colored people, while more than one-third of the total mortality was from among their number.

The greater mortality of colored people in large cities is probably due to the larger proportion of mulattoes among them. Mulattoes are less fecund, and have a larger proportion of female births and male deaths than either the pure white or black race alone. According to the census of 1870, there were 3,500 persons aged 100 years and above. Of these, 642 were native whites, 322 foreign-born whites, and 2,537 colored. Of the first, 383 were women and 259 men, or 676 males to 1,000 females; of the second, 187 were females and 135 males, or 721 males to 1,000 females; of the third, 1,652 were females and 885 males, or 535 males to 1,000 females. It is curious that there should have been so large a proportion of colored persons among the centenarians, as there are only about four millions colored to the thirty-eight millions of whites in the United States, particularly as all we have collected concerning this race has shown them to be shorter-lived than the whites.

Another proof of the decline of the race in the male line first, is seen in the frequency with which we meet with such passages as the following in genealogical, historical, and archæological research, viz.:—"Represented only through female descendants,"§ or, "the cases are few in which the best informed genealogical antiquary could show a male heir (*i. e.*, a person descended in an unbroken male line) to any of these heroes in any conspicuous position in the country," * or, "the name became extinct by his issue, an only daughter, marrying Mr. ——," &c. By reference to works on dormant and extinct hereditary titles of nobility, the frequency of the phrase "extinct from having no male issue," is quite noticeable.

This fact is further corroborated by Aristotle,† who says that "those who have been barren, and either after great care, or from any other cause, at last conceive, more frequently bear a daughter than a son." Hippocrates, Pliny,‡ and Lucretius§ are of the same opinion. The same authorities say that "some women never go to their full time, or if by dint of great care and the aid of medicine they do give birth to a living child, it is mostly a girl." Again, there is a much larger proportion of females among first‖ and last children than in intermediate births.¶ The greater the fecundity the greater the proportion of males, and *vice e versâ*. From all this it appears that there are more "only daughters" than "only sons."

"In in-and-in breeding," says Walker,** "I believe the generative power fails *first* or *chiefly* on the part of the male."

"You are, I think, probably right," says Mr. Knight, "in supposing that the powers of the male would first fail, though in nine cases out of ten or more the defect is in the female.

"I had reason to believe that in breeding in-and-in, to an injurious extent, the powers of the male fail first. I once, in the same season, reared two bulls, of which the parents were nearly related, and both proved perfectly impotent; at least both failed to get a single calf, though the young females bred well enough, whilst young at least."

This view of degeneracy is diametrically opposed to that of Devay,†† who says: "C'est presque toujours par les femmes que commence la dégénérescence des races et des familles."

Jews in Prussia have on an average, in their births, 117.79 males to 100 females, while the general population have only 106.50 males to 100 females, yet there are in the general population of Prussia, of all ages, 99.19 males to 100 females, while among the Jews there are only 96.72 males to 100 females. This difference is certainly too great to be accounted for by immigration and emigration, and is probably due to the greater viability of the Jewish woman, from which we may infer that the Jewess exceeds the Jewish man in years by a greater proportionate number than the Christian woman exceeds the Christian man. This, too, corroborates the statement already made, viz., that races decline in the male line first. An evidence of this decline is seen in the smaller stature of the Jewish man compared with the Jewish woman. The same thing may be observed among the Chinese and Japanese. Men whose ancestors have lived in cities for several generations are much shorter in stature than men who with their ancestors were born and bred in the country, while the women of the former class are not so sensibly, if at all, affected by city life; indeed, it would seem, as shown in another place, as if city life were rather favorable to "the sex" if the analogy of longevity holds. Of the stature of the human race Geoffroy St. Hilaire says:—

"Variations in stature in the human race are inclu-

ded in much narrower limits than individual variations. The size of women is less variable than that of men."

From the above it would appear that the *Jewish woman is exceptionally long-lived*, and the *colored man*, especially the *mulatto, is exceptionally short-lived*.

I am reminded that "we must always handle the manner or process of man's special creation with great reverence and caution. But if it shall ever seem allowable to apply to it the rule which prevails in reference to the lower creatures," we should be constrained to believe, from our researches and observations, that, from a *purely physical stand-point*, if the sexes were created separately, the woman was developed, evolved, or created first, and man, by a slower, more tedious process of evolution, was a secondary or higher development from the female, or if the original sexual condition were hermaphroditic, the male organization was eliminated from the female by developmental evolution. Man being the secondary creation is the first to exhibit physical decline or degeneration, and woman will consequently survive him in the process of final extinction of the race.

*Table exhibiting the number, proportion, and percentage of sexes in the population, births, and deaths, from some hereditary diseases and accidental causes, etc., occurring in the city of Philadelphia, from Jan. 1st, 1861, to Dec. 31st, 1871.**

* The above table was elaborated by the author from Geo. E. Chambers' (the Registrar) reports.

† In the author's paper on "Deaths from Cancer, occurring in Philadelphia from January, 1861, to Dec. 20, 1870, showing the relative proportion of males and females dying of this disease, and the percentage of women dying of Cancer of the Uterus" (Journal of Gynæcological Society, Boston, Sept., 1872, pp. 201–2–3–4; ext. in N. Y. MED. RECORD, Feby. 1st, 1873), he has shown that 2.32 per cent. more women die of Cancer than men, and that of all the women dying of Cancer, 28.66 per cent. die of Cancer of the Uterus, or 20.04 per ct. of the whole number of deaths from this disease without regard to sex; of these 39.2 per ct. die before the 45th year, and 60.8 per ct. after. Of all the women dying of Cancer, without regard to seat, 65.7 per ct. die after 45 years of age.

‡ The diseases referred to with the average age at death (as brought out in the paper above referred to) are—Cancer of Uterus, 49.08 yrs.; Cancer of Breast, 56.84 yrs.; Inflammation of Uterus, 27.94 yrs.; Ulceration of Uterus, 47.85 yrs.; Rupture of Uterus, 34.09 yrs.; Puerperal Fever, 29.55 yrs.; Child-bed, 31.58 yrs.; average age of all decedents from these affections, 39.53 yrs. The percentage dying at different ages was as follows:—15–20 yrs. 2.04 per ct.; 20–30, 23 per ct.; 30–40, 27.06 per ct.; 40–50, 18.27 per ct.; 50–60, 16.69 per ct.; 60–70, 8.07 per ct.; 70–80, 3.88 per ct.; 80–100, .92 per ct.; before the Climacteric, 61.88 per ct.; after the Climacteric, 38.12 per ct. Loc. cit., p. 2-2.

§ The proportion in Providence for 15 yrs. ending 1871 was 37 males to 100 females. In England, 1856, 4,069 males and 1,790 females died of Cancer, or as 41.3 males to 100 females.

* Governeur Emerson, M.D., on the excess of male over female deaths as exhibited in health reports of Philadelphia. American Journal Medical Sciences, 1835, p. 56; transl. into Annales d'Hygiene Publique by M. Villermé, 1836.

In Austria (1810) the females in the population exceed the males in numbers by a fifth. In Vienna, 1819, the females were nearly double the number of males.

MORTALITY IN UNITED STATES—CENSUS OF 1870.

The following table, from the Michigan Report, compiled by Dr. Baker, will show the ages by sexes of the living and decedents:—

Average age in years.

	Total.	Males.	Females.	Excess of Males.
Deaths, as per Census	24.79	25.17	24.39	.78
Living, as per Census	24.32	24.91	23.68	1.23
Deaths, as shown by Registration Returns	23.50	24.05	22.89	1.16
Deaths from Consumption, as shown by Registration Returns	34.95	36.89	33.14	3.75
All living, aged 20 and over, per Census	38.23	38.61	37.80	.81

TOTAL DEATHS BY SEXES.

Though there are but 89.50 males to every 100 females in the total population of the city of Philadelphia, or an excess of 5.5 per cent. of females and 110.65 males born to 100 females, yet 113.44 males die for every 100 females, and if still-births be excluded, still there remains a great excess in the proportion of male deaths, amounting to 112.29 to 100 females—being an excess of males amounting to 10.7 per cent. In 1832–3–4, the excess of male decedents amounted to 7.94 per. cent.* The deaths in Providence, R. I., for the 31 years ending 1870, amounted to 30,167, of which the sexes were about equal, while there were but 88.55 males to 100 females in the entire population. In the entire State of Rhode Island, for the 19 years ending 1871, there were 50,906 deaths, of which there were 97.7 males to every 100 females, while there were but 93 males to every 100 females in the population.

The United States census of 1870 gives 108.45 males to 100 females in the population, while in the 492,263 deaths of that year there were 112.5 males to every 100 females.

The average weekly deaths in London for the last 10 years, 1863–72, has been 788.8 males and 737.4 females, or as 1,069 to 1,000, while there are but 85 males to 100 females in the population.

DEATHS BY AGES AND SEXES.

By reference to the table it will be seen that 53.9 per cent. of all the deaths (excluding still-births) occurred before the 20th year of age, and 113.61 of these are males, to every 100 females; while of the remaining 43.7 per cent. who die after they have reached 20 years, 103.20 are males to every 100 females. It appears from these facts that from birth to 20 years, the viability of females is far greater than that of males, and though in adult life (after the 20th year) it is reduced, yet when we consider that there are but 89.50 males to every 100 females in the general population of all ages and a still smaller proportion of males among adults, the viability of males is much less than that of females. After reading this, it requires no effort of the reasoning powers to understand that the *proportion of females* in the population must *increase*, and this it does, even in the face of the larger accession of male immigrants; for in 1830 Philadelphia had 91.59 males to 100 females, while in 1860 the proportion was 90.93 to 100, and in 1870 it is probably less than 89.5 to 100.

*Proportion of Sexes among the Deaths in different Countries.**

Sardinia	1838	52.18	47.82

We see by this table that in every country measurably exempt from the influences of emigration, females are in excess, though there is an excess of 3 per cent. of males in the births.

STILL-BIRTHS.

From the moment of birth females have a higher viability than males. In Philadelphia, for the eleven years ending 1871, 4.8 per cent. of all the decedents were still-born children, of which there were 133.50 males to every 100 females, while in the total number of births there were only 116.65 boys to 100 girls. In Belgium, where the most accurate records are kept, 140 boys are still-born to every 100 girls in the cities; in the country districts, 169 boys are still-born to every 100 girls. The proportion of boys to girls in all births is, in cities, 105.29; in the country, 106.10, to 100 girls. This great excess of males in the still-born in country districts over cities, is very remarkable, and may be ascribed to larger size of child's head, and greater delay and less expertness in obstetrical aid. To this latter cause may be ascribed the greater mortality of women during the child-bearing period in the country over those in the city, as indicated by Quetelet's table.* I am constrained to believe, however, that the fact of a greater number of males being still-born than females is due to *defective development*, as well as the larger head. The fact of man being the type of the race, the highest degree of physical evolution yet exhibited by the human race, it follows that any defect or degeneration in development must be felt in the male first; and we feel warranted in asserting that the man is the first to exhibit signs of decline—in stature, weight, constitution, viability, &c. Thus we have a larger proportion of idiots, deaf, dumb, and blind among men than among women. So we have more malformations by defect among males, and more malformations by excess among females. Statistics show more idiots among men, and more insane among women. In Philadelphia, during the 11 years ending 1871, of the deaths from "malformation," 139 were males, and 87 females; or 159.77 to 100. In the city of Providence, for 15 years ending 1870, the deaths from this cause were, males 53, females, 33; or 162.42 to 100.

THE CERTIFICATES OF FAMILY PHYSICIANS.

By WILLIAM C. WEY, M.D.,

ELMIRA, N. Y.

An engagement between a physician and his patient, in its mutual obligations, is as binding, morally and legally, as any other implied contract, and the failure of either party to perform makes him liable for the consequences of his dereliction. In this respect the profession of medicine possesses no advantages over the trades or the ordinary commercial relations of society. Estimated by such a standard, medicine, while advanced to the dignity of a profession, is surrounded by and made subservient to the laws and usages which govern the arts and crafts, and is equally amenable to judicial review, discipline, and punishment. Unlike the arts and crafts, however, medicine is obedient to a law within itself, which may or may not find expression in a code of carefully-framed rules. Long before a written code of ethics found favor in the profession, which is a very modern suggestion, a sense of personal or individual honor among physicians served to keep inviolate the nature and terms of the engagement or contract between them and their patrons. The force and character of this agreement, though not strengthened by a written code, simply finds amplification in its precepts and declarations.

In a better, in one sense, though not in a more scientific or learned age, when a higher standard of honor prevailed, a written code was not required. Ignorance of professional ethics could not be accepted in extenua-

*Le Jeune, Memoire sur la Population, in *Journ. des Economistes*, 1847.

* Sur la Reproduct., Mortalité, &c. 1832, p. 68.

tion of their violation. In a looser period, with cheapened education, and, as a consequence, diminished honor and responsibility, a code of rules became necessary for the purpose of keeping the ranks in the profession informed and educated up to the standard of accountability current among the wiser and more loyal members of the brotherhood. In these days, as in former days, with or without a written code, a few lead the way, and the many follow or disregard the call, as they are impelled by education, habit, policy, or some other motive.

I am led to consider this subject in connection with the question—"Ought a family physician to grant a certificate in case of application for life insurance?"

I have no hesitation in asserting that it is no part of his duty to furnish information to a life insurance company in respect to the health of individuals who may have placed themselves under his professional care. Not only is it no part of his duty as a medical man, but it is virtually a betrayal of the trust and confidence imposed in unreserved relations between patient and physician.

Even with knowledge that the person to be insured is, and always has been, in such absolute health as to make reply to the questions asked on such an occasion a mere matter of form, and an endorsement of his physical and mental state, like endorsement of his credit or character, it is quite as much a professional act and service as if the physician's statement raised a doubt in respect to the integrity of the applicant's pulmonary or psychological functions.

If it is a friendly office purely, it carries professional significance along with it, thereby violating obligation on the one hand under cover of a personal favor, and communicating valuable information to a life insurance company on the other.

If the certificate is given for a fee, paid indifferently by the party seeking to be insured or by the company, it suggests an imputation that a moneyed compensation may influence the judgment to be rendered. This objection, in view of the paltry sum usually paid by an insurance company, is scarcely worthy of consideration. In the former case, it may be well to observe that an opportunity is offered an unscrupulous applicant and an equally unscrupulous "family physician" to combine, and for a purpose to produce a certificate, which shall reveal a standard of health upon which a policy of insurance will be sure to follow. If a physician, occupying the position of medical examiner for a highly reputable life insurance company, was found so culpable and criminal as to recommend a consumptive, in the last stages of disease, as a first-class risk, on whose life a policy was issued, it is not difficult to conceive of collusion between an applicant and a family physician, prompted by motives equally offensive and condemning.

It is exceedingly disagreeable to dwell on this feature of the subject, as evidencing loose morals in the profession. An ideal standard of medicine takes no cognizance of such illustrations of baseness. Every-day practical experience with the profession as it is, and not as it should be, or indeed as it would be, if raised to an even or uniform basis by education, has forced upon us the unwelcome conviction that, in spite of codes and journals and books and teaching from an endless variety of sources, the *average* men in our ranks are not above suspicion of being governed by selfish and mercenary motives.

The opinion of a reliable family physician, far beyond the recommendation of a medical examiner, carries weight with a life insurance company. Hence the importance of obtaining his approval of a risk. Paradoxical as it may appear, the physician knows the applicant, the corporeal applicant, more intimately than he knows himself. In the undisguised character of patient, his physical, mental and moral attributes have been clearly revealed to his attendant. Nothing has been withheld, simply for the reason that to keep back information would limit the ability of the physician to render prompt and efficient aid and service.

Considering the confidential relations thus engendered and the value of the information acquired by the physician, the usual questions asked in this connection by a life insurance company—"Have you been in the habit of seeing him frequently? Have you given him medical attendance? If so, for what diseases?"—must appear like an attempt harshly to invade the precincts of the sick-room, and cause the medical attendant to betray the interests of those who have implicitly confided in his truth and honor.

The questions above given cover the whole ground of a physician's intimate intercourse with his patient, laying bare his responsible and guilty acts as well as the infirmities for which he is not accountable.

Surely it is not the object of life insurance companies to seek to compromise the office of family physician, or to invite, or for compensation to engage, him to do violence to his scruples and convictions. The custom of requiring a family physician's certificate in application for life insurance was established as a matter of business, without considering the nature of his engagement to his patient or the extraordinary demand which it exacted.

It is remarkable that a common professional sentiment did not, long ago, protest against such an attempt to procure information, on the ground, already mentioned, of infraction of ethics, and disregard of individual obligation and propriety. That a more correct estimate of this question is current in the profession I am disposed to believe, from pretty large observation among my colleagues, and from the more general extension of life insurance interests in every city, village, and hamlet in the State. The subject is thus brought directly to the attention of medical men, and they are compelled to give it more than usual scrutiny,—such scrutiny as embraces the delicate nature of the duties of the family physician in a specific as well as in a more enlarged and comprehensive field.

ON METHOD IN THE EXAMINATION OF APPLICANTS.

BY A MEDICAL DIRECTOR.

THE physician, when called to pass judgment upon the life-probabilities of an applicant, is in very much the same position as the watchmaker whose opinion is asked about the quality of a watch. The latter first glances at the case, then opens it and reads the maker's name, and finally, having listened to the action of the escapement, inspects the complex machinery filling its interior. If fairly experienced in his art he will then pass a tolerably correct judgment upon the qualities of the watch.

In a very similar manner the physician should examine into the moral and physical antecedents and condition of the applicant. He should first look at the case,—his general exterior, his expression and complexion; whether, for example, he is emaciated by disease or bloated by alcohol; whether nervous and timid, or too eager to boast of his physical endowments and promise of long life. All these points can be carefully and quickly noted by the examiner during the brief time occupied by the interchange of the ordinary courtesies.

The maker's name, if genuine, tells as important a story to the watchmaker as the applicant's family his-

tory does to the medical examiner. A knowledge of the inherited tendencies to disease should be in the possession of the examining physician before he inquires, either by cross-examination or by direct exploration, into the physical condition of the applicant. Hence the second step of the examination should consist in ascertaining as correctly as possible the family history.

Next comes the personal history; and here the parallel no longer holds good. The watchmaker does not care to be told what injuries the watch may have met with, for, if these have been at all serious, he will be able to detect them by a careful inspection. The medical examiner, however, depends largely on the personal history of the applicant in forming his judgment of the desirability of the risk. The sicknesses and physical injuries of the past throw considerable light upon a person's life-probabilities; they also lead the physician to interrogate certain organs or functions more carefully than he otherwise would. For example, previous attacks of inflammatory rheumatism would call for a more than ordinarily careful investigation of the heart and lungs; and an attack of lung fever, so called, would lead us to cross-examine the applicant very thoroughly regarding the circumstances under which the disease first manifested itself, the symptoms developed, the length of time before convalescence set in, and the subsequent persistence of a cough.

In this connection I would venture the suggestion that, having listened to the applicant's answer to the broad question,—"What sicknesses have you had in your lifetime?"—we should "jog" his memory by interrogating the organs of the body one by one, commencing with the head and passing on down to the feet. Thus, for the head, we can put the following series of questions:—Are you subject to headaches? Have you ever had "fits" of any kind? Have you ever been out of your head? Are you subject to dizziness? Have you ever been paralyzed? Have you ever had any difficulty with your eyesight? Have you ever been troubled with a discharge from the ear? Are you subject to sore throat? In the same manner the various organs of the chest and abdomen may be interrogated in a very short time.

The question, "Have you any swellings or sores in any part of the body?" which is intended to elicit the necessary facts regarding the integumentary system, sometimes brings to light deeper and more serious troubles. The following incident, which occurred recently in one of our offices, illustrates the importance of this question:—

The applicant, an apparently healthy man, had answered all the physician's questions favorably, and was found upon physical exploration to have a sound heart and lungs. In answer to the question just mentioned, he said he had noticed for some little time past a small lump in the groin, but, as it had given him no trouble, he had paid no attention to it. The physician examined the lump and found it to be a small aneurism of the external iliac artery.

Aided by a knowledge of the applicant's personal and inherited weaknesses, the physician will be better prepared for the last step of the examination,—the physical exploration. If he were to resort to it at first, the ordeal of auscultation and percussion of the chest would be pretty sure to accelerate the heart's action to such a degree that he would not be able to form a correct idea of its habitual rate, rhythm and force. It is therefore better to postpone the physical examination to the last.

It is not the purpose of this brief article to discuss how this part of the examination should be conducted, but simply to suggest what seems to be the most practical and at the same time the most logical order in which to carry out the details of the investigation. By adopting a definite method and always following it in our examinations, we shall avoid the danger of omitting some important part of the inquiry. This will appear the more necessary if we but bear in mind that the applicant will rarely volunteer any information that may cause his application to be rejected, though he is ready to answer all our questions truthfully.

OUR LIFE INSURANCE DEPARTMENT.

To the Editor of The Medical Record.

I am much gratified to see that you have added the medical side of life insurance to the many other interesting and practical features of your journal. The articles presented are all of much practical value, and just this kind of information is sadly needed by the majority of medical examiners.

Permit me, as an examiner of some experience, to call attention to some points connected with the business, which I think deserve attention. . . .

The article in Record for May 15, entitled "On the Relation of the Medical Examiner to the Business of Life Insurance," by a Secretary, is very just and true, and certainly demands no more of examiners than a proper personal independence and appreciation of professional obligation would at all times prompt the *right-minded* to perform. But just here is the trouble, and the secretary evidently understands it, for he says it is this very want of personal independence which is far more dreaded by underwriters than any mere want of professional capacity. Unfortunately the two combined are not unfrequently met with, and I have seen and known of more than a few instances of such an utter want of both in the examiner as to make him the *subservient tool* of the agent. It is the agent's business to solicit risks, and it is his pecuniary interest to have those risks approved at the home office; so he is never backward in using an ass of a doctor if he can. And not infrequently does it occur that the agent purposely avoids giving business to a man he knows to be competent and independent, preferring a more *compliant* examiner.

I have been cognizant of this state of things for so long a time, and have seen but little, and very imperfect, effort made for its correction, that I have begun to think the companies were indifferent about it—supposed they were making fortunes rapidly under this kind of procedure, and did not care to make any additional effort to correct abuses.

If a remedy for this condition of affairs should be sought, I would suggest that one step in the right direction has been taken in securing the co-operation of your journal; another, and most prompt and decided check on these abuses, would be the securing of *competent and reliable medical* men as inspectors of agencies, paying such salaries as would command competent men, who would give the business their entire time. A competent medical man would, by the very nature of his professional training, and sharpened powers of observation, be capable of going into any agent's district, making the acquaintance of the physicians acting as examiners, and *others not so acting*, and render a far more correct opinion, *cæteris paribus*, than a non-professional inspector. . . . .

Permit me, in closing, to suggest that according to my observation here in the South, the tables of average weight to height are at least ten pounds higher than a correct estimate. Medical Examiner.

Original Lectures.

CLINICAL LECTURES ON PUERPERAL FEVER.

DELIVERED AT BELLEVUE HOSPITAL,

BY FORDYCE BARKER, M.D.,

PROFESSOR OF CLINICAL MIDWIFERY AND DISEASES OF WOMEN IN BELLEVUE HOSPITAL MEDICAL COLLEGE.

(Reported phonographically for the MEDICAL RECORD.)

LECTURE I.

DR. VAN WAGENEN read the following history:—

Annie ——, æt. 25, primipara. Labor natural. First stage, 2.26; second stage, 5.25 h.; third stage, 5 m.

Delivered Dec. 31, 12.30 A.M.

Dec. 31.—P.M.: Respiration, 28; pulse, 104; temp. 99½°.

Jan. 1.—Respiration, 28; pulse, 120; temp. 102.

Jan. 2.—P.M.: Respiration, 50; pulse, 145; temp. 105°. Patient is sweating profusely.

Jan. 3.—A.M.: Respiration, 40; pulse, 105; temp. 103°. Patient was sponged and the temperature fell.

Jan. 4.—Respiration, 30; pulse, 138; temp. 102°. Patient behaves in a very hysterical manner.

Jan. 5.—Respiration, 40; pulse, 120; temp. 101°.

Jan. 6.—Respiration, 36; pulse, 138; temp. 101°. P.M. Patient was relieved by catheter of ℥ viii. of urine.

Jan. 7.—Respiration, 30; pulse, 111; temp. 102°. 9 P.M.: Abdomen tympanitic, and very slight pain upon the right side.

Jan. 8.—11½ A.M.: Respiration, 60; pulse, 135; temp. 104°. Patient feels quite well. Ordered ⅛ gr. of morphine, stupes of turpentine, and quinine, grs. iii. q. 3 h. 3½ P.M.: Respiration, 36; pulse, 120; temp. 100°. 8 P.M.: Temp. 102⅘°. 12 midnight: Sol. morph. (U. S.) ♏ ii. Stupes and quinine continued. Slight tympanitis and tenderness.

Jan. 9.—6 A.M.: Sol. morph. (U. S.) ♏ ii. Slight tenderness and tympanitis. 9½ A.M.: No tenderness. Respiration, 30; pulse, 120; temp. 103°. Sol. morph. (U. S.) ♏ i. 12 M.: Respiration, 24; pulse, 123; temp. 103°. Some tenderness, especially upon right side of abdomen; no stool to-day; sleeps most of time. Sol. morph. (U. S.) ♏ i. and tr. verat. virid. ♏ iii. Catheterism. 2.45 P.M.: Ord. ℞ Tr. ferri mur. ♏ ss.; quiniæ sulph. ℈ i.; aquæ puræ, ♏ iss.; Syr. aurant cort., ♏ ii. M. Sig. ♏ ss. q. 3 h. and tr. verat. virid. gtt. iii. q. 1 h. 4.30 P.M.: respiration, 21; pulse, 120; temp. 101⅘°. Pupils contracted; tympanitis, and tenderness upon right side; tongue white. 6.45 P.M.: respiration, 27; pulse, 120; temp. 103. Patient sleeps all the time; pupils contracted; perspires freely. 10 P.M.: respiration, 24; pulse, 120; temp. 103°. Perfectly conscious and answers questions intelligently. Tr. verat. virid. gtt. v. and sol. morph. (U. S.) ♏ i. Some subsultus; no pain; ice to eat, and milk.

Jan. 10.—4 A.M.: Has received tr. verat. virid. in gtt. iii. doses every hour since 10 P.M. of the 9th, and sol. morph. (U. S.) ♏ i. doses every two hours. Pulse, 85; temp. 102°. Has been vomiting freely for about half hour dark greenish matter; no pain. Tr. v. v. gtt. iii. 7 A.M.: Patient has vomited considerably since 4 A.M. Sol. morph. (U. S.) ♏ i. and tr. verat. virid. gtt. iii. 8.30 A.M.: Respiration, 18; pulse, 90; temp. 100⅘°. No tenderness over abdomen upon percussion; ice discontinued. 9 A.M.: Patient received tr. verat. virid. gtt. iii., sol. morph. (U. S.) ♏ i., and ♏ ss. of the mixture of quinine and iron. 10.30 A.M.: Respiration, 24; pulse, 93; temp. 101¾°. Sol. morph. (U. S.) ♏ i. and tr. verat. virid. gtt. iii. There is slight pain over lower part of abdomen. 12 M.: Respiration, 30; pulse, 105; temp. 102. Patient has been awake and talking to the other patients. Sol. morph. (U. S.) ♏ ii., tr. v. v. gtt. v. 2 P.M.: Respiration, 28; pulse, 108; temp. 103¼°. Patient now has pain over whole abdomen; breathing mostly thoracic; limbs not flexed upon abdomen; has just vomited again about a quart of fluid of a light-green color. Sol. morph. (U. S.) ♏ i. tr. v. v. gtt. v. 3 P.M.: tr. v. v. gtt. iii. Vomited a little in about 10 minutes after taking the last medicine. 4 P.M.: Respiration, 20; pulse, 90; temp. 103°. 8 P.M.: No vomiting since 3.10 P.M.: Tr. v. v. has been continued every hour in gtt. iii. doses, and morphine in ♏ i. doses every two hours. Now, considerable pain over abdomen; sleeps constantly; easily aroused; answers intelligently. Respiration, 24; pulse, 115; temp. 103. Ordered tr. v. v. gtt. v., sol. morph. (Mg.) ♏ v. hypodermically. 10 P.M.: Some pain and tenderness. Respiration, 25; pulse, 108; temp. 103½. Sol. morph. (Mg.) ♏ vi. and tr. v. v. continued in three-drop doses. 12 midnight; Respiration, 16; pulse, 96; temp. 103¼°.

Jan. 11.—2 A.M.: Respiration, 16; pulse, 90; temp. 102⅝°. Respiration very shallow and irregular; one deep breath followed by 6 or 8 almost unnoticeable ones; pupils firmly contracted; thighs flexed upon abdomen; received tr. v. v. gtt. iii. and soon vomited about ♏ viii. of dark-green material; there is considerable abdominal tenderness. Respiration, 13; pulse, 88; temp. 102⅝°. 2.30 A.M.: Hiccough; medicine discontinued. 4 A.M.: Thorough opium narcotism. 6 A.M.: Respiration, 14; pulse, 90; temp. 102⅝°. During last two hours patient has taken ♏ x. of milk and ♏ ii. of brandy. 9.20 A.M.: respiration, 24; pulse, 99; temp. 103°. 11.20 A.M.: respiration, 30; pulse, 105; temp. 103⅜°. 1 P.M.: respiration, 30; pulse, 99; temp. 103. 2.30 P.M.: respiration, 24; pulse, 112; temp. 103½°. 5 P.M.: respiration, 18; pulse, 114; temp. 103. 8 P.M.: respiration, 21; pulse, 120; temp. 104. 9.25 P.M.: respiration, 21; pulse, 111; temp. 103½°. Patient wanders, and has tried to get out of bed. 11 P.M.: respiration, 18; pulse, 114; temp. 102¾°. Brandy ♏ ii. during last hour; thigh flexed upon abdomen.

Jan. 12.—1.30 A.M.: respiration, 24; pulse, 105; temp. 103½. Thigh extended. Sol. morph. (Mg.) gtt. vi. 3.45 A.M.: respiration, 18; pulse, 99; temp. 103. Slight vomiting; first within 25 hours. 6.30 A.M.: respiration, 21; pulse, 93; temp. 102°. Answers intelligently; pupils contracted firmly. 7 A.M.: Gave a warm enema of brandy, ♏ ss., milk and beef-tea, each ♏ ii., and quinine, grs. x. 8.30 A.M.: respiration, 18; pulse, 96; temp. 102⅘°. 10.20 A.M.: respiration, 27; pulse, 102. 12 M.: Patient has had a stool, quite solid. 12.15 P.M.: respiration, 18; pulse, 114; temp. 103¾°. Respiration irregular; slight delirium. Sol. morph. (Mg.) ♏ viii. 5.45 P.M.: respiration, 20; pulse, 120; temp. 103¼. Thighs flexed upon abdomen. Sol. morph. (Mg.) ♏ viii. hypodermically; no pain. 8.30: Enema of same material as above, with tr. v. v. 9 P.M.: respiration, 16; pulse, 105; temp. 103¾°. 11.20 P.M.: respiration, 12; pulse, 105; temp. 104; respiration extremely irregular.

Jan. 13.—4 A.M.: respiration, 30; pulse, 120; temperature, 103¾°. 6.30 A.M.: respiration, 30; pulse, 135; temperature, 103½. 9 A.M.: respiration, 28; pulse, 150; temperature, 105°. 10.30 A.M.: respiration, 24; pulse, 156; temperature, 106°. 1 P.M.: respiration, 18; pulse, 150; temperature, 106½. 4 P.M.: respiration, 36;

pulse, imperceptible; temperature, 107¼. Died at 4½ P.M.

From Jan. 11, at 6 A.M., until her death, the treatment was continued by using the tr. veratrum viride in doses varying from 1½ to 6 drops every hour or two hours; sol. morph. (Mg.) in doses, hypodermically administered, varying from ℥iii. to ℥viij.; quinine, stimulants, and nourishment given both by mouth and as injections. Vaginal injections of carbolic water and stupes of turpentine were used throughout.

Autopsy made on the 14th of Dec., by Dr. F. Delafield. Brain not examined; heart and lungs normal; liver soft and medium size; kidneys appeared normal; entire peritoneum and contained viscera thickly coated with yellow lymph (pus and fibrin); about 1 quart of purulent serum in the peritoneal cavity; peritoneum not congested. No change in pelvic cellular tissue; uterus bound to right side, coated entirely with lymph; internal surface appears normal. At the insertion of broad ligaments, uterine sinuses filled with puriform fluid, and small abscesses in uterine tissues. Fallopian tubes congested; ovaries congested.

GENTLEMEN: we have now had two cases die in this hospital of puerperal fever. We have no more of the disease at the present time.*

One woman has shown some symptoms of it, but has seemed to respond to the precautionary measures which have been adopted for its arrest.

The question for our consideration now is, what is puerperal fever?

It is that question which I propose to answer. I shall not enter into a detailed account of all the various opinions which have been presented with regard to its nature; for hardly any two authors agree.

There is, perhaps, no department of pathology in which the productions have been of a higher intellectual order than those we already have in our possession upon this one subject.

I already have upwards of 30,000 pages upon this subject in my own library, and yet variation in opinion is characteristic of the whole.

At one time it was believed to be a peritonitis; at another a phlebitis; another class of observers have believed it to be an inflammation of the peritoneum associated with an inflammation of the veins of the uterus and its lining membrane, each or all combined.

In short, a vast number of authors, who are men of the highest intellectual order, and have had the greatest opportunities for observation, have taken the ground that the fever was a local inflammation of some of the tissues, or some of the organs connected with the uterus, occurring during the puerperal period, and that the constitutional symptoms were due entirely to these local inflammations.

The more recently expressed views, which are the currently accepted ones by a great majority of the profession of Germany and France, and to a certain extent in Great Britain, are, that it is an error to suppose that it is a purely local inflammation, but that it is a constitutional poison resulting from the absorption of pus, and carrying it into the circulation, undergoing a peculiar degeneration or decomposition, constituting what is known as septicæmia.

Then, again, there have been a class of men, to whom I belong, who regard puerperal fever as an essential and distinctive disease, having a special poison, the nature of which has not been determined, but which is just as distinct in its character as is the special poison of scarlet fever, typhus fever, small-pox, erysipelas.

My own belief is, that it has a special poison, characterized by certain general phenomena which always belong to the disease, with anatomical lesions which take the epidemical type of the seasons or of the locality in which it occurs; that it may be or it may not be accompanied with any of the local lesions; that it differs from inflammations in its nature and its results, but any and all of the inflammations may be present.

We are aware that it produces purulent deposits, and if they have an external manifestation anywhere it is to be regarded as an effort of the system to eliminate the poisonous element, and the prognosis is more favorable; but when the deposits take place in the internal organs it must be inevitably fatal; that it may be or may not be accompanied by septicæmia; but more frequently in prolonged cases, such as those which last for five or eight days, it is accompanied with septicæmia, but in other cases it is not.

Now, as these views are contrary to the current opinions of the day, I am bound to give my reasons for them. You must not accept them unless they are satisfactory to you. You will do well to examine all the arguments *pro* and *con*, and form your own distinctive personal conclusions and opinions upon all medical subjects, for there is no greater barrier to the progress of medical science than to accept the opinions of medical authors simply because they are regarded as medical authorities.

The principal reasons for the views which I hold with regard to puerperal fever may be embraced under four heads.

First.—That puerperal fever has no special characteristic anatomical lesions.

In one epidemic you will find one lesion, perhaps it may be peritoneal inflammation; this probably is more frequent than any other, and at the same time the epidemic has shown itself where no peritoneal inflammation has existed. In another epidemic all of the lesions may be referred to the thoracic cavity, and purulent or sero-purulent deposits will take place in the cavities of the pleura and pericardium. This shows to us that the peritoneal lesions are not an essential characteristic of the disease.

In the year 1862 we had an epidemic of puerperal fever in this hospital, in which the patients exhibited all the general characteristic symptoms and phenomena, but autopsies showed an entire absence of all lesions in the peritoneum, uterus, uterine sinuses or ovaries. There were found the same kind of pathological lesions in the pleura and pericardium as are seen upon the peritoneum when the lesions are manifested there.

Sometimes the lesion is found principally in the plugging up of the veins of the uterus.

Virchow teaches that it is always so; that the open mouths of the sinuses become blocked up by little thrombi; that these thrombi degenerate, become purulent, and, secondarily, produce inflammation of the lining membrane of the veins; from which pus is carried into the circulation, and constitutional disturbance is the result.

While, however, this may characterize one form of epidemic, it may be absent in nine others. So again you will find all these entirely absent, and the uterus itself will be broken down in its structure, and there may be evidence of gangrenous degeneration of the walls themselves; but this too shows itself only in connection with certain epidemics, and is not characteristic.

In still other cases, and such epidemics have been seen in this hospital, the patients have died, but there was *no lesion* to explain the death. Some authors assert that the lesions are not present, because they are not looked for, and that pus can always

* January 23.

be found. Pure pus alone, however, will produce no serious disturbance in the system in many instances, as is well known, if it does pass into the circulation.

Second.—These lesions are not sufficient to explain the cause of death or the progress of the disease. I think that this may be safely asserted as a fixed law with reference to this disease. The more intense and rapidly fatal the disease, the fewer are the lesions that are found. Just in an inverse proportion to the violence and severity of the disease is the amount of the anatomical lesions. The cases are not very infrequent in which the patients have manifested the first symptoms and died within twenty four, thirty-six, or forty-eight hours, and the more violent the disease is, the more rapid and violent its course, the less of anatomical lesions are found at post-mortem; and from this we have a demonstration that it is not the lesions which cause the death. I became convinced of this fact many years ago, and I arrived at that conclusion by the most minute examination in the way of pathological lesions, in the most violent cases. I would not detract from its value in the least by any experience which I possess to-day, and I think it is a very common mistake to regard these results as the original cause of the disease.

The intense violent poison kills the patient before there is any time for these distinctive changes to take place, which constitute in the minds of many the characteristic features of the disease.

Third.—We may have the most intense inflammation of the pelvic organs, and the disease not be puerperal fever. The autopsical lesions and symptoms in such cases are very different from what is associated with these inflammations when connected with puerperal fever. The patient may have all the violent symptoms described as characteristic of peritonitis, such as intense pain, flexure of the thighs upon the body, exquisite tenderness, etc., and yet only have peritonitis modified simply by the condition of the woman in a puerperal state, following its usual course and terminating in the same way, and no puerperal fever at all. This patient has had puerperal fever, but has had none of the exquisite tenderness which requires the knees to be drawn up, yet has had some pain and some tenderness upon pressure. The same thing is true of phlebitis. This may occur after or previous to confinement, and may not be a severe disease.

Fourth.—The lesions differ essentially from those produced by inflammation. In an ordinary case of peritonitis the result is an intense capillary injection of the surface of the peritoneum, and the production of plastic lymph.

If the peritoneal lesion is the predominant feature in the puerperal fever, we have no bright scarlet hue, but the dark hue from venous and capillary congestion. The effusion, instead of being an adhesive fluid, is commonly so only in a very slight degree, and is generally made up of broken-down pus, flakes of lymph, a pus always sanious and sometimes colored with blood. In the same manner I might go through with the lesions of phlebitis and point out their distinguishing characteristics, but my time is now too limited.

The next characteristic of this disease which shows that it is dependent upon a special constitutional poison, is the fact that it is contagious. I believe the evidence is complete which proves that puerperal fever is contagious. This is not so with regard to special inflammations.

This character, that of the contagion, is sufficient of itself to protect it from being considered as a pyæmia or septicæmia. There are numerous illustrations where some physicians, who have been exposed to puerperal fever, with or without hospital practice, and who have exercised the greatest precaution, have had every woman die, with whom they were present during their confinement, with puerperal fever; while another physician in the same locality will not lose a single patient with the disease. Has it ever been known that one surgeon exposed to septicæmia or pyæmia has thus rendered himself more dangerous to his other patients, while all other surgeons of the same neighborhood were exempt? This alone is sufficient to demonstrate that there is something distinct between the poison of puerperal fever and that of pyæmia or septicæmia. At the same time I not only admit, but assert, that pyæmia and septicæmia do very often occur in connection with puerperal fever.

Some thirty years ago an epidemic of erysipelas broke out in a town some twenty miles from where I was then practising medicine. During the prevalence of that epidemic every woman who was confined in that vicinity died of puerperal fever. The association of erysipelas with puerperal fever has been very often noticed, and some writers have spoken of the poison of the two as being identical; but I do not think there is sufficient proof that they are identical. In this epidemic, however, there was one circumstance which was sufficient to illustrate at least the close affinity which the two poisons bore to each other.

I also believe, contrary to the assertion made in special text-books, that puerperal fever is not confined to hospitals in large cities.

I have just referred to one epidemic where it was associated with erysipelas, and can refer to other epidemics in the country where it has been associated with exanthematous diseases, or entirely independent of any of them, yet all occurring in rural districts, which does away with the idea that it is a hospital disease.

Why is it untenable to suppose that the poison of puerperal fever produces septicæmia, while we know that erysipelas produces septicæmia and pyæmia, and that we also have them occurring in connection with the blood-poisons, as typhus, scarlet fever, erysipelas, etc.?

I will recur to my original points in answer to this, viz.: that puerperal fever is a constitutional, specific disease, having its essential poison, which acts through the medium of the blood, producing its local lesions, its specific forms of development according to certain elective affinities, dependent on the nature of the epidemic surrounding it.

This is my gospel, and I only ask you to consider the question for yourselves.

The clinical history and treatment will be considered at our next lecture.

Original Communications.

CONTRIBUTIONS TO OTOLOGY.

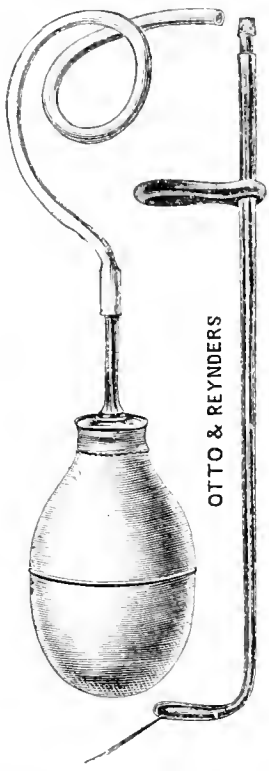
By O. D. POMEROY, M.D.,

NEW YORK.

1. *A Fenestral Eustachian Catheter.*

THE object of this instrument is, as its name implies, the catheterization of the Eustachian tube by means of an instrument passing through the throat instead of the nostrils, as is done with the ordinary catheter. The claim set forth with the above instrument is, that its introduction behind the uvula is much more easily and rapidly effected than by the ordinary instrument, and with less violence. When inflation only is needed, the instrument at one insertion may be

passed, first to the mouth of one tube, and then to the other, by simply turning the beak of the catheter to the opposite side of the throat. The instrument consists of a hard rubber tube, seven and a half inches in length; breadth, at its larger portion, one-fourth inch, tapering to the beak, which is a little more than one-eighth of an inch in thickness. At the larger extremity is a tip for the adjustment of a rubber tube; beyond this, at a distance of an inch and a half, is a perpendicular *guide* passing in an opposite direction to the bent extremity of the tube (in the wood-cut it is wrongly placed), showing the direction of the beak of the instrument when in position. The bent portion of the tube is one inch and three-sixteenths in length (for children it may be about three-fourths of an inch in length), and forms an angle of 70° to 75° with the straight portion of the tube. Within a line or line and a half of the extremity of the tube is the aperture for the injection of air or fluids, and which is the size of a



number one Bowman probe, and is placed at an angle of 50° with the bent portion of the tube; that is, not quite in the end, but a little beyond it, so as to throw the stream of air or fluid *from* the operator rather than *towards* him.

By inspection, this aperture will be found to be nearly in the axis of the Eustachian tube when the instrument is in position.

The catheter is used in the following manner, to wit: It is attached to a Politzer bag, with the usual perforation (for filling with air), by means of a rubber tube; the instrument is then caught in the left hand by its extremity (not by the guide), and, turned on the flat, passed along on the dorsum of the tongue, until opposite the aperture behind the uvula, when it is suddenly turned upwards, and passed to the region of the tube; if the tonsils are enlarged, presenting a too narrow cleft for this semicircular turn, then it must be passed in with the beak turned upwards, and the tongue depressed, either by the instrument or a tongue-spatula.

When it is well behind the uvula, it may, for the right side, be turned so that the guide stands about at an angle of 50° with the horizon, when the aperture in the beak of the instrument will be opposite to the fossa of the Eustachian tube; the opposite turn for the left side brings the instrument in position for the left tube. In all cases it will be well to slightly draw the instrument towards the operator, after its passage behind the uvula, especially if the latter contracts upon it, and against the back wall of the pharynx, which so frequently results. If the uvula persists in this position it is advisable to withdraw the instrument before attempting the opposite tube, as, under these circumstances, much violence might result (*i.e.*, in the excursion of the beak of the instrument from one tube to the other). The proper test as to whether the tube has been placed in position is, first, the facility with which the cavity may be inflated; and, second, in applying a small portion of a very strong caustic solution, it may, by the rhinoscope, be seen whitened exactly where the aperture of the tube was placed during the injection of the solution. The writer, with a twentieth of a drop of a saturated solution of nitrate of silver, has frequently cauterized a minute disk of mucous membrane within the fossa of the tube. The inconstant position of the faucial extremity of the Eustachian tube has not by the writer been observed, as described by some, the position being, according to his experience, sufficiently uniform to give little or no annoyance; but even if it is a little irregular in location, the rhinoscope detects it easily enough.

Any introduction of a faucial catheter under sight by means of the rhinoscope is regarded by the writer as so nearly impossible as to be wholly impracticable. The injection of the tympanic cavity with air by means of this instrument is readily done by compressing the rubber bag when the instrument is in position, and may, if the throat is irritable, be done in a second. If a powerful effect is desired, the aperture in the catheter may be made larger, when all the inflation desired may be attained.

This operation is more readily done ordinarily than Politzer's.

For the injection of fluids the following manœuvre is indicated, and we will assume that nitrate of silver is used: With an atropine dropper, or any convenient instrument, a fractional part of one drop, or two, three or six drops is deposited on an artist's palette, a card, or even a piece of white writing-paper; the beak of the catheter at its perforation is immersed in the drops with the rubber bag compressed (the thumb or finger on the perforation in the bag), then it is allowed to fill with air from the beak of the catheter (and not from the aperture covered by the thumb), by which means the drop is drawn into the tube through this minute aperture. When applied to the Eustachian tube, a second pressure on the bag injects it into the fossa of the tube, and sometimes a little way into the tube itself, in the form of a coarse spray. If a really fine spray is needed, a very minute aperture may be made, but this will not sufficiently inflate the cavity with air, and will give some trouble to keep it from becoming clogged. I had not before stated it, but it is intended to inflate the cavity as well as apply the remedy at the same time.

In ordinary catarrh of the tube I prefer not to throw the solution far into it, and not at all into the cavity, which is so liable to result from ordinary catheterization.

This instrument is not new, so far as injection of the cavity with air is concerned, but, with its general scope the author thinks it may come under the head of "a useful modification of an instrument." As this was used some time before I had heard of Cutter's catheter, and as its construction is essentially different, I have thought best not to make any special allusion to it.

In the cut the spray emerging from the end of the tube is somewhat imperfectly represented.

2. *A Case of Suppurative Inflammation of the Middle Ear, with exfoliation of the whole of the temporal bone, except the lower portion of the external auditory meatus, and the inner portion of the petrous bone. Recovery with slight facial paralysis of the same side.*

John Eddington, aged twenty months, applied to the College clinique on July 26th, 1871, for a discharge from the right ear, which had continued for the last three months, and now accompanied by great pain. There was a pale-looking, boggy swelling over the mastoid region, without distinct signs of fluctuation, which I at once pretty freely incised, without evacuating pus.

In two or three days, however, a purulent process was inaugurated. The child previously had head symptoms which were partially relieved by the operation. A poultice was applied to the wound.

On the 28th, there was considerable cellulitis extending about the auricle and towards the front. Another incision was made, enlarging the old wound upwards and forwards towards the greatest amount of swelling; the bone was felt to be rough and of unequal depth.

Sept. 1st.—Swelling less; child looks much better generally.

Sept. 4th.—The bogginess has extended further upwards, which resulted in the making an incision still further in the same direction. At the upper end of the wound the probe suddenly passed a half inch into the mastoid cells. After the last division of tissue the patient continued to do moderately well for the next three months, although there was great swelling of the tissues in front of the auricle, tempting one to incise, but from the proximity of large vessels it was thought to be an unsafe procedure. Water almost from the first could be passed from the external auditory canal through the aperture made by the incision. Partial paralysis of the muscles of the face of the same side resulted in about six weeks from the commencement of treatment.

About Oct. 1st, a bit of dead bone was first observed behind and a little above the external meatus, at first entirely immovable, but after a week or two was found to be movable, but apparently extending deeply into the side of the head.

After about a month the bone was grasped by a stout pair of forceps and some traction made, but it produced so much hemorrhage, that further effort was desisted from by the advice of Dr. Agnew, who was frequently consulted. The discharge, as might be inferred, was highly offensive, and solutions of carbolic acid and chlorinated soda were freely used.

On Dec. 26th, the mother returned to the hospital with the child, and bringing the sequestrum which had so long resisted removal. It consisted of almost the whole of the temporal bone, except a small part of the lower portion of the external auditory canal, and a little of the inner portion of the petrous bone. The specimen almost surrounds the external meatus, and contains apertures for the three semicircular canals. The specimen shows the corrosive action of the pus it was so long time bathed in. Within two weeks after the removal the facial paralysis very greatly diminished, and the other symptoms showed amelioration.

The mother is directed to gently syringe the ear two or three times a day, sending the water as before from the external canal through the mastoid opening. The latter is diminishing in size. About one month subsequent to the last date, a swelling extended from the old wound downwards towards the neck, which was at once incised, giving permanent relief.

At the present (July, 1872), the child is doing well; there is a little facial paralysis; the aperture through which the sequestrum passed is nearly closed; the discharge is very moderate; general health of the child is good, and it is growing satisfactorily. The question here repeatedly arose as to the propriety of forcibly removing the sequestrum. It was thought that if violence was used in dragging away the piece of bone, a meningitis might be set up, or dangerous hemorrhage would result from the tearing or breaking of some of the larger cerebral vessels. It was consequently decided to not meddle with it, allowing it to be separated by natural processes. It is perhaps worthy of remark that no vertigo or other head symptoms resulted from syringing the ear, although it was done in a thorough manner. The above is thought by the writer to be the largest sequestrum from the ear lately on record.

The case of Dr. Agnew's, where the *whole* of the internal ear was removed by himself, approaches nearer to this in size perhaps than any other recently observed. I had naturally enough watched for an unfavorable prognosis, but up to the present date the patient remains in a fair state of health.

ATHETOSIS.

By WILLIAM A. HAMMOND, M.D.

Professor of Diseases of the Mind and Nervous System, and of Clinical Medicine, in the Bellevue Hospital Medical College, etc.

[Read before the Medical Library and Journal Association, New York.]

There are several diseases, one of the chief manifestations of which is involuntary movement—the consciousness of the patient remaining intact. But that which I am about to bring to the notice of the Association had certainly never been recognized or discriminated from others somewhat similar till the publication of my Treatise on Diseases of the Nervous System, in which work I described it under the name of athetosis, and gave the details of two cases, one of which had come under my personal observation. Since then other cases have been noticed both in this country and in Europe, and the affection has been generally regarded as being entitled to a separate place and as being distinct from any hitherto known to exist as a pathological entity.

The name athetosis is derived from the Greek Ἀθέτος (without fixed position), and is specially applied to designate the chief phenomena of the disease, which consists in an inability to keep the fingers and toes from continued motion. The movements are not disorderly, like those of hysteria and chorea, nor so tremulous as those of paralysis agitans, and the various forms of sclerosis hitherto described. They are regular, and are to some extent under the control of the will—that is, by a strong effort of volition the patient can for a short time prevent them, but they soon reassert them-

selves, notwithstanding his most strenuous endeavors to keep the muscles quiet. Even during sleep the movements continue.

In two of the cases which have come under my notice, and of which I have complete histories, there were in the first instance paroxysms of epileptiform character. In a case which I exhibited to the class of the Bellevue Hospital Medical College last winter there had been no such attacks. They were not observed in Dr. Allbutt's case, nor in two which are now under my care.

The involuntary movements which occur in the fingers and toes are not simple oscillations such as are present in paralysis agitans and sclerosis of the brain and spinal cord, but are slow, and are apparently performed with deliberation. The thumb and little finger are more affected than the other fingers. Owing to the constant exercise, the muscles of the forearm become greatly enlarged and hard, like those of an athlete.

Pain is very generally complained of in the contracting muscles, and in one case caused very great distress.

The sensibility of the skin over the affected parts is lessened, and a feeling of numbness prevails more or less extensively over the side of the body corresponding to the disordered motility. In all other parts it is normal.

The causes of the disease have not been clearly made out as yet. In two of my cases, the patients were intemperate, as was Dr. Hubbard's case, but Dr. Allbutt speaks of his patient as a "temperate woman." Thus far, of the six cases known to me, two have been women.

Relative to the prognosis, no case that has come to my knowledge has been materially benefited by treatment, but death has not yet ensued in any instance. I am disposed to regard the disease as being slow in its progress, but as not being amenable to the action of remedial measures. In each of my own cases there has been a steady advance in the severity of the peculiar symptoms, but the general strength of the patient has not been materially impaired.

If attention be paid to the situation in which the disease is manifested and to the character of the movements, no difficulty will ordinarily be experienced in arriving at a correct diagnosis. Still, it will probably not be considered out of place if I briefly recall the main features of those diseases with which athetosis may possibly be confounded. I am, I must confess, more desirous of doing so, for the reason that such a comparison will show that the disease now under consideration is in reality a distinct affection.

DIFFUSED CEREBRAL SCLEROSIS.

In this disease there are muscular contractions, but they are tonic and permanent, and the affection almost invariably begins in infancy and leads to atrophy or arrest of development of some part of the brain.

MULTIPLE CEREBRAL SCLEROSIS.

Tremor is one of the principal symptoms of this affection, but tremor, though the result of muscular action, differs very essentially from the apparently deliberate and obviously regular movements of athetosis. Besides, tremor never leads to the hypertrophy of muscle so characteristic of athetosis. Moreover, another marked phenomenon of multiple cerebral sclerosis, festination, is absent in athetosis.

CEREBRAL HEMORRHAGE.

In cases of secondary degeneration of the spinal cord, resulting from cerebral hemorrhage, there are often involuntary movements, but they are always the consequence of attempts at voluntary motions, and, in addition, the history of the case will prevent any mistake being made in the diagnosis.

MULTIPLE CEREBRO-SPINAL SCLEROSIS.

In this disease the involuntary movements which are in the nature of tremor make their appearance after paralysis, and are only manifested when voluntary movements are made. There is usually festination. These points are sufficient for diagnosis from athetosis.

CHOREA.

Chorea is generally a disease of childhood. The involuntary movements are irregular, and the disease ordinarily yields readily to treatment. There is no pain, and sensation is not disturbed. The movements in chorea cease during sleep, while those of athetosis continue.

PARALYSIS AGITANS.

In this affection there is tremor, and not entire muscular contraction. There is no pain, no anæsthesia. The tremor usually ceases during sleep, and there are often intermissions during which the patient is comparativly quiet. There is no tendency to the tonic contractions which seem to ensue late in the course of athetosis.

EPILEPSY.

I should never have thought of mentioning this disease in contradistinction to athetosis, were it not that M. Garnier* imagines that athetosis is nothing more than the unilateral epileptiform convulsions, which almost every one has seen, and which are well described by Dr. Hughlings Jackson. Certainly if M. Garnier had ever seen a case of athetosis, or had even carefully read my description of it, he could not possibly have made the mistake of confounding it with any form of epilepsy. To be sure, athetosis often begins with epileptiform convulsions, but so do many other cerebral diseases. The spasms to which he refers are paroxysmal and temporary, while the movements of athetosis are continuous.

Relative to the morbid anatomy and pathology, nothing is known, as no post-mortem examination has yet been made in any case of athetosis. Physiology would, however, indicate the corpus striatum, and perhaps also the optic thalamus, as the seats of morbid process, and the diseased condition is probably sclerosis, which in its turn is the result of slow inflammation.

As regards the treatment, nothing has yet been efficacious in arresting the onward march of the disease, though galvanism has apparently exercised a slight controlling power.

Two cases of this interesting disease are described in my work on Diseases of the Nervous System. One of them occurred in the practice of Dr. Hubbard, of Ashtabula, Ohio, and one in my own practice. This latter patient is here this evening, for examination by the members of the Association.

One other was before my class at the Bellevue Hospital Medical College last winter, and formed the subject of a clinical lecture.

Two others are now private patients of mine. All these cases present the same general features, and are undoubtedly instances of the same disease.

One case† has been reported by Dr. Clifford Allbutt, as occurring in the Leeds General Infirmary, and which

* Dictionnaire Annuel des Progrès des Sciences Médicales. Paris, 1873, p. 42, Art. *Athetose*.

† *Medical Times and Gazette*, January 27, 1872.

this able physician at once recognized as a case of athetosis.

There are thus six cases positively known to me, though my friends, Prof. Gross, of Philadelphia, and Barker, of this city, have informed me that similar cases have occurred in their practice.

Progress of Medical Science.

Wounds Produced by Leaden Bullets.—Dr. Desneux reports a simple method, which he has employed successfully in three cases where he was desirous of determining the presence of lead in gun-shot wounds. Attaching to the end of a flexible sound or probe a pledget of charpie or lint, moistened with a solution of nitric or acetic acid, or simply vinegar, he introduced the instrument into the wound, allowing it to remain there a few minutes. Then removing it, he dipped its extremity in a solution of iodide of potassium. If there had been lead in the wound the yellow color characteristic of the iodide of lead was immediately produced.—*Unione Medicale*, Nov., 1872.

Treatment of Gonorrhœa by the Inhalation of Turpentine.—In a recent article on the "Inhalation of Balsams," Prof. Dittel, of Vienna, reported marked success for this method of treatment in pyelitis and renal catarrh. Prof. Zeissl has pursued the same method in two cases of gonorrhœa, and cured one of them in twenty-five and the other in eighteen days. He believes with Weikart that the anti-blennorrhagic action of these balsams is not due to the ethereal oils but rather to the resinous principles. These latter are always detected in the urine during treatment, while there is no trace of the former.

It was observed in the first case that the oleum ether, terebinth., purchased from the apothecaries, was very slow in showing itself in the urine, and not in sufficient quantity to accomplish the desired result. The oleum ethereum pini, on the other hand, appeared much sooner after inhalation. Accordingly, the latter was chiefly used, or a mixture of it and turpentine. Zeissl believes that the balsams are decidedly curative in their action, and if used should be made to pass through the respiratory system. He believes, however, that the expense of these drugs and the long time required for treatment will preclude them from being generally adopted.—*Allg. Wien. Med. Zeitung*, 16. 1873.

Blood-Poisoning by Septic Matters.—At a recent meeting (*K. K. Gesellsch. der Aerzte*) held on the 16th of last May, in Vienna, Prof. Stricker communicated the results of some experiments which had been made in his laboratory by Drs. Clementi and Thin, to determine the character of septicæmic poisoning. The interest of the report arose from the discussion which Davaine's researches have provoked. This latter experimentalist claimed to have made the following discoveries: After injecting beneath the skin of an animal's neck a single drop of putrid blood the surrounding tissue became extensively infiltrated, and death soon followed with symptoms of septicæmia. The blood of this animal was then employed to inject other animals in a similar way, and was found to be more poisonous than the original putrid blood. A third and fourth animal was then injected, each with the blood of the preceding one, and in this way 24 in all were experimented on. The results seemed to show that the toxic power of the septic material increases by dilution. Stricker undertook to test these statements. He inoculated 25 animals with healthy, 23 with putrid, and 73 with blood diluted by transmission. Of the first series 4 died. Of the second series 11 died. In experiments with diluted blood, where it had passed through 13 different animals, 53 of the 73 died. From this it appeared that even the very small amount of $\frac{1}{1250}$ of a cub. centimetre of poisonous material could cause death when injected hypodermically. Davaine's statement that organisms form in the blood and increase by every transmission was not sustained by investigations. Stricker found numerous colorless bodies in the blood of these animals, but he did not regard them as organisms, but rather as protoplasmic bodies.

The following facts he regards as ascertained:—

1. That transmission greatly increases the injurious and fatal action of putrid matter.

2. That the original disease was infectious, but that through inoculation it became contagious.

3. That, though it be not proven, yet it is probable that the special poison is a living contagion (*contagium animatum*), for such rapid proliferation is only possible in organized material.

4. That the poison is diffusible, and is not destroyed by boiling.—*Allg. Wien. Med. Zeitung*, 20, 1873.

Glycerine of Borax in Facial Erysipelas.—Prof. D. M. Salazar, of the Hospital Nacional, Madrid, reports that he has cured eight cases of facial erysipelas in 48 hours by this remedy. Notwithstanding the rapidity with which the affection disappeared, there were no consecutive pathological affections. In one case, the disease had existed three days before treatment was commenced, and there was bilious vomiting, intense cephalalgia, high fever, inflammation of the entire face, and some phlyctenulæ in the vicinity of the right lower eyelid and the root of the nose. He applied the solution to the diseased parts with a brush and then covered them with a mask of raw cotton. After 24 hours all the symptoms, local and general, were notably diminished, and the next day all the phlyctenulæ had disappeared and desquamation was commencing. All medication was then discontinued, except that a decoction of sambucus and althæa was used as a wash to favor the desquamation. —*El Amfit. Anat. Espan.*, Mar., 1873.

Variations in the Weight of the Body in Children's Diseases.—In France the first observation made to determine the relation between the weight of the body and the activity of a fever were made by Lorain. His attention was chiefly directed to cholera. Thaon has made more extended researches, and has laid down the following rule, which, though true in the main, is certainly faulty in individual instances. He states that "in fevers the weight of the body should be in inverse proportion to the height of the temperature." His results may be summed up as follows:—

1. In typhus he found that during the first two days of the disease or of a new exacerbation the weight increases, the reason of which being that more fluids are taken in than urine excreted. At the same time there is a determination of blood to the skin and various other organs, as Verneuil has shown in all febrile diseases. After the third day the commencing diarrhœa and deficient supply of nutritive material causes loss of weight. When, however, the fever has become stationary the bodily weight frequently remains unchanged. At the time of the slow decadence of the fever the weight diminishes very quickly, because the body is relieved of the products of combustion by the kidneys, skin, and lungs. In abortive typhus the decrease in weight is still more rapid, and may in one day equal one-fifteenth the entire weight of the body.

When the normal temperature is restored the body

continues to lose weight because the products of combustion will continue to be excreted for some further time. During convalescence the weight seldom remains stationary, but usually begins to increase, at first steadily and then more rapidly. The least new complication causes loss of weight. Thus the regular increase of weight is an important diagnostic symptom in normal convalescence.

2. In croupous pneumonia the weight of the body falls during the entire continuance of the fever, but notably when the fever breaks. Then it continues to diminish as long as there is induration of the lung. At the same time and after the fall of the temperature there is an excessive sediment in the urine. These facts have not been observed in catarrhal pneumonia.

3. In small-pox the increase in weight is closely related to the swelling of the skin. Thus it diminishes slowly until the sixth day, on the seventh increases rapidly, reaches its maximum on the twelfth day, and then falls again quickly.

4. In chronic diseases it is important to estimate the weight from time to time, so as to judge of the action of medicines, as cod-liver oil, etc.—*Archiv. de Physiol. Schmidt's Jahrb.*, 2, 1873.

Reinfection in Constitutional Syphilis.—In a recent number of the *Berliner Klin. Wochenschrift* (46, 1872) Köbner has collected 45 cases of syphilitic reinfection, and has added to them eight others which have come under his own observation. He believes thoroughly that syphilitic persons may be liable to fresh infection, but thinks that the proof of it lies in fresh induration, with its proper characteristics, attended by an incubation of several weeks' duration. In several cases the diagnosis could be confirmed by confronting the infecting with the infected person. Among other conclusions the following are drawn from his investigations:—

1. Constitutional syphilis is entirely curable.

2. He does not agree with Diday that there is any definite period, as 22 months, at which time the disease may be eradicated from the system. Nor does he approve of inoculation with syphilitic virus to determine whether the original disease was cured or not.

3. Many of the inveterate or so called tertiary affections, as sarcocele and exostoses, are only to be regarded as local products or the remains of a previously existing disease, and not as symptoms of a general infection, and their significance is not of so much importance for the general system as for the special parts affected. This may explain a fact which is frequently observed, viz.: that sound children may be born of parents who have tertiary syphilis.

4. In more than two-thirds of all these cases where the cure was so complete as to render them liable to a second infection, the treatment was mercurial, and internal preparations were employed rather than the inunction method. The author therefore concludes that mercury is one of the best curative agents in syphilis.—*Schmidt's Jahrb.*, 2, 1873.

Croup.—Dr. W. W. Parker, of Richmond, Va. (*Virginia Clinical Record*), relates a case of croup in which inhalations of lime proved efficacious. The most dense vapor is not at all unpleasant, and can be borne as well as the ordinary atmosphere of a heated room.

Rupture of the Œsophagus.—Dr. James S. Bailey, of Albany, N. Y. (*Phil. Med. Times*), reports the history and post-mortem appearances in a case of rupture of the œsophagus occurring near the cardiac orifice of the stomach, causing collapse and death in twenty-four hours from its occurrence. In this case the accident was probably due to a violent fit of vomiting. The lesion in a sound œsophagus is a rare one. Von Oppolzer reports having seen but one case.

Infantile Uterine Hemorrhage.—Howland Holmes, M.D., of Lexington, Mass. (*Boston Med. & Surg. Journal*), records two cases of this character, which came under his own observation. In one case, on the fifth day after birth, blood flowed from the vagina for a period of about three days, and varied in quantity from one to three drachms each twenty-four hours. No subsequent hemorrhage occurred, and the child is in good health. The second case was a similar one. Both children were of healthy parentage, and weighed at birth 8¼ and 8 pounds respectively.

G. W. Foster, M.D. (*Boston Med. & Surg. Journ.*), also relates a case of this character occurring in a child on the fifth day after birth. The hemorrhage continued in pretty uniform quantity—two or three drachms *per diem* until the eighth day, when it ceased spontaneously. The case acquires especial interest from the fact (in addition to the hemorrhagic tendency of the mother) that a sister of the mother and her child both presented similar phenomena a few days after birth.

Thrombosis of the Cerebral Arteries.—Dr. John A. Lidell, of New York (*Am. Jour. Med. Sciences*, April, 1873), records ten cases of *thrombosis* of the cerebral arteries, which have been met with much less frequently than *embolism* of these arteries.

Old topers are liable to be carried off by thrombosis of the cerebral arteries, because their habit of drinking to excess increases the coagulability of the blood, and, at the same time, renders the cerebral blood-vessels liable to the occurrence of vaso-motor paralysis with dilatation of their calibre, and stagnation of their contents—a circumstance which strongly favors the formation of blood-clot. Thrombosis of the cerebral arteries must, therefore, be looked upon as an occasional consequence of chronic alcoholism.

Hernia.—Thomas Bryant, F.R.C.S., Surg. to Guy's Hospital, in his "Practice of Surgery," remarks that where a hernia can be kept up by a truss, and the patient is likely to remain in a civilized country, where trusses can be obtained, any operation for the radical cure is an unjustifiable one; to risk the life of a patient on a theory of a cure, with the probability that the patient will be rendered less liable to its descent, when a truss has to be worn subsequent to the operation as a matter of safety, is a practical delusion.

Dengue.—W. E. Whitehead, M.D., U. S. A. (*Pacific Med. & Surg. Jour.*), treated recently 127 cases of dengue fever, and is convinced that it is an indigenous yellow fever, running a course precisely similar to the latter, the fever lasting from 48 to 72 hours, with increased temperature in the evening, having a characteristic odor very similar to the transudations in yellow fever. The disease spreads by the action of fomites, and is, he believes, not contagious.

Iodide of Potassium in Syphilitic Skin Diseases.—Dr. McCall Anderson (*Med. News & Library*) lays down the following rules with regard to the employment of iodide of potassium in the treatment of syphilitic skin diseases:—

1st. The longer the interval which has elapsed between the contraction of the syphilitic taint and the development of the eruption, the more confidently may we substitute it for mercury.

2d. If the patient is cachectic, it is, as a rule, to be preferred to mercury, except in recent cases of syphilis, when the mercurial vapor bath, or some such treatment, is more likely to prove successful.

3d. The more extensive the tertiary eruption, the more certain it is to yield to the iodide of potassium; although to this rule there are numerous exceptions.

4th. If there is any tendency to syphilitic disease of the nostrils or neighboring parts, iodide of potassium should be withheld, or given with great caution, for, if it produces coryza, it is very apt to aggravate the morbid condition of the parts.

5th. It should be given in full doses.

It is generally advisable to prescribe it in combination with a bitter, and, in cachectic patients, a little iron is a valuable addition, as in the subjoined prescription: Ammonio-citrate of iron, ʒ iij.; iodide of potassium, ℈ i.; syrup of ginger, ℥ vi.; comp. inf. of gentian, ℥ viij.; water to ℥ xxiv. A table spoonful in a large wine-glassful of water, thrice daily.

Urethral Suppositories in Gonorrhœa and Stricture.—Henry E. Woodbury, M.D., Washington, D. C. (*Phil. Med. Times*, May 3, 1873), uses successfully in the treatment of gonorrhœa and stricture the following remedial agents: Tannin, persulphate of iron, nitrate of silver, and morphia. He considers nitrate of silver and morphia the most efficient from his experience in about 20 cases. The grounds upon which he advocates the use of suppositories in these diseases are as follows: By their use in gonorrhœa the remedy is kept longer in contact with the unduly active mucous membrane than by any other method; while in stricture their lubricating qualities exercise a soothing effect upon the irritated surface, and prevent too rapid healing of the parts.

Ear-Cough.—Dr. J. Solis Cohen, of Phila. (*Phila. Med. Times*, May 3, 1873), has a patient subject to ear-cough—a peculiar spasmodic cough produced by touching any part of the external auditory meatus. Recently he gave him a dose of twenty grains of quinine, which induced a cough exactly similar to the ear cough from external irritation. This cough continued until the influence on the system subsided.

Action of the Intercostal Muscles.—Thomas Dwight, Jr., M.D., Prof. of Anatomy at the Medical School of Maine (*Boston Med. & Surg. Journ.*, May 1, 1873), concludes that the action of the intercostals during ordinary respiration is very slight, if indeed they act otherwise than as ligaments. Both sets, at the upper part of the chest, tend to raise the ribs. Owing to the fixing or drawing down of the lower rib, both sets in the lower part of the chest may tend to draw the ribs downward. By sudden contraction, drawing ribs together, they are muscles of spasmodic expiration. Position, muscular action, disease, deformity, and various slight and undefinable causes, may modify the action of any of them.

Conium in the Treatment of Insanity.—Dr. Daniel H. Kitchen (*Am. Journ. Insanity*, April, 1873), in an excellent article on this subject, speaks of the valuable experiments with *conia* hypodermically administered by Dr. J. W. Burman, of the West Riding Lunatic Asylum.

Twelve cases are related in which this drug was successfully given. His conclusions on its action are as follows: 1st. Muscular relaxation. 2nd. Duration in proportion to dose. 3rd. Physiological effect in proportion to purity of the article used. 4th. The brain is not affected directly by conium. 5th. Pulse and temperature both reduced after a full dose. 6th. A gentle perspiration covers the whole body as soon as the physiological effects are observed. 7th. No appreciable effect on any of the secretions. 8th. Quietness lasts from two to four hours, and then disappears, leaving only a sense of lessened muscular energy. 9th. Conium, not acting on the brain, may safely be given in all febrile diseases. 10th. Conium, when applied to the skin, causes slight redness.

Treatment of Poisoning from Rhus Venenata and Toxicodendron.—James C. White, M.D., Prof. Dermatology in Harvard University (*N. Y. Med. Journ.*, March, 1873), has an important paper "On the Action of Rhus Venenata and Rhus Toxicodendron upon the Human Skin"—the first being popularly known as poison-sumac, poison-dogwood, etc.; the latter, as poison-ivy, poison-vine, etc.

The treatment, when the inflammatory process is well developed, is the selection of applications appropriate to a simple eczema of the same stage. In the great majority of cases he has found black-wash, ℥ j, lime-water, Oj. by far the best application to the affected parts, used as an evaporating lotion upon thin and old linen or cotton cloth, for half an hour to one hour at a time, two or three times a day. He has used in connection with it, to moist or excoriated parts, a powder of oxide of zinc ʒ j., starch ℥ j., or plasters of oxide of zinc or diachylon-ointment, as in the management of ordinary eczema. In the black-wash, possibly, there may be three elements at work: first, the alkali as antidote, if it is of any avail at such periods; second, the action of cold from evaporation upon the local hyperæmia; and third, the astringent effect of the mercurial powder upon the diseased tissues. In all cases of poisoning he has been entirely satisfied with its effects, however extensive in distribution or advanced in development the inflammatory condition of the skin. Only, upon the thickened epidermal coverings of the efflorescences in the palms does it seem ineffectual. For these special manifestations he applies solutions of corrosive sublimate, from one to two grains to the ounce of water, in the same way as the black-wash is used upon the other parts.

Leprosy in the Sandwich Islands.—Samuel Kneeland, M.D., Boston, Mass. (*Boston Med. and Surg. Journ.*, March 6th, 1873), writes concerning the asylum for lepers, which contains about 20 patients, and is situated in the outskirts of the town of Honolulu. The sexes are equally divided, and of all ages from over 50 to 5 or 6 years. Though some of the cases were horrible to look at, he was told that many worse ones had recently been sent to the national asylum on the island of Molokai. The two usually described varieties coexisted in the same person. The first symptom is, in most cases, a tuberculous condition of the skin over the eyes, and on the forehead, cheeks, and chin; the skin looks as if indented with small pits, like those on the top of a thimble. After a while the flexors of the fingers begin to contract, with loss of sensation, gradually creeping up the hands, with loss of the nails, and finally of the phalanges. The skin over the whole body gradually becomes affected, preventing its nutrition, finally destroying the digestive powers, and arresting nutrition. The patients stated that they suffered little or no pain. All ages are affected, and all ranks of society. It is almost inseparably mixed with syphilis, which has raged like wildfire in these islands since the visit of Capt. Cook. No treatment seems of

any avail, except to remedy the syphilitic taint; tonics, stimulants, alteratives, have alike been tried in vain. In regard to its origin, there is a general belief that it was brought from China; it was not known in these islands until 1848, at which time it was said to have been introduced by Chinese. The disease is incurable, and the only remedy is segregation of the affected. The physicians of those islands believe that leprosy is contagious. In the two years ending March 31, 1872, there were at the Kalihi Asylum 202 lepers —124 males and 78 females, including 26 children under 14 years of age; and since its establishment nearly 600 cases have been treated there; most of these, as they grow worse, are sent to the National Asylum on Molokai, but 29 have died at Kalihi. Up to the same date, nearly 600 had been received at Molokai, of whom 200 had died, about 400 remaining there at that date, who, sooner or later, will perish.

Treatment of Erysipelas.—E. Wigglesworth, Jr., M.D. (*Boston Med. and Surg. Jour.*, Feb. 27th, 1873), gives the translation of Dr. V. Kaczorowski's paper on "The Treatment of Erysipelas," published in the *Berliner Klin. Wochenschrift*, Dec. 30th, 1872, in which the author believes that erysipelas is an infectious disease, dependent upon the presence of micrococci, a belief justified by the concurrent testimony of Von Recklinghausen, Waldeyer, Hueter, Klebs, and Orth. His treatment is, on the one hand, to repress the development and the extension of the globular bacteriums, and, on the other, the support of the resisting power of the organism, the activity of the heart, by stimulation and an easily digestible diet.

To obtain the first result, those parts of the skin which are affected already by erysipelas are rubbed, by means of the finger or a little sponge, every three hours with a mixture of carbolic acid and oil of turpentine (1:10), but very gently; the skin of the neighborhood, however, more energetically. The whole district rubbed is then covered with a soft linen compress moistened with concentrated lead-water (1:100), and finally the parts affected already by the disease are again covered, outside of this compress, by thicker linen cloths dipped in ice-water and lightly wrung out, or by a bladder of ice. The external enveloping compresses with ice-water are changed as often as they begin to grow warm. Internally, the patient takes lemonade or a weak solution of chlorate of potassa, to alleviate the accompanying stomato-pharyngitis and prevent diphtheritic depositions, and every one or two hours a teaspoonful of strong wine, to support the action of the heart.

This treatment has been very effective during the last few months in the epidemic which occurred in Posen, Germany. He has never seen a relapse when this treatment has been pursued.

Aniline Poisoning from a Crimson Neck-Handkerchief.—Joseph G. Richardson, M.D., Philadelphia, Pa. (*Philadelphia Medical Times*), reports the case of a farmer, 74 years old, who was severely poisoned by wearing a crimson neck-handkerchief, newly dyed of a crimson color. The microscope demonstrated that the cause of the mischief was aniline.

The treatment consisted in the liberal application upon soft linen rags of slippery-elm mucilage—which he subsequently stated was the first thing that gave him any relief—and in the administration of a mixture composed of Morphiæ acet. gr. i.; Spt. ether nit. f ℥ ss.; Potass. bromid. ℥ i.; Aq. menth. pip. f ℥ iij ss.; Syr. zingiberis, f ℥ ij. Of this a tablespoonful was given every four hours, to allay the pain, fever, and restlessness at night. Under these remedies the disease rapidly yielded, and the patient was cured.

A Compact Uterine Sound.—Henry E. Woodbury, M.D., of Washington, D. C. (*Philadelphia Medical Times*, March 1, 1873), gives a description, with cut, of a compact and convenient uterine sound which may be carried in the pocket. The ordinary sound may be altered to this form, by introducing a joint and slide.

Etiology of Typhoid Fever.—Dr. P. W. Payne, of Franklin, Indiana (*The Clinic*, March 8, 1873), relates five cases of typhoid fever which he believes were referable to the decay of vegetable matter in a well, from which the families of these patients procured their drinking-water. The water had the smell and taste familiar to those who have drank water from an old well, curbed with oak boards or slabs. Sawdust had been used for grading up the lot around the well, and some had drifted into it from time to time.

Poisoning from Camphor.—H. C. Hall, M.D., of Crawfordsville, Iowa (*The Clinic*, March 8, 1873), records a case of poisoning by spirits of camphor, which was taken by an old man, 80 years old, to relieve his diarrhœa. Ipecac. in large doses, combined with 20 grs. of bromide of potassium, were given with success.

Combination for Chronic Diarrhœa.—Rayer (*Union Medicale*, No. 73) advocates the combination of cinchona, charcoal, and bismuth in the management of chronic diarrhœa, in these proportions: Subnitrate of bismuth, ℥ j.; cinchona, yellow, powdered, ℥ ss.; charcoal, vegetable, ℥ i.; M. chart. xx. S. Two or three times daily during the intervals between meals.

Removal of Tongue and Lower Jaw.—William H. Hingston, M.D., of Montreal (*Canada Medical and Surgical Journal*, March, 1873), recently removed the tongue and lower jaw from a man, aged 71 years, for a cancerous mass which involved the whole sublingual region, extended along the lower jaw, from a little below the median line on the right side to the second molar tooth on the left, and eating away, in its progress upwards, the frænum and a considerable portion of the under surface of the tongue. The patient made a quick recovery. He was presented before the Medico-Chirurgical Society of Montreal, about four months after the operation, with no great amount of deformity. Speech was restored to some extent, notwithstanding the entire ablation of the chief organ which gave it articulate utterance.

Cerebro-Spinal Sclerosis.—Stiles Kennedy, M.D., Prof. Anatomy and Physiology, Delaware State College (*Review Medicine and Pharmacy*, March, 1873), thinks that Dr. Hammond's diagnostic lines are too tightly drawn among the scleroses of the nervous system, especially those accompanied by tremor.

He recites Dr. Hammond's definitions of multiple cerebral sclerosis and multiple cerebro-spinal sclerosis, based upon 20 cases, and states that he has failed to discover these distinctions from his experience of 12 cases, three of which he records. From these cases, therefore, he thinks that by accepting the pathology of Dr. H., in this class of cases, the title of *cerebro-spinal sclerosis, involving the hemispheres*, must be added to his nomenclature.

Oxide of Zinc for Night-Sweats.—The most ancient and venerable remedy for night-sweats is aromatic sulphuric acid, in infusion of cinchona, or ser-

pentaria, etc. According to the *Pacific Medical and Surgical Journal*, the best remedy is the following:— ℞ Oxidi zinci, gr. xxx.; Ext. hyoscyami, gr. xv.; M. f. pil. x; Sig.: Take one at bed-time.

Is Salivation Desirable in Syphilitic Iritis?—Dr. A. D. Williams, St. Louis, Mo. (*Med. Archives*, March, 1873), protests against the following remark of Ricord, made in his speech before the British Medical Association, in 1872, on the treatment of syphilis: "There is but one case in which I approve of salivation, and that is where there is iritis. When this occurs, and salivation is brought on, the inflammation of the iris subsides." Dr. Williams expresses his disbelief in even the *desirableness*, much less *necessity*, of salivation in the treatment of specific iritis; so far as he can judge, *mercurialism* is a hindrance to the progress of the cure rather than a benefit. Mercury, even to the extent of salivation, will not prevent the formation of those adhesions between the pupillary margin of the iris and lens, which always interfere materially with vision. "Mercury," he says, "is *necessary* in the treatment, but never to the extent of salivation—certainly not too severe salivation. The local treatment is all-important. This consists in the *energetic* use of atropine in the eye, so as to dilate the pupil to the fullest extent."

ARTICLES IN OUR EXCHANGES.

HYGIENE.

Vitiated air. Tidy, C. M. *Med. Press and Cir.*, March 5.

On the sanitary state of Rome. Aitken, L. *Br. Med. Jour.*, March 22.

The starvation of the young. Diday. *Lyon Méd.*, March 2.

Statistical researches on the mortality of Plancher-les-Mines (France). Poulet. *Gaz. Méd. de Paris*, March 29.

ANATOMY.

Lectures on human anatomy (III.). Rivington, W. *Med. Press and Cir.*, March 5, 12, 19.

Case of complete transposition of viscera. Yeo. *Ibid.*, March 12.

Partial absence of pectoral muscles. Yeo, B. *Br. Med. Jour.*, March 15.

On the distribution of the nutrient arteries of the medulla. Duret, H. *Archives de Phys. Norm. et Path.*, March.

Contribution to the physiology of the pneumogastrics (conclusion). Arloing & Tripier. *Ibid.*

On the unity of the human species. d'Halloy, d'O. *Revue Scientifique*, March 1.

The theory of sexual selection of Darwin. Perrier. *Ibid.*, March 15.

Fœtal monstrosity. Philipeaux. *Gaz. Méd. de Paris*, March 15.

PHYSIOLOGY.

Researches on the physiological effects of alcohol and essence of absinthe in pathological conditions:—Epilepsy. Magnan. *Archives de Phys. Norm. et Path.*, March.

The influence of the nerves on nutrition (II.). Power, H. *The Practitioner*, March.

On the physiology of the circulation in plants, in the lower animals and in man (illustrated). Pettegrew, J. B. *Edinburgh Med. Jour.*, March.

Development and experimental physiology. Marcy. *Revue Scientifique*, March 1, and *La Tribune Méd.*, March 29.

Functional therapeutics by physical agents. Dally. *Gaz. Méd. de Paris*, March 1, 8.

Researches with regard to modifications in the composition of the bones. Papillon, F. *Ibid.*

A method of estimating the gas contained in human blood. Lepine. *Ibid.*

Observations on the respiratory sense. Carville. *Ibid.*

Effects of the admission of air into the arteries and veins. Muron. *Ibid.*, March 15.

Experiments on the influence of change of barometric pressure upon the phenomena of life. Bert. *Le Bordeaux Méd.*, March 26.

Researches on the number of white globules in the blood in erysipelas (continued). Malassez. *Le Mouvement Méd.*, March 29.

On the production of animal heat. Jolly. *La Tribune Méd.*, March 9 and 23.

Researches on protoplasmic life. Crace-Calvert. *La France Méd.*, March 5.

GENERAL MEDICINE AND PATHOLOGY.

Etiology of enteric fever. Kennedy, H. *Med. Press and Cir.*, March 5.

On anthracosis (coal miners' lung, black-spit) (concluded). Heine, T. W. *Ibid.*, March 12.

On disseminated suppuration of the kidney secondary to certain conditions of urinary disturbance. Dickenson, W. H. *Ibid.*

Case of irritation from renal calculus producing hypertrophy of the adipose tissue surrounding the kidney. Hamilton, E. *Ibid.*

Description of the heart, lungs, kidneys, and small intestines of a girl, æt. 10, who had been exposed to the poison of scarlatina. Foot, A. W. *Ibid.*

Case of acute tuberculosis, tubercular meningitis, diseased condition of solitary glands of intestine. Nixon. *Ibid.*

Case of rupture of the aorta. Yeo. *Ibid.*

Case of cirrhosis of liver in a boy of seven. Foot, A. W. *Ibid.*

Case of diphtheritic gangrene of pulmonary vomicæ. Yeo. *Ibid.*, March 26.

Case of fatty degeneration of heart in a boy of 19. Nixon. *Ibid.*

Remarks on M. Pettenkofer's views on cholera in India. Murray, J. *Br. Med. Jour.*, March 1.

Erysipelas after vaccination. Bolton, W. T. *Ibid.*

Cases of exophthalmic goitre (Gravis's disease). Dobell. *Ibid.*

Case of extra-thoracic suppuration with discharge into the lung. Sansom. *Ibid.*

Case of aortic disease. Habershon. *Ibid.*

Lecture IV. Chronic Bright's disease with large white kidney. Johnson, G. *Ibid.*, March 15, 22.

Strain in its relation to the circulatory organs. Fothergill, J. M. *Ibid.*, March 15.

Sequelæ of pneumonia and pleurisy. Lawrence, H. C. *Ibid.*

On vomiting from habit. Tuckwell, H. M. *Ibid.*, March 22.

The anatomical relations of pulmonary phthisis to tubercle of the lung. Fox, W. *Ibid.*

General sarcoma of the serous membranes in a rat. Lionville, H. *Archives de Phys. Norm. et Path.*, March.

The origin of granular tubercle. Thaon. *Ibid.*

Observations on the nature of typhoid affections. Cazalis & Regnault. *Ibid.*

Historical and critical article on tuberculosis. Grauchер, H. *Ibid.*

Discussion on the epidemic of cholera of 1866 (continued). *Bulletin de l'Acad. Royal de Méd. de Belg.* Nos. 1, 2 and 3.

Note on the treatment of whooping-cough by belladonna. Kelly, C. *The Practitioner*, March.

On the treatment of lumbago and rheumatism with actæa. Bartlett, J. J. H.

On Migraine. Dale, W. *Ibid.*

On the use of digitalis in the failing heart and deli-

rium of acute disease. LITTLE, J. *The Dublin Jour. of Med. Sci.*, March. (Paper and discussion.)

On the etiology of enteric fever in connection with its relations to the strumous diathesis. (Paper and discussion.) KENNEDY, H. *Ibid.*

Case of bronzed skin. DARBY. *Ibid.*

Case of disease of the heart and arteries. LITTLE, J. *Ibid.*

Case of endocarditis and valvular disease, the result of an injury. M'SWINEY. *Ibid.*

Case of mitral valve disease. HAYDEN. *Ibid.*

Case of pericarditis. LYONS. *Ibid.*

Case of lymphosarcoma or lymphadenoma. GAMGEE, A. *Edinburgh Med. Jour.*, March.

Acute rheumatism in private practice. HADDON, J. *Ibid.*

Case of dilatation of the bile ducts. STEWART, G. *Ibid.*

Case of hydropneumothorax. BOUCHARD. *Jour. de Méd. et de Chir.*, March.

Tubercle of the genito-urinary organs. Premonitory symtoms of tubercle. GUYON, F. *Ibid.*

Complicated case of intermittent fever treated by eucalyptus and a solution of the bromochloride of sodium. *Ibid.*

Late researches on the subject of phthisis pulmonalis. *Revue Scientifique*, March 15.

Mode of causing variolous pustules of the face to abort. REVILLOD. *Gaz. Méd. de Paris*, March 8.

On the cause of the rise in temperature in patients affected with pleurisy, who have been operated on by thoracentesis. LABOULBENE. *Ibid.*

On the evolution of heat, and conjugate rotation of the head and eyes in attacks of apoplexy and general paralysis. HANOT, V. *Ibid.*, March 22.

A medical study of the drinkers of vermouth. DECAISNE. *Ibid.*

Two cases of chronic dysentery—pathology. CORNIL. *Ibid.* and *Le Mouvement Méd.*, March 15.

On the contagion of erysipelas. PUJOS, A. *Le Bordeaux Méd.*, March 9.

Notes on the treatment of rheumatism by propylamine. GIRARD. *Le Bordeaux Méd.*, March 16.

Case of dry gangrene. HAMEAU. *Ibid.*, March 26, 30.

New researches on the variations of temperature in uræmia and in puerperal eclampsia. BOURNEVILLE. *Le Mouvement Méd.*, March 8, 22.

Case of insidious typhoid; marked thoracic phenomena; death by progressive asphyxia; infarction of spleen. SEVESTRE. *Ibid.*

On tuberculosis of glands. THAON, L. *Ibid.*, March 15.

Case of chronic pleurisy and hepatitis. HANOT. *Ibid.*

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, July 1, 1873.

THE PREVENTION OF CHOLERA.

THE appearance of cholera in some portions of this country excites a lively apprehension of an epidemic in some of the larger cities and ports of entry. Such concern on the part of the public, although it is of almost annual occurrence, always partakes of a seriousness which it behooves all health officers to consider. It is always impossible to say when this dreaded scourge may come, but in the present state of sanitary science it is always possible to be prepared for it. During the past twenty-five years we have had all sorts of theories as to the origin and spread of this disease, its march has been accurately mapped out from one country to the other, the dates of its appearance in different localities have been faithfully kept, and no pains have been spared to place upon record all the meteorological phenomena connected with particular epidemics. Although much has been learned from such studies, and many theories have been based upon them, much more remains to be investigated before the medical public can satisfy itself that it has solved many of the questions of the greatest possible importance.

There are some points, however, in connection with the subject of cholera upon which the profession as a whole are pretty well agreed. One of these has reference to the influence which human intercourse has upon the spread of the disease, and another to the peculiar modification of the contagiousness by localizing causes. And these are after all the questions in which the public, alarmed by the probability of another epidemic, are mainly interested. There has been no difficulty in causing any community to accept these doctrines, and there is none of that conventional opposition to the necessary sanitary precautions and hygienic regulations which have been noticed in epidemic visitations of other diseases. The people are only too anxious to have the strictest sanitary regulations adopted, and are willing to aid the health authorities by a consistent obedience.

In connection with the subject of the portability of the disease, the question of quarantine is invested with great interest. Although there are many eminent sanitarians who disbelieve in its efficacy, and although we may not be able to explain certain circumstances connected with the spread of the disease in a locality where rigid quarantine was said to have been enforced, we have no reason to assume that such quarantine was useless. Would it not be as safe to admit that the sanitary regulations were not as perfect as they might have been? At all events, the weight of evidence is altogether on the side of quarantine, and in face of the well-authenticated statements in regard to its great utility, any medical man, or any medical body would take upon itself a grave responsibility in advising against its enforcement. We are convinced that any laxity in the quarantine regulations would be fraught with the gravest consequences, aside from the bad moral effect which such proceedings would have upon the public mind. It is a matter of congratulation for the profession as well as the public, that the present Health Officer of the Port is thoroughly alive to the responsibilities of his office, and is peculiarly fitted to meet any emergency which may arise. In all his endeavors in this direction he will be cordially supported by his brethren and the public at large.

The influence of filth and defective drainage in propagating and inviting the disease is another point upon which sanitarians and the public are alike agreed. The present condition of our streets is, under the circumstances, very fair. In view, however, of the urgent necessity of preparing for an epidemic, there is great room for improvement, for honest, thorough, and untiring efforts on the part of our Police Department. There is something more needed than an occasional resolution from the Health Board to have this or that mass of rubbish removed; something more than a promise to disinfect this and that locality; even something more than cleaning out the cellars in our lower wards.

In regard to the subject of filth and drainage, there are some matters the importance of which the public should be made to appreciate. These have reference to the known tendency of the disease to propagate itself through the agency of the changes which take place in the discharges of choleraic patients, and which changes are aided by defects in drainage. Upon these points, and upon many others which may occur to every practical physician and every sanitarian, the public should be informed. Such information should be furnished by the Health authorities, who by this simple means may do much to conquer the dread of an invasion, and, in case the disease does come, may give the people the best possible chance to check its spread.

REORGANIZATION OF THE HEALTH DEPARTMENT.

We regret to say that our anticipations of improvement in the present Health Department have failed to be realized at the very outset of its career. It does not seem possible for men who have once tasted the intoxicating draught of official patronage to emancipate themselves from its malign influence. The promise that our "reform Mayor" was to infuse a Utopian element of unselfishness, purity, and justice throughout our municipal administration, having been violated at the fountain-head, it was certainly unwise to look for such a spirit in any of the branches proceeding therefrom. Still, as regards the Department whose operations particularly concern us as medical men no less than as citizens, we confess to having indulged expectations founded upon the reputation of two of the commissioners, Chandler and Vanderpoel, without having sufficiently calculated upon the character of the two others. Our hopes were almost confirmed by the principles of action enunciated by the new Board—principles, however, which it seems were destined to be honored quite as much in the breach as in the observance. That peculiar and secret force termed in political parlance "pressure," has evidently caused the fair bubble of "Civil Service Reform" to collapse.

We have a high personal regard for Dr. Day, the gentleman selected to act as Sanitary Superintendent; but to elevate a man confessedly inexperienced in sanitary affairs to a position of such vast responsibility, particularly at so grave a juncture, is an experiment, we are bound to say, which cannot be justified upon any considerations of public welfare. Yet, recognizing his capacity in other fields, we trust that he may not fail in the performance of his new and difficult duties, and that he may finally prove equal to the best of those who have preceded him. His particular good fortune in this emergency is the aid of a good lieutenant, Dr. E. H. Janes, whose recent valuable services we find, with agreeable disappointment, have not been entirely ignored.

Among the Inspectors and Assistant Inspectors we are glad to recognize many familiar names; but in their respective apportionment in the two classes, manifest injustice has been done to old, well-tried, and accomplished officers.

One of the most conscientious and efficient of the old inspectors has suffered the apparent degradation of being reduced to an inferior grade, and others among the old Assistant Inspectors, who were in every respect worthy of being promoted, have simply been retained in their positions to see new men placed over their heads. Here, again, we perceive how "Civil Service Reform" has been obliged to yield to "pressure," as it has been likewise in the discharge of several excellent clerks, simply to create vacancies. It is sufficiently evident, upon an examination of the number of removals and reappointments, that an agreement was entered into by which one-half of the force was to be sacrificed under any circumstances to the exigencies of the occasion.

The deposition of Dr. Russel, the Registrar, is only consistent with the general inconsistency described. The entire profession of the city, except, perhaps, Dr. Stephen Smith, desired his retention, and almost all of our distinguished physicians gave expression to that feeling, but were astonished and indignant at the indifference shown to their wishes in a matter of such interest to Sanitary Science.

We had hoped that the Registrar elect had retired upon laurels previously won in that capacity years ago; that in writing his tedious reports for the public prints he had at last relieved his great responsibilities to the public, and satisfied his ambition as an authority on sanitary matters; but in this, too, we were mistaken. We are, however, assured upon the authority of the *New York Times*—Stephen Smith's constant eulogist and mouth-piece—that Dr. Harris's return to the position of Registrar is likely to result in a decided improvement. The *Times* is here unusually vague in expression, but we sincerely trust that it foreshadows some possible improvement upon Harris the Registrar of old, as we all remember him.

In truth, we cannot congratulate either the profession or the public upon the measures adopted in reorganizing the executive bureaus of the Health Department. Political expediency and compromise have been but poorly concealed under the gown of Justice. The new and well-disposed and right-minded element in the Board, instead of neutralizing the one pernicious spirit that remained from the old, has failed to successfully encounter so insidious an influence. The alchemist may learn to transmute the baser metals into gold, or to convert the noxious gas into the pure diamond, but he may never hope to accomplish the metamorphosis in human character, motive, and action of evil into good.

THE PROPOSED REMOVAL OF BELLEVUE HOSPITAL, N. Y.

The recent passage of the law to provide for the selection of a site for, and the erection of, a new city prison, has brought up a subject for discussion interesting to the public generally, and the profession particularly. By the terms of the Act, a commission, consisting of the Mayor, the Comptroller, and the President of the Board of Aldermen, is to decide upon a suitable site for the building within ninety days from the passage of the said act. As might be supposed, the commission have already entered upon their labors. The attention of the members has been turned to the eligibility of the grounds of Bellevue Hospital for such a purpose. The subject has been under such serious consideration that the buildings have been examined with that end in view. Of course no idea is seriously entertained of turning the hospital, as such, into a prison, the only question with the commission being the removal of the buildings, and the construction of a

model jail in their place. It is contended by such as are in favor of such a project, that the buildings are wholly unfit for their present purposes; that their long use as hospitals has made them hot-beds for pyæmia and erysipelas. There is so much said by the daily press *pro* and *con* upon this subject, that a committee of the Board of Aldermen have undertaken to investigate the matter, and the Commissioners of Charities and Correction have directed that a report be made by a committee of the Medical Board. The latter report, the object of which is to prove that Bellevue Hospital is to all intents and purposes in excellent condition, has been published. Although we must admit that there are a great many circumstances which explain an apparent increased mortality—circumstances connected with the class of patients treated, their condition when received, the large number brought there with incurable diseases simply to die, and the number of severe accidents admitted—still there is no doubt that the buildings need to be improved, a matter which is by no means an impossibility. But whatever we may say of the buildings cannot be said of the site. Bellevue Hospital can improve its buildings, but not its situation. It is needed just where it is, and in no other place can it better serve the interests of charity and science.

THE POLICE SURGICAL SYSTEM.

THE new charter for the city provides for the appointment of twenty-two police surgeons. Instead of complying strictly with the provisions of the said charter, the Police Commissioners have hit upon the novel plan of appointing four medical gentlemen in each precinct, each one of whom is expected, on the call of the officer of the district, to attend upon members of the police force, and upon injured citizens at police-stations for a stipulated fee of three dollars a visit, and five dollars for a night call. This plan is open to many objections, and cannot fail to embarrass the commissioners and the surgeons employed.

First, there is good reason to doubt the legality of such appointments; secondly, there is a great liability on the part of such as may have the power of calling in medical aid, of exercising gross partiality to one or two of the medical men in a precinct. Thirdly, the surgeons are not subject to any of the regulations which are necessary for the prompt compliance with orders from superiors in office,—a circumstance of the greatest importance to the discipline of every police force. Fourthly, the expenses of such attendance must be greatly in excess of the old system. The commissioners must, however, try the experiment before they can be satisfied.

DICTIONARY OF MEDICAL TERMS.—The new edition of "Dictionary of Medical Terms," by MM. Robin and Littré, has been laid before the *Académie des Sciences.*

DR. ERSKINE MASON, President, in the Chair.

RESECTION OF ELBOW-JOINT.

DR. C. K. BRIDDON presented a specimen of resection, with the following history:—

The boy Cavanagh, from whom this specimen was removed, came under my observation in the fall of 1872. He was a delicate, undersized child, of ten years, without history of hereditary predisposition to articular disease, and with good sanitary antecedents up to the time when he met with an accident, which was regarded as trivial at the time of its occurrence, in the early part of June; at that time he fell down a flight of three steps, and made no complaint of being hurt until three days afterwards, when he called his mother's attention to his left elbow, which was slightly swollen and painful. These conditions gradually increased, and in about three weeks an opening formed spontaneously behind the olecranon, and continued discharging for about a month, when it closed. When the abscess opened the pains ceased entirely, and the functions of the joint were in a measure restored. Shortly before seeing me, he had been suffering from an exacerbation of pain, occasioned by an inflammatory swelling on the inside of the forearm. At this time the boy's condition was as follows: his left upper extremity was wasted, the wasting being most marked in the flexors and extensors of the arm; the elbow was the seat of a fusiform swelling, the largest diameter of which was situated immediately across the articulation; the limb was maintained in a condition of flexion, at about a right angle, but admitting of considerable alteration, without eliciting manifestations of pain; there was no heat or discoloration about the joint proper; but two inches below, on the inner aspect of the forearm, was a small inflammatory swelling which, on being incised, gave exit to about two drachms of pus.

The limb was put in an immovable apparatus; he was recommended the best dietary the circumstances of his parents would permit, and was directed to take cod-liver oil and ferruginous tonics.

In December I examined the parts again; the opening on the inner aspect of the forearm had degenerated into a sinus, which led to carious bone, and by a little manipulation a probe introduced through it could be made to traverse the joint; there was preternatural mobility, admitting of considerable lateral displacement of the articular extremities, but such movements gave no sensation of crepitus. I regarded the joint as irretrievably disorganized, but determined to try the effects of more prolonged rest until his general condition was improved—advising perseverance with the means that had been used before, and the reapplication of immovable apparatus.

In the early part of the present year, finding his general condition much improved, and that of the joint as before, I advised resection of the articulation, and the operation was done on the 29th of January, in the presence of Drs. Krackowizer, John Howe, and George Thompson. The proceeding was easily accomplished, through a single medio-posterior incision; little blood was lost, no ligatures were required, the integuments were brought into apposition by a few sutures, and the limb was put up in a splint which

could be placed at any angle, and which left the joint entirely exposed to view.

Examination of Parts Removed.—Section of lower end of humerus traversed the condyles three-quarters of an inch above the lowest articular surface. Section of ulna one-quarter of an inch in advance of tip of coronoid process; of the radius, quarter of an inch below its head; the cut surfaces were all sound; the articular surfaces were almost entirely divested of cartilage, and covered with granulation tissue; at the base of the coronoid process, on its inner side, was a sinus passing through the osseous tissue, and leading into the articulation; the synovial membrane was everywhere in a condition of pulpy degeneration.

Remarks.—Results obtained from excision of this joint vary. In some cases the member is little better than a flail, over which the unfortunate owner has little or no control. In such cases the shafts of the bone have been too much encroached on, too much has been removed. In another class of cases anchylosis results either from sparing too much in the operation, or neglect in enforcing passive motion at an early period; but in the majority of cases we are justified in anticipating a more or less complete restoration of the function of the limb, and, what is equally satisfactory, in the operations made on children, growth of the part is not much interfered with. In connection with this latter statement, I would refer to some observations made before the Medical Section of a late session of the French Association for the Advancement of Science, by Ollier of Lyons. The Doctor supports the theory of the peripheric growth in bones. In 1867 he had shown that irritation of the diaphysis of a long bone excites elongation of the bone; irritation of the conjugate cartilages arrests growth, and that not by the more rapid soldering of the epiphysis, but by disturbance of the process of ossification. A more important observation made by the learned Professor, and one more directly bearing upon the subject I am considering, is the fact he insists upon, that the conjugate cartilages play unequal parts in the development of bones. The humerus grows especially through the upper conjugate cartilage, the ulna and cubitus through the lower cartilage, so that the bones entering into the composition of the elbow-joint have only limited influence in the development of the arm. It is just the reverse with the knee and the bones which form it, and practical surgeons are well aware that resections of the knee are particularly liable to be followed by arrest of growth as regards length, especially if the epiphysal line is encroached on.

Stated Meeting, March 26, 1873.

DR. ERSKINE MASON, President, in the Chair.

DR. POST presented a specimen, with the following history:—

NECROSIS OF LOWER JAW.

Eliza McGowan, aged 7 years, was brought to my clinic January 16th, 1873. She had a great swelling on the left side of her face, evidently of an inflammatory character, with a sinus behind the ramus of the jaw. On opening the mouth, dead bone could be seen and felt, corresponding with the left side of the lower jaw. The swelling commenced last July, when she had a molar tooth extracted.

I introduced into the mouth a chiropodist's forceps and seized the denuded bone, and with a twisting motion, applied with some force, I succeeded in extracting this large portion of dead bone, including the whole mass of the jaw from the left temporo-maxillary articulation to the space between the anterior and posterior bicuspid teeth.

A week after the operation the inflammatory swelling had subsided, and I found that new bony matter had been formed along the base and ramus of the jaw, so as to complete the outlines of the bone, except the alveolar portion.

Nothing is known as to the cause of the necrosis in this case. The patient had not taken mercury, and had not been exposed to the fumes of phosphorus.

STONE IN THE BLADDER—LITHOTOMY.

CASE II.—*March* 15, 1873. A. B., æt. 14 years, was brought to me by his father, who stated that he had suffered from symptoms of vesical irritation for two years past, and that during the last six months his sufferings at the time of passing urine, and immediately afterwards, had been very severe. I sounded him, and readily detected the presence of a stone. I could not, however, feel it with a finger introduced into the rectum. The patient's general health had not become seriously impaired.

March 18th.—I performed bilateral lithotomy, with the assistance of Drs. Hinton, Minor, Leale, Maguire, etc., anæsthesia having been induced by the inhalation of the vapor of ether. After incising the neck of the bladder, I introduced my finger and readily felt the stone. I seized the stone with forceps, and applied considerable tractile force, but did not succeed in extracting the stone. I then introduced through the wound, into the bladder, Sims's rectum dilator, and, turning the screw, I stretched the wound, after which I introduced the forceps and extracted the stone without the slightest difficulty. The calculus weighed 186 grains, and was of an ovoidal shape, and very rough on the surface. It was analyzed by Mr. Francis Buck, and was found to consist of uric acid within and of phosphate of lime on the surface. The patient's condition seemed very comfortable when he recovered from the anæsthesia.

March 19, 1 P.M.—I found the patient crying out with pain, which he referred to the hypogastric region, which was tender on pressure. His face was flushed, his surface warm, and his pulse 120 and full. There was no tympanitic distention of the abdomen. The folded sheet under the patient was wet with urine, which dribbled from the wound. The wound was free from swelling and presented a healthy appearance.

I ordered a solution of sulphate of morphia, gr. j. to ℥j.; two teaspoonfuls to be given immediately, and one teaspoonful every hour afterwards, until there should be a decided mitigation of pain. I also directed a warm cataplasm of flax-seed over the hypogastric region.

7 P.M.—I found that the patient had taken only one dose of the anodyne, after which he had slept, and there had been no return of the pain. His face continued flushed, pulse 150, and softer and smaller than in the morning. Ordered two drops of tincture of veratrum viride every two hours.

March 20, 1 P.M.—Patient more comfortable; pulse 125; skin moist; no desire for food; calls frequently for drink; has taken no nourishment since the operation but a little milk and beef-tea. Continue veratrum viride. Increase amount of nourishment, if he can be induced to take it.

March 21, 2 P.M.—Had return of pain last night, but was promptly relieved by one teaspoonful of solution of morphia. He appears better this morning; he lies quiet, his skin is cool, and face no longer flushed. Pulse 102; has some appetite; wound looks well; urine continues to dribble away.

March 22.—Continued improvement; pulse 96.

March 26.—Still improving slowly; pulse 90; no urine has yet flowed through the natural channel.

Stated Meeting, April 9, 1873.

Dr. Erskine Mason, President, in the Chair.

CANCROID OF ORBIT.

Dr. Knapp presented a tumor of the orbit removed by operation from a patient who presented himself four months ago with an epithelial growth in the lachrymal region and surrounding parts. The patient was not seen again until two days before the meeting, when he informed Dr. Knapp that six weeks previously he suffered a severe attack of inflammation in the growth, since which time the disease had progressed to a remarkable degree. When examined by Dr. Knapp, it was found that the entire left cornea had sloughed and that the disease had made progress in all directions. The patient was importunate for an operation; and, appreciating the tendency of the disease to spread over the face and be attended with all the horrible sequelæ so often witnessed in such cases, the appeal could not be withstood. Dr. Sands saw the case, and, although the difficulty of removing the disease was very great, coincided in the expediency of the operation. The operation was accordingly performed. A vertical section was made through the eyelids, and the eyeball enucleated in the usual way. The growth, which involved the inner wall of the orbit, the antrum, the floor of the orbit, and root of nose, was finally dissected out and removed. The hemorrhage was considerable, but was very soon arrested by plugging the cavity with sponges, which were still *in situ* at the time of reporting the case.

On examination the growth was found to be a true example of cancroid; the bulk of it was hard like scirrhus, scattered throughout the substance of which were evidences of rapid growth in the preponderance of cell elements, the softened and vascular condition of this particular part.

The prognosis was of course bad, a return of the disease being apprehended in a short time.

In conclusion, he remarked that he was not in favor of using chloride of zinc in these cases, first, because its action could not always be limited; secondly, because whatever can be done with the zinc can be accomplished with the knife.

Dr. Mason was of the same opinion, and referred to three cases in which he had employed it—two cases of mammary cancer, one case of cancer of orbit—without the slightest benefit.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 17th, 1873.

Dr. Austin Flint, President, in the Chair.

IRREGULAR UTERINE ACTION IN LABOR.

Dr. William T. Lusk read a paper on "The Etiology and Indications for Treatment of Irregular Uterine Action during Labor," of which the following is an abstract:—

To avoid confusion he proposed using the term "labor-pains" in the sense of uterine contractions, a distinction made necessary in our language by the frequency with which it is stated that women are having strong pains, when upon examination there is only a feeble measure of uterine contraction, the word "pains" evidently here signifying nothing more than an unduly severe amount of physical suffering.

With regard to precipitate labors as a consequence of excessive uterine action, are they not to be regarded with apprehension? Precipitate labors are not very uncommon at Bellevue Hospital. He has never noticed anything peculiarly unfavorable in their action.

It is to the violent straining that the accidents enumerated are really attributable. They occur in women who possess an undue degree of reflex irritability, which impels them to excessive use of the diaphragm and abdominal muscles. These cases do not call for bleeding, but for the subcutaneous injection of morphia, or best of all, the production of complete anæsthesia by chloroform, so as to suspend the action of the voluntary muscles.

However, revolutionary as it may seem, there is tolerably good ground for questioning the pretty generally accepted opinion that in the independent action of the circular, oblique, and longitudinal layers of muscular fibres which may be demonstrated in the pregnant uterus, the key to the abnormal forms of uterine action is furnished us. The existence of such layers is not of course denied; their importance has unquestionably been greatly exaggerated by the desire of the anatomist to answer the questions of the obstetrician.

There is strong *à priori* reason to doubt whether the uterus during labor ever contracts except in its totality. The evidence to the contrary in the case of the so-called strictures is more apparent than real.

Pains which may be good enough to accomplish the organic changes of the cervix in multiparæ, may be utterly inadequate for the same purpose in primiparæ. It is losing sight of this comparative difference which has led observers to commonly attribute to the rigid os of the primiparæ the blame that properly attaches to the relatively insufficient uterine action.

In the treatment of this affection there is no occasion to resort to bleeding, to tartar emetic, or to plastering the cervix with belladonna ointment. In the course of time the tonic contraction generally disappears of itself. But while it lasts the patient's condition is one of acute suffering. To allay this suffering, the physician is frequently called upon to use morphia either by the mouth or hypodermically.

Opiates frequently accomplish wonders in one of two ways. Owing to the prolongation of the labor and its attendant pain, the patient's nervous energies have become exhausted. The arrest of the pain enables the woman to sleep, and with the recuperation of power that comes upon awakening, good pains follow which bring the labor to a happy termination.

In other cases, after the employment of opium, or the administration of an anæsthetic, the parts apparently relax, and an acceleration of labor follows. Opium, when it produces this effect, has been regarded as an oxytocic. Now in these cases we have first the arrest of pain, then the occurrence of regular uterine action, and as a consequence the rigid os yields. It is possible that the beneficial effect of the anodyne or anæsthetic is due directly to their quieting action upon the spinal nerves. The uterus derives its motor nerves chiefly from the sympathetic system. When from disease of the spinal cord there is total paralysis of the lower extremities and bladder, labor has been known to proceed undisturbed.

It has been surmised that the nerves of the uterus, derived from the cerebro-spinal system, possess inhibitory properties. If it be true, it readily explains how severe pain may suspend uterine action, and how the tran-

quillizing of pain would restore to the motor nerves their full energy.

In cases where anodynes and anæsthetics fail, favorable results may occur from rupture of the membranes.

On some occasions we find, on examination, the cervix partially dilated, a segment of the head presenting, but the cervix continues hard and unyielding. The patient is noisy, and screams out with every pain. In a number of instances he has had an opportunity to demonstrate in the presence of members of the Bellevue Hospital staff the speedy disappearance of all rigidity, with complete dilatation, by simply asking the woman to hold her breath, and reinforce the uterine pains by the action of the auxiliary muscles. With his finger upon the cervix he has known a very few pains, thus reinforced, to put an end to a long period of delay and suffering.

In all cases where we desire to quickly overcome rigidity, or where other methods have proved ineffectual, we possess a certain means in the use of the Barnes Dilator, which acts most beneficially by both the mechanical pressure it exercises on the cervix, and by stimulating the dormant energies of the uterus.

The speaker then laid down the distinction between good pains and those of an opposite character, which, he thought, was not quite so simple as might at first appear. Good pains have nothing to do with mere frequency, or the suffering of which they are the source.

It is often difficult, toward the close of pregnancy, to distinguish between colic pains due to fecal accumulation, or the presence of gases in the stomach and intestines—troubles to which pregnant women are specially disposed—and uterine contractions of a painful character.

In normal labors the pulse becomes more rapid at the beginning of each pain, and continues to increase in frequency until the pain has reached its acme, when a gradual declination follows. But sometimes labor is attended by marked febrile symptoms. There exists not only rapidity of pulse during the intervals of the pains, but a continuous elevation of temperature. Now if at the same time the uterine contractions are the source of extraordinary suffering, there is strong reason for suspecting that the labor is complicated by inflammatory conditions of the organs concerned in parturition.

In the treatment of a pathological weakness of pains, one or two courses are open to the obstetrician: he may either effect delivery by resorting to a judiciously selected operative procedure, or by applying the whip and the spur he may seek to compel the uterus to perform its proper function.

Both from training and inclination the author prefers in most, if not all cases, to adopt the first alternative. Yet he is not quite ready to deny that ergot may be profitably employed at even an early stage of labor. He has seen small doses of ergotine given in the Prague Hospital, with the view to awaken such a degree of uterine activity as would suffice to bring about the moulding of the head in a moderately contracted pelvis. The ordinary formula consisted of: ℞. Ergotine, ʒj.; tinc. cinnamomi, syr. āā ℥j. M. et sig.: Teaspoonful every 3 or 4 hours.

In these cases it appeared to produce good results, and certainly did no harm, unless perhaps by leading to the postponement of a more vigorous line of treatment.

He mentioned a plan for supplementing weak pains that has been long employed by practitioners, for which two rules have been more recently formulated by Kristeller, consisting of regulated pressure made through the abdominal walls upon the fundus uteri. This method, to which Kristeller has given the name of *expressio fœtus*, in some cases enables us to bring about delivery without the employment of an extractive force. Yet the number of such cases is limited, and its principal application will always, it is likely, be found as a support to other operative procedures belonging to midwifery. Those who are not accustomed to resort to this plan, will be astonished upon trial to find how much a scientifically applied *vis a tergo* facilitates forceps deliveries, and extraction following versions.

Dr. Fordyce Barker remarked as follows:—My relations to the author of this paper would forbid me as a matter of taste from expressing my opinion with regard to it in any logical form, or in the way of a logical criticism, yet I will take the liberty to make a few criticisms upon some particular points without entering upon a general discussion of the paper.

The first criticism which I will make is in regard to the use of the term uterine pain as synonymous with uterine contraction. Practically there is a very decided difference between them, and I think that the author in his paper did not carry out his proposed idea at all, for he made the term uterine pain equivalent to uterine contraction. Now there are cases where uterine contractions go on and a complete result is attained without true uterine pain. There are cases where complete dilatation of the cervix is accomplished, and the patient is utterly unconscious of pain throughout the entire process, but the uterine contractions have resulted in their proper and due effects. This is true also in some cases, although more rare, where uterine contractions take place more completely with the second stage of labor.

I think that a great deal of the discussion in medicine has come from the loose use of terms. But to pass to more practical points in connection with the paper aside from the use of terms, and in relation to the subject of irregular contraction, it perhaps might not be unprofitable to just glance at the progress which has been made in our physiological appreciation of this subject.

It has been the regret of my life that I had not the early and complete training as the author has shown, and as many of the younger members now present have had. With this deficiency in my early training, because at that time the opportunities were not afforded for such thorough physiological study, I find myself obliged to analyze at length before I can correctly appreciate cases, and learn facts and ideas. This progress in physiological study is illustrated by glancing at the views of standard authors upon this subject of irregular uterine contraction.

Mercereau, who was a great man in his day, referred to this irregular contraction as being almost exclusively due to plethora and congestion, and the treatment which he recommended was bleeding, and sometimes anodynes, warm baths, etc. At that time nothing was known of the physiology of the nervous system as applied to the explanation of such irregular manifestations.

Then came Denman, the great English author, who wrote a book which every one who practises midwifery at the present day can read with profit. He was, however, entirely ignorant of the physiology of the nervous system as we understand it now, and he asserts in the most positive terms that there is no pain that occurs in labor but what is useful. His whole object while writing upon this topic was to show the impropriety of resorting to any measures to arrest pain. His

teaching utterly leads to the neglect of many of those methods of treatment which, at the present day, not only relieve suffering and exhaustion, but save many hours of labor and absolutely save life.

Perhaps as historical reminiscence, I may be permitted to refer to a case of considerable interest, one which, at the time of its occurrence, made a great sensation, and which has been quoted by writers and teachers from that day to this. I refer to the case of Princess Charlotte, only daughter of George IV., whose life, I believe, was sacrificed by the application of principles which were in accordance with the medical doctrines of that day, but whose life and the life of her child would have been saved had she been attended by any practitioner now present.

The case was referred to as an instance where death was the result of a concealed hæmorrhage, and teachers have been in the habit of referring to the romance of the story, that Sir Richard Croft, who was the Princess' attending physician, to avoid the censure and mortification attending the result of the case, placed a pistol to his head and shot himself.

What are the facts relative to this case as they have recently been published in the memoirs of Baron ——? The Princess was taken in labor, it being in her first child, on the 4th of Nov., 1817. Previous to her labor she was kept upon a low diet, laxatives being frequently given, and she was bled several times in addition, so as to prevent inflammation and plethora. She was taken in at 5 o'clock, the first symptoms being rupture of the membranes and discharge of the liquor amnii. The labor continued through the day and night of Tuesday, although all these authors state distinctly that the discharge became greenish and fetid; but because the pains continued regular in their recurrence, although feeble, no advance being made, yet no question was raised with regard to the use of instruments or the adoption of any measures for the immediate delivery of the woman. At 7 o'clock Wednesday night she gave birth to a dead child. Every effort possible was made to resuscitate it, but it never breathed. For some time the Princess seemed perfectly well. The placenta did not come away, and hour-glass contraction occurred; the placenta was then forcibly delivered, and as the memorandum says, with the escape of but little blood. The Princess remained quiet for some time and had a little sleep, but about 12 o'clock she awoke, appeared restless, tossed about, was a little delirious, and the physicians in attendance began to give her stimulants. She died at 1 o'clock on Thursday morning. It will be noticed that this lady was not delivered for 54 hours after her labor began; although for 30 hours before, the signs of the death of the fœtus were quite distinct, and the mother was in an exhausted condition; the idea of instruments was not suggested to the minds of her attendants, and in fact their use would have been improper, in accordance with the doctrines of that day.

At the post-mortem examination ℥ iv. of bloody serum were found in the pericardium, no other disease being found, or abnormal appearance except a few ounces of fluid was found in the uterus, varying according to writers from ten to twenty ounces. It was very evident that she did not die from post-partum hemorrhage. She probably did die from pulmonary embolism, which took place between 12 and 1 o'clock the night of her death. It is quite evident that here was a case in which death resulted from an ignorance of true physiological principles. In all probability had the Princess Charlotte been managed as any intelligent man would manage her at the present day, her own life and that of the child would have been saved. In that event the Duke of —— would probably never have been George IV., Queen Victoria would never have been queen of England, and it is impossible to estimate how immensely important as influencing, not dynasties merely, but nationalities and peoples in England, France and Belgium, because political existence at that time involved the fate of all Europe, were the operations of the medical attendants of the Princess Charlotte, for all rested upon the knowledge and skill of the profession of that day. With our knowledge and the resources at our hands, in all human probability the result would have been entirely different.

But to return to the paper itself: I will make a few remarks first in relation to the stricture of the neck of the uterus. Stricture at this point was defined by Dewees as occurring in two forms. One form in which the stricture is at the os externum from the irregular contraction of the uterus preventing the proper dilatation, and the other form where we have the stricture of the cervix uteri after the head has passed, preventing the shoulders from passing through, constituting the contraction of the neck of the uterus about the neck of the child. Now it seems to me that there is a decided difference between feeble, irregular uterine contractions having reference to the first stage of labor, and dilatation of the cervix and the feeble uterine contractions having reference to the second stage of labor and the expulsion of the contents of the uterus. I think they are due to different causes, and that there is a difference as to the appropriate treatment for each condition. I think that physiologists will tell us that a different class of nerves are involved in the process connected with the dilatation of the cervix uteri, from that involved in the process of the expulsion of the contents of the uterus.

I have not seen a case of hour-glass contraction for more than twenty years in my own cases. I have seen it in consultation, and then it has occurred from just those causes which the author in his paper has mentioned, and which are defined for the first time.

In relation to the stricture of the cervix uteri, I will add another cause which was not mentioned, and that is from paralysis of the muscles of that part due to the uterine contractions having forced the head below the symphysis pubis, and as the labor goes on the anterior lip becomes pressed between the fœtal head and the symphysis, and so paralyzes those tissues that it prevents normal contraction.

When I find this condition, I think labor is very frequently shortened by hours, by introducing one or two fingers and pushing the lip up and holding it up until the head has escaped from it.

With regard to stricture of the perinæum, I believe there is an enormous difference in the nervous susceptibility of different patients. I used to see cases, before the use of anæsthetics, of excessive spasmodic rigidity of the perinæum, which now never occurs in my own practice. I think in most cases this is one very much of the same sort of paralysis of the muscles which I referred to as causing paralysis of the anterior lip. In this case the pressure is from the head upon the perinæum, the mucous membrane of the vagina very frequently becomes dry, and the reflex action is such as to give rise to excessive uterine pain, without any results. I find that these cases are most satisfactorily managed and the labor most rapidly completed, by placing the woman fully under the influence of an anæsthetic and introducing, it may be, a large quantity of some unctuous substance, such as lard, cold cream, or sweet-oil into the vagina.

In regard to ergot and *expressio fœtus*, I have only to say that I have had no practical experience as re-

gards the value of ergot in increasing uterine pain and regular power. I have been for some time determined in my own time to make a trial of it after the manner recommended in this paper. It seems to me to be based upon sound philosophical reasoning. I have resorted to expressio fœtus for years, long before it was brought out by Kristellar, supposing that almost everybody was familiar with it. During the last hours of labor I am in the habit of making firm pressure over the uterus, and I believe that I have shortened many cases of labor materially by adopting this measure.

Dr. A. C. Post stated that the practice of expressio fœtus was one which from time immemorial has been practised by the Tartars of Central Asia. It is their custom to select the strongest man in the tribe to embrace the woman in his arms and by this mechanical pressure to facilitate the progress of the labor.

Dr. Garrish remarked upon points of practical importance.

Dr. Hubbard said that he had derived the most benefit in making pressure upon the abdominal walls by the use of a roller bandage. In one case the pain had entirely ceased from some cause which could not be made out, but by placing a bandage about the patient tightly, the pains commenced and the woman was soon delivered.

With reference to the use of ergot he has not, of late years, been in its favor. He has been in the habit of using opium for an oxytoxic effect, according to the plan recommended by Dr. Barnes.

The Academy then adjourned.

Stated Meeting, May 15th, 1873.

Dr. S. S. Purple, Vice-President, in the Chair.

MORTALITY OF VARIOUS STATES OF THE UNION.

Prof. J. C. Dalton was appointed orator for 1873.

Dr. Charles P. Russel read a valuable paper on "Mortality in the various States of the Union," and concluded with a tabulated statement of death-rates during the past year in the principal American and foreign cities—derived from official sources. He was largely indebted for the foreign figures presented to the courtesy of American consuls in their respective posts. The figures of American, Italian, and British cities were generally furnished him by officers in charge of statistical bureaus. This table is the most comprehensive one of the kind ever presented.

The highest death-rate in the United States, according to the table, was given by Memphis, viz.: 46.6 in each 1,000 inhabitants; in Savannah, the mortality was equal to 39.2 in each 1,000 inhabitants; in Vicksburg, 36.5; in Troy, 34; in Hoboken, 32.9; in New York, 32.6; in Newark, 31.6; in New Orleans, 30.6; and in Boston, 30.5. These were the highest figures of mortality. The other principal cities furnished the following death-rates: Philadelphia, 26.1; Brooklyn, 28.1; St. Louis, 20.1; Chicago, 27.6; Baltimore, 25.1; Cincinnati, 20.5; San Francisco, 17.2.

Of the larger British cities, Dublin yielded the greatest death-rate, viz.: 29.9 in each 1,000 inhabitants; that of Manchester being 28.6; of Glasgow, 28.4; of Leeds, 27.9; and of Liverpool, 27.1. The death-rate of London was as low as 21.4—less than that of any other important British city.

On the continent of Europe, the highest death-rate was noticed in Prague, Bohemia, viz.: the enormous one of 48.9 in each 1,000 people. It was excessive in Cadiz, Spain, where it was equal to 44.7; in Munich it was 41.8; in Rome, 36.7; in Naples, 35.7; in Florence, 35.1; in Athens, 33; in Berlin, a city with little less population than New York, it was 32.3, or nearly equal to our own; in Bologna, Italy, it was 32.2; and in Vienna, Genoa, Stockholm, and Nice, 31.8. The large mortality of the last-mentioned city is owing to the many deaths of invalid strangers sojourning there. High death-rates prevailed also in Havre, Rotterdam, Leghorn, Venice, and Milan, ranging between 31 and 30. In Paris it was stated as only 21.1—but all deaths by strangers and travellers are there excluded.

The lowest mortality was given by the Swiss cities in Zurich, Geneva, and Basle—13.9, 19.4, and 20.9 respectively—and Christiania, Norway, 20.7. Algiers, Africa, gave a death-rate of 33.6. That of the Indian cities of Bombay and Calcutta was by no means high, being 29.2 and 25. In Madras, however, it was 35. In Montreal it was 37.3, and in Havana 35.1. The highest known death-rate prevailed in Valparaiso, Chili, viz.: 66.9 in each 1,000 inhabitants. This was the only South American city heard from.

Dr. W. M. Chamberlain made some "Remarks upon the Principles involved in the Mechanical Treatment of Uterine Displacements," as a novelty, without urging it, as he had employed it in only four or five cases of anteflexion, and retroflexion or retroversion, but with success. The paper will appear in a future issue.

Dr. Peaslee said that Dr. Russel's paper was, of course, more accurate and comprehensive than any other previously published, and the statistics would be accepted as facts.

In regard to the subject of Dr. Chamberlain's paper, he stated that it was a pretty extensive one, but the principle advocated was the one for adoption; the instrument was a new variety of instrument already employed. He referred to a paper which was read some ten or fifteen years since at the meeting of the State Medical Society, in which from 120 to 150 varieties of pessaries were presented; since that time nothing had been introduced which exhibited a new principle. The principle of the prop was the one to be adopted in the construction of pessaries, and if the vaginal wall was not long enough, the lower end of the prop should be behind the symphysis pubis. The danger from distention of the vagina, on the introduction of instruments, had been overdrawn, but it was not often necessary to do it if the prop was applied correctly. He would not hesitate, however, to distend the vagina if the patient was relieved thereby.

Instruments generally were made too strong, and consequently defeated their object. They should be light, and, as far as shape is concerned, should be adapted to particular cases. One patient could wear a circular instrument, while another would require it to be elongated, the former being unbearable. The gynæcologist should know what the possibilities are, and be guided accordingly. Pessaries should be made of a perfectly smooth rubber tube, but, so far as his experience goes, makers have not as yet made them to suit him. Dr. Chamberlain's instrument would answer well in cases of sufficient tonicity of the vagina.

The Academy then adjourned.

MEDICAL LIBRARY AND JOURNAL ASSOCIATION OF NEW YORK.

Stated Reunion, May 22, 1873.

Dr. John C. Peters, President, in the Chair.

DIAGNOSIS OF PELVIC HÆMATOCELE.

Dr. Charles Carroll Lee made "Remarks upon the Diagnosis of Pelvic Hæmatocele." The following were his conclusions:—

"Hæmatocele sometimes, and perhaps often, occurs without recognition. For, if it be liable to be overlooked when the effusion has been so great as to cause profound shock and exhaustion to the patient, the lighter forms of the malady are much more apt to escape detection.

"Its occurrence, as a possibility, should be borne in mind whenever we meet with cases of obscure shock and sudden prostration in women; and if to this feature be added severe abdominal or pelvic pain and retching, or persistent vomiting, without other evident cause, its existence will be highly probable. It is not necessary that the rectal or vaginal tumor should exist at the beginning of the disease; when the patient is supine and the blood diffused throughout the pelvic cavity this is not likely to occur immediately, although its absence renders an absolute diagnosis impossible.

"In milder cases the conditions with which it is most likely to be confused are pelvic cellulitis and pelvic peritonitis; I say nothing of uterine displacements, as very little skill or knowledge is requisite to discriminate between these conditions and the tumor caused by hæmatocele; the uterine sound alone is necessary.

"As regards cellulitis, although the inflammation is as sudden as the onset of hæmatocele, the swelling it produces is never sudden; moreover, the swelling is generally lateral at first, in or about the broad ligament on either side, while in hæmatocele it is believed to be always in the posterior cul-de-sac, although Courty states that Chassaignac had charge of a case where the effusion was entirely confined to the anterior cul-de-sac. In cellulitis the tumefaction is hard and resistant from the first, while in hæmatocele it is at first soft and fluctuating, and only hardens as the contents gradually coagulate—the contrary being here, also, true of cellulitis when the swelling gradually softens, especially when it terminates in abscess.

"In *pelvic peritonitis* the differential diagnosis is perhaps more difficult, as the pain is here not only sudden, but sometimes quite severe; but ordinarily it is certainly less acute than in hæmatocele, and never produces collapse or fainting, which is so strongly indicative of internal hemorrhage. Like cellulitis, it commonly occurs after parturition, or follows operations upon the uterus, while hæmatocele is most common after an arrested menstruation, although it may occur at any period. The pelvic swelling that follows peritonitis is less notable in size than an ordinary hæmatocele; it forms very slowly, and is hard and "boggy," without elasticity or the feeling of fluctuation. When pelvic peritonitis occurs during menstruation, as occasionally happens, the discharge is suddenly arrested or suppressed; whereas hæmatocele occurring at such a period does not necessarily arrest the flow.

"Both cellulitis and pelvic peritonitis are believed to be always associated with functional activity of the generative organs; while traumatic hæmatocele may evidently occur at any time, without regard to either menstruation or parturition.

"Although it has not been my intention to discuss either the prognosis or treatment of hæmatocele, it may be stated in general terms that the prognosis is good, and the best treatment a judiciously expectant one—by rest, opium, gallic acid, and the local application of cold if the hemorrhage be severe, in the first stage; in the second, tonics and hot injections into the vagina or bowel, limiting evacuation of the contents of the tumor to such cases only as threaten to cause septicæmia."

Dr. Peaslee remarked that the subject was of great interest, especially in its diagnostic features. He referred to the signs of hæmatocele, pelvic cellulitis, and ovarian cyst, and considered the distinguishing of the latter from hæmatocele ordinarily an easy matter; but he spoke of a complicated case which he saw in consultation with Dr. Mitchell, of Brooklyn, in which this gentleman gave up the idea of hæmatocele and fell back upon pelvic cellulitis, or ovarian cyst. The patient died, and an ovarian tumor was found adherent to everything it touched; the cyst held about three pints, of which half was pus and the rest was common viscid fluid. The speaker learned from this case that an ovarian cyst may increase within forty-eight hours to one of the size related.

The Association adjourned.

Correspondence.

A PRIZE BY THE EMPRESS OF GERMANY.

Berlin, *May 1st*, 1873.

To the Editor of the Medical Record.

Sir.—May I request the favor of your granting a place in the columns of your journal to the enclosed Circular, which opens a literary competition on subjects deeply interesting to all those who would fain alleviate, to the best of their powers, the miseries of war?

I have the honor to be, Sir,
Your obedient servant,
von Holleben.
Chairman of the Central Committee of the German Associations for the relief of wounded and sick soldiers in time of war.

Circular.

For the purpose of advancing the cause of humanity, under the symbol of the red cross in time of peace, Her Majesty the German Empress, upon the occasion of the World's Exhibition at Vienna, has deigned to offer two prizes in the sum of 2000 thalers each for the following two essays:—

No. 1, for the best manual of technical surgery in war.

No. 2, for the best treatise on the Geneva Convention.

And in addition thereto, Her Majesty has granted a like sum, both for awarding premiums to articles to be used for sanitary purposes in the field, exhibited at Vienna, and for purchasing the same.

The undersigned Central Committee, charged with the duty of carrying out Her Majesty's designs, request all persons desirous of competing for the prizes, to observe strictly the following rules deemed essential in making the award:—

The manual referred to under No. 1, in describing the different methods of dressing wounds and applying bandages, and the surgical operations occurring in war, must concisely and briefly state the present standpoint of technical surgery in war, so as to form an indispensable companion and practical assistance for every army surgeon.

The essay under No. 2 must contain a history of the Geneva Convention, and a statement and examination of the results experienced in carrying it into effect, together with suggestions for its further development by additions and modifications.

The prize essays, written in German, French or English, must be sent to the undersigned Central Committee not later than the 15th May, 1874.

They must be without signature, but distinguished by a motto and accompanied by a sealed envelope, reproducing this motto on the outside, and containing within the name and residence of the author.

On the 18th of October, 1874, the birthday of His Imperial Highness the Crown Prince of the German Empire, the prizes will be awarded to the essays to which they shall have been adjudged by a jury composed of three members, designated severally by the Austrian Patriotic Aid Association for wounded soldiers and the widows and orphans of soldiers at Vienna, by the International Committee at Geneva and the undersigned Central Committee.

The author will have the right to publish the essay which shall obtain the prize, but if within a period of six months from and after the date of the award he shall not have availed himself of such right, it will revert to the undersigned Central Committee.

THE CENTRAL COMMITTEE OF THE GERMAN ASSOCIATIONS FOR THE RELIEF OF WOUNDED AND SICK SOLDIERS IN TIME OF WAR.

VON HOLLEBEN.

BERLIN, *May* 1, 1873.

TREATMENT OF CHOLERA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The time is approaching when it will become necessary for physicians in this vicinity to consider what course of treatment they will adopt in cases of cholera. For it is true that up to the time of the epidemic of 1866 there was nothing like unanimity on the subject. And the diversity of opinion has given opportunity to flippant and thoughtless physicians to speak of cholera in terms very commonly used by the laity, as a disease about which the medical profession is quite in the dark.

There is no occasion for any such admission, if we keep in mind the true history, which is, that cholera is almost necessarily fatal when the second (algid) stage is fully established; that it is useless to expect that any method can be discovered which will restore the patient from that condition of collapse; but that in the first stage, before the circulation is materially affected, treatment is very efficacious, and we have a prospect of saving a very large proportion of our patients.

What, then, is the course to be pursued? An experience with cholera in 1849, '54 and '66, in the last of which epidemics I had charge of the Brooklyn Cholera Hospital, has satisfied me that the method which promises a great degree of success is the administration of calomel, in frequently repeated doses, until the discharges lose their characteristic watery appearance and become green or brown, and have a fæcal odor. In the *New York Medical Journal* for December, 1866, I published a concise report of the epidemic of that year in Brooklyn, with my hospital experience. After trial of various methods during the first two weeks of the continuance of the hospital, the administration of calomel was adopted as the regular treatment, and daily observation showed it to have a very powerful and favorable influence upon the disease. The whole mortality was, of course, very great; for most of the patients were brought in in the stage of collapse, and past all help; but of thirteen patients entering in the first stage twelve were treated exclusively with calomel, and recovered; the only one entering in that stage who was not treated with calomel, died; fifty-seven entered in collapse, of whom twenty-three were treated with calomel, and of these, six recovered, three exhibited partial reaction, and four passed out of collapse and died in the third stage.

Such an experience makes it probable that if this method were adopted in private practice, where patients are often seen at the very outset, or before the algid condition has been reached, the mortality of the disease would be very materially lessened. It is a treatment which has found favor to some extent before, but has not been pursued so perseveringly, or perhaps on so well-defined principles, as to lead to its establishment as a well-recognized method. It has the support of the ablest and wisest of this generation of physicians, the deeply-lamented Niemeyer.

My practice was to give it in ten-grain doses, repeated every hour until colored discharges were produced; and their appearance was always attended with relief of the epigastric distress and other symptoms; with improvement in the pulse, and restoration of warmth in cases which were running into the stage of collapse. Niemeyer says: "I have had the best results from cold compresses frequently applied to the abdomen, and from the administration of calomel in doses of one grain every hour."

In 1849, I treated a number of cases with venesection, after the method then in repute with the East India surgeons. I recollect two cases of recovery from the stage of collapse, in one of which there was no radial pulse; on opening the vein no blood flowed, but by continually stripping the arm from the wrist to the elbow, it came drop by drop, and after awhile gradually increased, so that, after half an hour's effort, there was a moderate stream, and warmth began to return to the surface. The essential pathology of cholera consists in a remarkable change in the blood, by which its red corpuscles lose their power of oxygenation, and there is consequently a general arrest of the circulation. The first blood that flows, when a vein is opened in the second stage of the disease, is dark and viscid, and the red corpuscles are found to be disorganized. Now it is highly probable that calomel, acting primarily on the portal circulation through the intestinal mucous membrane, relieves secondarily the congestion of the systemic capillaries, thereby arresting the destruction of the red corpuscles, while it eliminates the choleraic poison by the bowels.

There are other points in the treatment of cholera which are of great importance, and which are generally recognized by the medical profession. In this brief communication I will only refer to them, so far as to say that all nourishment in the first or second stage is hurtful, as no food can be digested; that opium is useless, unless at the very outset; that alcohol has no effect in restoring the warmth; that external heat is useless, and the warm bath very injurious, and friction of no avail; but that as near an approach to repose as it is possible to attain, with cold affusion, and moderate draughts of water or bits of ice, with sinapisms to relieve the cramps, with the continued use of calomel, will give us the best results we can obtain.

WM. HENRY THAYER, M.D.

BROOKLYN, June 9, 1873.

THE STATE MEDICAL SOCIETY OF NEW JERSEY.—The 107th meeting of the State Medical Society of New Jersey was held May 29th and 30th at Mount Holly. The next annual meeting will be held at Long Branch.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from June 5, 1873, to June 18, 1873.

SMITH, A. K., Surgeon. Assigned to duty as Chief Officer, District of New Mexico. S. O. 84, Department of the Missouri, June 4, 1873.

ALEXANDER, C. T., Surgeon. Relieved from duty in Department of the Missouri, to proceed to St. Louis, Missouri, and on arrival, report by letter to the Surgeon-General. S. O. 113, A. G. O., June 5, 1873.

GRAY, C. C., Surgeon. Assigned to duty as Post Surgeon, at Fort Clark, Texas. S. O. 96, Department of Texas, May 26, 1873.

TOWN, F. L., Surgeon. Granted leave of absence for 30 days, with condition to make satisfactory arrangement for medical attendance during his absence. S. O. 104, Department of the East, June 5, 1873.

FRYER, B. E., Surgeon. Assigned to duty at Fort Wood, N. Y. H. S. O. 106, Department of the East, June 7, 1873.

BREWER, JNO. W., Assistant Surgeon. Assigned to temporary duty at Fort McHenry, Maryland. S. O. 106, C. S., Department of the East.

MILLER, G. McC., Asst. Surgeon. Relieved from duty in the Department of the South, and ordered to Department of Arizona. S. O. 113, C. S., A. G. O.

LIPPINCOTT, H., Asst. Surgeon. Relieved from duty in Department of the South, and ordered to Department of Arizona. S. O. 120, A. G. O., June 16, 1873.

KOERPER, E. A., Asst. Surgeon. Granted leave of absence for 30 days. S. O. 112, A. G. O., June 4, 1873.

MEACHAM, FRANK, Asst. Surgeon. Granted leave of absence for 30 days. S. O. 118, A. G. O., June 12, 1873.

YEOMANS, A. A., Asst. Surgeon. When relieved by Asst. Surgeon Matthews, to comply with orders received from War Department. S. O. 106, C. S., Department of the East.

DELANY, A., Asst. Surgeon. To report in person to the Commanding General, Department of the South, for assignment. S. O. 120, C. S., A. G. O.

PATZKI, J. H. Asst. Surgeon. Granted leave of absence for 4 months, with permission to go beyond sea. S. O. 115, A. G. O., June 7, 1873.

MATTHEWS, W., Asst. Surgeon. Assigned to duty at Fort Sullivan, Me. S. O. 106, C. S., Department of the East.

KING, WM. H., Asst. Surgeon. Relieved from duty in Department of the Missouri and ordered to Department of the South. S. O. 113, C. S., A. G. O.

BYRNE, C. B., Asst. Surgeon. Relieved from duty in Department of the Columbia, to proceed to Baltimore, Md., and on arrival, report by letter to the Surgeon-General. S. O. 113, C. S., A. G. O.

Medical Items and News.

DR. JAMES L. BANKS has been appointed attending physician to the Presbyterian Hospital, N. Y., *vice* Dr. E. C. Seguin, resigned.

HEALTH BOARD APPOINTMENTS.—Dr. W. De Forrest Day, Sanitary Superintendent, Dr. Elisha Harris, Registrar of Records.

CHOLERA has made its appearance in Nashville, Memphis, Cincinnati, Paducah, and Washington. The number of deaths reported up to June 21st, were as follows:—Nashville, 253; Memphis, 71; Cincinnati, 14; and Washington, 1; Paducah, 5.

YELLOW FEVER.—The report of the existence of yellow fever cases in Brooklyn is without foundation.

BROOKLYN BOARD OF HEALTH.—The new Health Board have appointed the following officials: *Sanitary Superintendent*, Dr. B. A. Segur; *Registrar*, Dr. James Watt.

DR. JAMES L. BROWN.—The following resolutions were presented by a committee of the New York Obstetrical Society, appointed at the meeting subsequent to the death of Dr. James L. Brown, to express the sense of the Society on the sudden loss of its esteemed President:—

Whereas, It has pleased Divine Providence to take from our midst our beloved President, Dr. James L. Brown, therefore be it

Resolved, That we deeply mourn our loss in being thus suddenly deprived of an able and devoted President, whose wise counsels and judicious labors were always of the highest value to this Society.

Resolved, That by the death of Dr. Brown we have lost a friend and associate whose warmest interest and hearty co-operation have been with us since the very foundation of our Society, and whose unceasing and zealous exertions have largely contributed to its present position and success.

Resolved, That in the removal in the midst of an active career of one so qualified to adorn its ranks, the medical profession of this city has sustained a severe loss.

Resolved, That we tender our heartfelt sympathy to the bereaved family of Dr Brown.

Resolved, That a copy of these resolutions be sent to the family of Dr. Brown, and that they be published in the medical journals of this city.

Signed { T. G. THOMAS, E. R. PEASLEE.

CHAS. S. WARD, *Secretary*.

ST. PETERSBURG ACADEMY OF MEDICINE.—Lidia Rodelrena, a wealthy Russian lady, has just presented to the St. Petersburg Academy of Medicine $40,000, to endow a department for the medical instruction of women.

LAPHAM.—Dr. Increase A. Lapham, of Milwaukee, has been appointed Chief Geologist of Wisconsin.

NEW YORK DERMATOLOGICAL SOCIETY.—At the annual meeting of this Society, held recently, the following officers were elected for the ensuing year: *President*, Dr. R. W. Taylor; *Secretary*, Dr. Lucius D. Bulkley; *Treasurer*, Dr. F. Le Roy Satterlee; *Executive Committee*, President and Secretary *ex-officio*, and Drs. F. D. Weisse, F. P. Foster, and T. A. McBride.

THE QUEENS COUNTY MEDICAL SOCIETY, N. Y.—The annual meeting of this Society was held May 27th, 1873, and the following officers were elected: *President*, Dr. Edwin Webb, of Hempstead; *Vice-President*, Dr. S. Hendrickson, of Jamaica; *Secretary and Treasurer*, Dr. Wm. D. Wood, of Jamaica; *Censors*, Drs. Ault Muller, Davidson, and Taylor; *Delegate to the State Medical Society*, Dr. Ornton: *Delegate to the Kings County Medical Society*, Dr. P. Y. Frye; *Delegates to the State Medical Association*, Drs. Whiting and Woodend.

SIGNS OF FRACTURE OF THE BASE OF THE SKULL.—Dr. R. M. Hodges (Boston *Med. and Surg. Jour.* May

15th, 1873) has an instructive clinical lecture on "Bloody, watery, or other discharges from the ears, nose, or mouth, as signs of fracture of the base of the skull."

THE STATE MEDICAL SOCIETY OF CALIFORNIA.—The officers of this Society for the present year are: *President*, T. H. Pinkerton, M.D.; *Vice-Presidents*, Drs. J. M. Browne, C. A. Kilpatrick, F. W. Hatch, H. M. Biggs; *Permanent Secretary*, W. T. Wythe; *Assistant Secretaries*, Drs. A. B. Caldwell and T. Ross; *Treasurer*, J. E. Oatman, M.D.; *Board of Censors*, Drs. G. G. Tyrell, G. W. Graves, E. A. Stockton, L. Robinson, and W. S. Thorne.

The late meeting was held in Sacramento; the next annual session will be held in San Francisco.

ST. THOMAS' HOSPITAL, of London, enjoys the princely income per annum of £30,000.

DEATH OF NOTED ENGLISH PHYSICIANS.—Dr. Bence Jones, of London, Senior Physician of St. George's Hospital, the pupil of Liebig, friend and biographer of Faraday, and Honorary Secretary to the Royal Institution of Great Britain, died recently. Dr. Tyler Smith, of London, died June 20th.

SUSPENSION OF MEDICAL JOURNALS.—The Journal of the Gynæcological Society, the Michigan University Medical Journal, and the American Psychological Journal are no more.

CINCINNATI ACADEMY OF MEDICINE.—The officers of this Association for 1873 are as follows: *President*, John H. Tate, M.D.; *First Vice-President*, A. C. Kemper, M.D.; *Second Vice-President*, Byron Stanton, M.D.; *Recording Secretary*, J. W. Hadlock, M.D.; *Corresponding Secretary*, N. P. Dandridge, M.D.; *Treasurer*, W. T. Brown, M.D.; *Librarian*, C. S. Muscroft, M.D.; *Trustees*, Drs. W. P. Thornton, J. J. Quinn, and C. S. Muscroft.

KENTUCKY STATE MEDICAL SOCIETY.—At the annual meeting of this Society, held recently, the following officers were elected for the ensuing year: *President*, Dr. J. W. Thompson, of Paducah; *First Vice-President*, Dr. J. M. Keller, of Louisville; *Second Vice-President*, Dr. R. M. Fairley, of Hopkinsville; *Recording Secretary*, Dr. J. A. Larrabee, of Louisville; *Corresponding Secretary*, Dr. J. D. Jackson, of Danville; *Treasurer*, Dr. L. B. Todd, of Lexington; *Librarian*, Dr. D. S. Reynolds, of Louisville.

The place of the next annual meeting is Shelbyville, on the first Tuesday of April, 1874.

TENNESSEE STATE MEDICAL SOCIETY.—At the late annual meeting of this Society the following officers for 1873 were elected: *President*, Dr. C. C. Abernethy, of Pulaski; *Vice-Presidents*, Drs. Woodson, of Gallatin, Wright, of Chattanooga, and Pearce, of Union City; *Corresponding Secretary*, Dr. Curry, of Nashville; *Recording Secretary and Treasurer*, Dr. J. D. Plunkett, of Nashville.

The next meeting will be held at Chattanooga on the first Tuesday in April, 1874.

THE PRESENTATION OF A VALUABLE LIBRARY.—The Minister of Public Instruction in France has purchased the elegant ancient and modern collection of books, belonging to the late Dr. Daremberg, and presented it to the Library of the Faculty of Medicine of Paris.

MENTAL ALIENATION.—Dr. Beaugrand says that, notwithstanding the various anxieties which beset the career of medical men, mental alienation is rare among them; and he gives the following table of Parchappe: artists, 9.60 per cent.; lawyers, 8.41 per cent.; clergymen, 4.15 per cent.; medical men, 3.85 per cent.

NEW YORK ACADEMY OF MEDICINE.—At a stated meeting of the Academy, held May 1st, 1873, Dr. Austin Flint, President, in the chair, Dr. C. E. Brown-Séquard made remarks on "The Importance of Frequent Auscultation and Percussion of the Chest in Cases of Organic Brain Disease." He cited cases, occurring in animals and man, showing that injuries to the brain will produce emphysema, pneumonia, and diseases of the liver, stomach, and kidney. Pneumonia is oftener produced when the injury is on the right side of the brain, rather than on the left side.

He referred to 188 tuberculous cases, compiled from various sources, in which the origin of the disease was traced to inflammation of the brain, showing it to be not of accidental occurrence.

His conclusions were as follows: In animals which have received brain-injury, inflammation of the lungs may follow. The injury, in this manner, causes death. In man the same effect is shown by actual experiment. The life of man may be saved, after injury to the brain, by early auscultation and percussion.

Dr. A. C. Post inquired if there was not a strong reciprocal action of diseases of the lung upon the brain.

The speaker replied that the mechanism of diseases of the brain upon the lungs is different from the action of the lungs upon the brain, but it was quite possible that Dr. Post's query would prove to be true. It was a subject demanding further investigation, and he would be happy to furnish any member of the Academy who might wish to make further researches some facts which he had already collected.

MASSACHUSETTS BOARD OF HEALTH.—The Fourth Annual Report of the State Board of Health for 1872, compiled by George Derby, M.D., Secretary, contains 473 pages of interesting and valuable reports on the following subjects: "Sewerage; Sewage; The Pollution of Streams; The Water-Supply of Towns," by Drs. Wm. Ripley Nichols and Geo. Derby; "Additional Analysis of Evidence as to the Use and Abuse of Intoxicating Liquors," by P. Emory Aldrich; "Character of Substances used for Flavoring Articles of Food and Drink," by Henry K. Oliver, M.D.; "Drainage for Health," by Henry F. French; "Infant Mortality," by Edward Jarvis, M.D.; "The Food of the People of Mass.," by Geo. Derby, M.D.; "The Adulteration of Milk," by Dr. A. H. Nichols and Prof. J. F. Babcock; "Causes or Antecedents of Consumption," by Henry I. Bowditch, M.D.; "The Adulterations and Impurities of Food," by Prof. H. B. Hill; "The Homes of the Poor in our Cities," by Frank W. Draper, M.D.; "Report of the Butcher's Slaughtering and Melting Association;" and Report on "Small-Pox in Mass. during Thirteen Months ending with Feb. 1st, 1873." The members of the Board are as follows: Drs. H. I. Bowditch, Warren Sawyer, Richard Frothingham, R. T. Davis, P. Emory Aldrich, G. V. Fox, Geo. Derby.

INTESTINAL OCCLUSION.—Dr. W. O. Johnson (Harv.) (*Boston Med. and Surg. Jour.*, April 24th, 1873) gives a *resumé* and analysis of the quasi recent and late papers on "Intestinal Occlusion," by S. Foster Haven, Jr., M.D.; A. P. Duchaussoy, of Paris; Wm. Brinton, M.D., of London; Dr. Edouard Henoch, of Berlin, C. Hilton Fagge, M.D., of London, and Drs. Heiberg, Kuettner, W. Gruber, Treitz, etc.

Original Lectures.

CLINICAL LECTURES ON PUERPERAL FEVER.

DELIVERED AT BELLEVUE HOSPITAL,

BY FORDYCE BARKER, M.D.,

PROFESSOR OF CLINICAL MIDWIFERY AND DISEASES OF WOMEN IN BELLEVUE HOSPITAL MEDICAL COLLEGE.

(Reported phonographically for the MEDICAL RECORD.)

LECTURE II.

THE following clinical history was taken from the note-book of Dr. Early, House Physician:—

Miss S——, æt. 24. German domestic; well-developed woman. Always been healthy. Nothing of special notice abnormally during pregnancy. Taken with labor Feb. 1, 1873.

Feb. 2.—27 hours after the commencement of labor, forceps were applied. Perinæum was slightly ruptured, and two sutures were applied. At 10.30 P.M., patient was comfortable.

Feb. 3.—Pulse, 80; temp. 100°. P.M.: pulse, 96; temp. 103¼°. No pain; milk appearing.

Feb. 4.—A.M.: Respiration, 24; pulse, 106; temp. 104⅓°. Had pain in abdomen all night. Thirsty. Ordered solution of morphia (U. S.) ℥ ii., and tr. aconite (Fleming's), ♏ii. every hour, also 3 pills for bowels. P.M.: Respiration, 28; pulse, 108; temp. 103½°. Pain less; slight tenderness over abdomen. The pills having had no effect, an injection was ordered. Given sol. morph. (U. S.) ℥ ii. and tr. aconite, ♏ii. every 2 hours.

Feb. 5.—Respiration, 18; pulse, 100; temp. 101°. Has some pain in right iliac fossa, also tenderness. Ordered morphine.

Feb. 6.—Respiration, 22; pulse, 108; temp. 101⅘°. Complains of pain, and there is some tenderness over abdomen. Ordered morphine.

Feb. 7.—Respiration, 32; pulse, 20; temp. 102⅔°. Has diarrhœa and vomiting. Matter vomited greenish and watery. Marked tenderness over right side; very nervous. Ord. tr. aconite (Fleming's) ♏ii. every hour. sol. morph. (U. S.) ℥ iiss. 9 P.M.: Has complained of pain all the evening. Ord. sol. morph. (U. S.) ℥ iii. 11 P.M.: Pain continues. Cannot sleep. Ord. sol. morph. (U. S.) ℥ iii.

Feb. 8.—A.M.: Pulse very rapid; temp. 102°. Skin hot and dry. Both cheeks red, swollen and painful. Tongue dry. Ord. tr. aconite (F.) ♏ii. every 2 hours; Quiniæ sulphat. grs. x. t.i.v. Liq. plumbi et opii to face. Brandy and extra diet. No diarrhœa this morning. P.M.: Respiration, 38; pulse, 128; temp. 102⅔°. Now complains of great pain in head and abdomen, and there is some abdominal tenderness. Tongue clean, but very red. Vomited this afternoon. Skin hot and dry. Ord. sol. morph. (U. S.) ℥ iii. at once. Whiskey during night, and aconite and quiniæ continued. 11 P.M.: Sol. morph. ℥ss. on account of severity of pain.

Feb. 9.—3 A.M.: Sol. morph. (U. S.), ℥ss. 9.30 A.M.: Respiration, 24; pulse, 128; temp. 102⅘°. Slight abdominal tenderness and slight pain, and patient feels better; slight tympanitis; catheterization; vaginal douche; face better; aconite, quiniæ and brandy continued. 7.30 P.M.: Respiration, 28; pulse, 140; temp. 101½°. Pain and tenderness over abdomen; skin warm and moist. Treatment continued.

Feb. 10.—9.30 A.M.: Much pain; abdomen tender and very tympanitic; feels very bad. Ord. injection for bowels and continued treatment. 2.45 P.M.: Respiration, 60; pulse, 140; temp. 103½°. Respiration sighing. Morphine and brandy. 5 P.M.: Respiration, 12; pulse, 142; temp. 103¾°. 9 P.M.: Respiration, 42; pulse, 132; temp. 104⅗°. Sol. morph. (Magendie's) ♏ xv. hypodermically. 11 P.M.: Respiration sighing, 48; temp. 105°; pulse unable to count. Complains of some pain in head, back, and abdomen; delirious; no vomiting. Died Feb. 11, 1.45 A.M.

Autopsy, Feb. 11, by Dr. Delafield. Brain not examined; heart normal; lungs normal; both pleura covered with pus and fibrin; liver rather large and soft; spleen large and soft; kidneys normal. Peritoneum, venous congestion, coated with fibrin and pus, small amount of purulent serum in cavity. *Uterus* well contracted; peritoneal surface congested and coated with pus and fibrin. Internal surface and walls normal; in right side, some of the sinuses at insertion of lateral ligament full of puriform fluid. Bladder normal. Pelvic sub-peritoneal tissue normal.

To-day, gentlemen, I will call your attention to a few points in connection with the general symptoms of puerperal fever. We are accustomed in this hospital to have cards placed above each patient, upon which are kept a special record of the respiration, circulation, and temperature. These essential symptoms are those which first indicate any striking abnormal departure from a healthy condition; and the characteristic features of the puerperal fever, wherever it occurs, whether associated with peritoneal symptoms, or phlebitis, or with lesions of the thoracic organs, or all these morbid conditions combined, or without any of them, are a morbid increase in temperature, increase in frequency of pulse, as well as change in character, and increased frequency of the respiration. Any puerperal woman who shows a temperature over 100°, a pulse over 100 to the minute, and a respiration over 24 to the minute, must be considered as being in abnormal condition; and these phenomena oftentimes appear before any other symptoms which will attract attention.

If you will study the best works you have access to, you will probably be led to believe that puerperal fever is almost invariably ushered in by a chill or repeated chills; but please do not accept what they have to say upon this point, for the fact in the case is that chills may or may not be present. Some of our most fatal cases are entirely free from chills throughout the whole course of the disease. None of the patients we have had in this hospital this winter have had chills with any degree of prominence. Pain and abdominal tenderness are unreliable symptoms in this disease. The pain, even where the peritoneal lesion is the most prominent one, has no special proportion to the extent of the lesion, for it is very often absent or almost absent, or a very inferior symptom, where post-mortem may reveal the most extensive effusions of plastic and sero-purulent material. Tympanitis also is not characteristic; and with regard to all three of these symptoms, the history of the case attached to these remarks affords a very fair illustration. The absence of pain, however, must not be regarded as evidence of the absence of the peritonitis, and it is important to avoid this error.

For the fluctuations in the pulse, temperature, and respiration, the clinical record of the case read in your hearing also affords a most faithful and satisfactory illustration. While the variations may be markedly different in different cases, yet the record of this single case will, if carefully studied, afford an exponent of

the liabilities of the disease. There is another feature of the disease to which I wish to call your special attention. This is one of the most treacherous diseases you will ever be called upon to treat. The patient may be in the most dangerous condition when the symptoms would lead you to suppose that she is better. The patient herself may say that she is better; there may be less pain, if pain has been prominently present, there may be less tympanitis, fever may have subsided, and desire for food returned, and even the patient may have a good appetite just before death.

Since our last meeting there have appeared in the hospital three cases of this disease. One died within an hour after admission; another who appeared to be convalescing until one day ago, when symptoms of an appalling character made their appearance, and in all probability the patient will die; the other one is at present improving, and also is expected to recover. Her temperature is 101½°; pulse, 72; and respiration, 18. There is considerable effusion into the abdominal cavity, but under the influence of opium, stimulants, etc., she at present is doing very well. This is a disease, therefore, which requires the most careful watching, and it will not answer to suspend treatment simply because the symptoms have ceased.

We now pass on to the consideration of the question of treatment.

When the peritoneal symptoms are the leading features, there is some pain, but the general features of the case are very different from those of purely inflammatory peritonitis. The limbs are usually extended, respiration abdominal as well as thoracic, usually some pain, but not intense, some tenderness upon pressure, but nothing like that which occurs in the idiopathic form. For the control of the pain, such doses of opium may be used as will hold it in complete subjection; but it does not usually require such free administration of this drug as in connection with the idiopathic cases. It will be noticed, by the clinical record read, that varying doses of the U. S. solution of morphine were used at somewhat varying intervals sufficient to allay all irritation from the pain. For the control of the nervous irritation which is especially manifest with peritoneal complications, we have no agent which can be compared with that of morphine. It is sometimes astonishing to what degree this remedy can be carried and not transcend the point of tolerance.

The only rule which can be given with regard to its administration, is to completely control all pain and nervous irritation, and the amount which will be required to do this must be learned by experience. We usually commence by giving such quantities as are represented by 5 or 10 drop doses of Magendie's solution, once an hour or two hours, and continue, it may be, to a point just short of producing narcotism.

Where the case is not complicated with the peritoneal lesion, but perhaps is associated with phlebitis, sometimes no opium at all will be required, and, if administered, greater care must be exercised, for the patient is in greater danger of becoming narcotized; but when the peritoneal lesion is present the toleration is sometimes enormous. It is not the quantity given, but the effect produced, that is to govern its use; but when the respirations have been brought down to 12 per minute, it should not, as a rule, be continued in the same doses which have been administered to produce that effect. It is in these cases, where there is apparently no peritoneal lesion, but the secondary lesion is chiefly phlebitis or metro-phlebitis, that we find the quinine so valuable. My habit is to give from ten to fifteen grains at a dose, night and morning.

Another point in the treatment is, that it should be adapted to the special form of the epidemic which is exhibited, and to meet the indications of each special case. Each epidemic having its own special type and nature, it is important not to fall into the rut of any special method of treatment, and it is in recognizing the leading features of the epidemic, and the leading features of every case in the epidemic, that constitutes the skill of every man in the management of this disease.

The first special indication in its management is to eliminate as much as possible the poison from the system; but I have found by experience, and I am becoming more convinced of the fact, that we are able to accomplish but very little in the way of elimination. It is not like a special poison taken into the stomach, which can be vomited, and all the results we have to deal with is what has been produced by the poison absorbed before the mass was removed.

In such diseases, however, as typhus fever, scarlet fever, and those belonging to that class, the doctrine of elimination, theoretically, is very well indeed, but, practically, I do not believe it to be of much value.

In all these cases it is well, however, to see that the kidneys perform their function well—see that there is no accumulation in the primæ viæ, acting as an irritant. But aside from this, any treatment which depresses the system should be carefully prohibited.

I believe that the great point in the treatment of this affection is to sustain the vital powers, counteract the special local effects, and bridge the patient over, while the effects of the poison are being produced.

Another indication is to control the vascular and nervous system.

With a pulse ranging from 100 to 160 perhaps, it can be readily seen that the vital power is rapidly being worn out. At the same time, if there is a tendency to the local lesions from the transmission of this poison, it can be seen that the effect is produced very much more rapidly; hence we regard it as an essential indication to control vascular excitement.

For this purpose we have an agent which I regard as superior to all others, and that is the veratrum viride. It is the agent which I have employed for many years.

It will reduce the pulse when the excitement is due to an inflammatory process with an almost absolute certainty.

As regards its safety, I find a vast number of physicians who hesitate to administer it, regarding it as unsafe on account of the occasional explosions which occur, in the form of nausea and vomiting. Now it will do this sometimes if given in too large doses, and the patient will present the appearance as if in a state of collapse, which to persons unacquainted with the effects of this article appears to be extremely alarming. The surface may be cold, countenance pallid, pulse become very slow and feeble,—and this condition I have frequently seen, but have come to learn that these phenomena are not dangerous. This condition is purely temporary and the patient passes out of it in a comparatively short time, even if not given anything; but if diffusible stimulants are administerd and mustard plasters applied, they *very soon* come out of this apparent condition of collapse. In idiopathic peritonitis this condition is a benefit, for afterwards the pulse can be held with the greatest ease.

In this disease we commence by giving five drops once an hour or two, and increasing to eight or ten until we bring the pulse from 120 or 130 to 80,

if possible. In a very large majority of cases it can be brought down to this point, but in some we cannot get it below 100. Where there is great nervousness present, perhaps it cannot be done, for the influence of the nervousness has a powerful effect, as is well known to all medical men. The condition of the nervous system in the unmarried woman particularly, who may be suffering from this disease, is sometimes an important complication.

Pelvic cellulitis is the most common form of local lesion, when the poison is not sufficient to produce puerperal fever.

This patient who is before you now is aged 17½ years, and was admitted to the hospital in December. Everything in connection with her confinement was normal, and she did very well for three days, when she began to complain of pain in the abdomen, which located itself more particularly upon the right side.

This was considered as evidence that there was a tendency to an abnormal action in the abdominal cavity.

The processes of involution were interrupted or retarded by the inflammatory action which was taking place in the ligamentous region, in the cellular tissue surrounding the uterus, as evidenced by the pain, tumefaction, and tenderness upon pressure, determined by a physical examination. The tendency in these cases is either to terminate by resolution or suppuration, and if the latter takes place we have the various forms of pelvic abscess occurring. Sometimes the suppuration is the cause of the peritonitis. This patient has been treated by the use of suppositories of opium, the administration of ten grains of quinine twice a day, and the application of the tincture of iodine over the tumor, and at the present time she is doing very well.

It has also come to be a rule with many of us to avoid all operations upon the pelvic organs of the female when puerperal fever is prevailing, because of the great tendency under these circumstances to result in cellulitis and affections of like character.

In certain forms of this disease and at certain seasons of the year, there is a tendency, almost impossible to overcome, to the formation of pus.

There are also other points to which I wish to call your attention, in relation to puerperal fever.

One of the tendencies of this disease is to eliminate the poison by the formation of other diseases.

In accordance with this tendency we sometimes have a suppurative arthritis, or mammary abscess, it may be, instead of a metritis. In such cases, the inflammation of the mammary gland is the result of an effort upon the part of the system to get rid of the poison: it is nature's problem for the cure of the disease. Here also it is to be noticed, that the mammary abscess is something entirely different and distinct from the ordinary inflammatory abscess.

When these events occur, I always feel that the safety of my patient is very much increased, and that she will probably get well, where the tendency is to the formation of external suppuration, whether it be in the breasts or joints or pelvic cavity. The tendency to get well is decidedly increased, and the prognosis is more favorable. Where, however, the disposition tends to the formation of pus in the internal cavities, especially serous cavities, the prognosis is very unfavorable, because the suppuration when found cannot be removed without producing shock.

The other point upon which I wish to speak is in relation to the use of quinine as a remedy to control the tendency to suppuration.

For more than fifteen years I have insisted upon this point, and have been able in repeated instances to point out the influence which quinine has in controlling the tendency to the formation of pus. Now in all those cases in which there is manifested a tendency to suppuration, I place my patients upon quinine and rapidly carry it up to the point of tolerance, this point being indicated by a tendency to hyperæmia of the brain, manifested by ringing in the ears, confused noises in the head, etc.

Experiments have demonstrated that it is an agent of great value in preventing the development of pyæmia and septicæmia. In the *use* of this article I find that the most frequent defect is the altogether too small doses. It is of no use to give it in three-grain doses, but it must be administered in such quantities as will produce its positive constitutional effect, and carry it to the point of tolerance soon.

I am accustomed to use it in from 10 to 15 grain doses morning and evening, 10 in the morning and 15 in the evening, or even 15 in the morning and a scruple at night.

The point of tolerance in these cases is exceedingly variable. In some cases 25 or 30 grains will be given each day for several days without producing any of the cerebral symptoms of cinchonism. The doses of quinine may be doubled, and perhaps tripled, without disagreeable symptoms, by combining it with the bromide of potassium.

It is now also well established that quinine has the power of reducing the animal temperature of the body, and in some instances the effect realized has been a reduction of temperature of 2 within one hour, if given in the manner referred to.

We therefore may obtain from quinine its full effect in supporting nerve-power, in arresting the formation of pus, and also obviating the presence of pyæmia and septicæmia. I teach this doctrine, because it is the result of my own experience and observation, and have taught it for many years.

There are two points in relation to its administration of which I wish to speak. First, it is objected to, administered in such doses as I have mentioned, because it may produce paralysis of the motor power of the heart. This tendency, however, may be counteracted by the use of stimulants, and fully avoided by giving half-ounce doses of whiskey once in 3 or 4 hours.

Again, if it is manifest that there is striking tendency to pyæmia and septicæmia, and the patient complains, from the administration of moderate doses, of ringing in the ears, confusion of ideas, etc., thus preventing its administration in proper doses to prevent this tendency, the early reaching of this point of tolerance can be counteracted by the combination of bromide of potassium in 15 or 20 grain doses with each dose of quinine. In this way, as I have before mentioned, the doses of quinine may be doubled at least, if not tripled, without serious inconvenience.

The essential agents therefore which we employ in the treatment of this disease are morphine, quinine, stimulants, veratrum viride, bromide of potassium, together with such antiseptic means as tend to prevent the formation of disintegrating clots in the cavity of the uterus, and the absorption of the septic material. In all cases vaginal injections should be used, twice a day, of carbolic acid water, 40 or 60 grains to the pint, for the purpose of washing away all clots and débris of lochial discharge, which, if left to undergo decomposition, might furnish septic material liable to be absorbed in the open uterine sinuses.

There is a tendency this season to the formation of an exceedingly offensive lochial discharge, consequently a great tendency to septicæmia, which requires extraordinary care in fulfilling this indication.

This, gentlemen, embraces what I have to say to you upon the subject of puerperal fever, and we will next turn our attention to a subject which may be of a kindred nature, viz., mammary abscess. This we will study more completely at our next lecture.

Original Communications.

AN EXAMINATION OF THE MEDICAL EVIDENCE IN THE TRIAL OF MRS. E. G. WHARTON,

ON THE CHARGE OF ATTEMPTING TO POISON EUGENE VAN NESS, ESQ.

By S. C. CHEW, M.D.,

PROFESSOR OF MATERIA MEDICA AND CLINICAL MEDICINE IN THE UNIVERSITY OF MARYLAND, BALTIMORE, MD.

THE science of medical jurisprudence rests to a great extent upon authoritative decisions which have been made upon special cases. Its questions, however, belong to the domain of physical science, which does not regard authority merely as such, but looks only to carefully ascertained facts; and it is therefore of the highest importance for a really valuable application of medical jurisprudence to the administration of the law, that its recorded cases should be the result of faithful study and accurate report.

It is evident, also, that such a misrepresentation of the facts of a case as may cause false conclusions to be drawn is, if wilful, a crime against society of the gravest character, since it tampers with the sources whence the administrators of the law derive their knowledge, and thus corrupts the very fountain-heads of justice.

I purpose to narrate in this paper the prominent facts of a very important case in legal medicine which has occurred in my own practice, partly to put upon record a truthful report of the same, and partly to correct any erroneous impressions in regard to it that may have been gotten from other sources.

The annals of toxicology furnish few cases of greater intrinsic importance, or that have more generally attracted the notice of the profession, than the two trials of Mrs. E. G. Wharton, at Annapolis, Md., the one in December, 1871, on the charge of poisoning General W. S. Ketchum, and the other in January, 1873, on the charge of attempting to poison Mr. Eugene Van Ness. The present article will consist chiefly of an examination of the second of these trials. From the social positions of the parties alleged in the State's indictment to have been poisoned, and also of the accused, great interest was excited in the community in which the events occurred; and this became more wide-spread from the fact that witnesses and experts were summoned to give testimony from various and remote parts of the country.

For the same reasons the trials were reported with much minuteness of detail by many journals, and were more or less commented upon by others both here and in Europe.

Under these circumstances it is not at all surprising that strenuous efforts should have been made by the counsel for the defence to break the force of the State's allegation of poison having been administered, as affirmed by its medical and chemical witnesses. Various means were resorted to with this view, natural enough perhaps as the devices of lawyers, but when suggested or countenanced by physicians, such as to cause fully as much indignation as surprise on the part of all fair-minded members of the medical profession.

Thus, when in the former trial several members of the Faculty of the University of Maryland had expressed an opinion under oath that the death of Gen. Ketchum was due to poison, it was perhaps not very strange that the prisoner's counsel should endeavor to lessen the weight of such damaging testimony by suggesting the existence of a bias in the minds of these witnesses in favor of their colleague, who conducted the chemical examination of Gen. Ketchum's remains. Such an intimation was easily thrown out; it might possibly have effect upon some ignorant and impressible juror, and, therefore, however grossly unjust and palpably untrue, the opportunity it offered of effecting a desired end was too good to let pass. Such slight considerations as injustice and untruth could not be allowed to stand in the way of a specious argument; so that with the understanding of the duties of advocacy, which, it is to be feared, prevails too widely, the use of such an argument before a jury ought not perhaps to cause much surprise.

Very different, however, must be the estimate put upon the conduct of members of the medical profession, who could deliberately publish such aspersions upon professional witnesses as are contained in two articles, the one by Dr. J. J. Reese, in the *American Journal of the Medical Sciences* for April, 1872, and the other by Dr. H. C. Wood, Jr., in the New York MEDICAL RECORD for April 15, 1873.

I have elsewhere commented upon Dr. Reese's review of the Wharton-Ketchum trial, and have shown his unfairness as a critic in suppressing portions of testimony, and also the errors of logic with which he was chargeable in his effort to make the facts of the case square with the ill-founded theory that has been advanced by another, and adopted to a certain extent by himself.* In this paper, Dr. Reese arraigned the medical witnesses from whose views he professed to dissent, on the charge of "glaring departure from propriety," and also of prejudice in the formation and expression of their opinions. Going beyond the range of matters pertaining to his own profession, he censured the Attorney-General of Maryland for the mode in which the case was conducted for the State, and even undertook to rebuke the Judges upon the bench for certain of their rulings in court.

Let it be remembered that Dr. Reese's article was published in the interval between the first and second trials, and that it was shown in evidence taken in the second trial that it had been widely circulated in pamphlet form in the county in which that trial was to be held. Some may find in this circumstance an explanation both of the character of the article and also of its opportune appearance.

At the second trial of Mrs. Wharton, on the charge of attempting to poison Mr. Van Ness, Dr. Reese again appeared as a medical and chemical expert, accompanied this time by his colleague, Dr. H. C. Wood, Jr. As I have sufficiently examined Dr. Reese's testimony and his comments upon the first trial, I shall consider here Dr. Wood's connection with the second trial, and the notices of it which have emanated from his pen since its conclusion. That trial resulted, as is well known, in a divided jury, eight voting for conviction and four for acquittal. It is to be observed that, as Dr. Reese's pamphlet had appeared previously to the second trial, so Dr. Wood's first publication upon the subject came out in the pages of a non-professional

* See *Richmond and Louisville Medical Journal*, July, 1872.

journal, at a time when it was generally believed that a new trial would take place.

With the view, perhaps, of giving more force to their attack upon the Faculty of the University of Maryland, these witnesses in their examination in chief announced themselves as Professors in the University of Pennsylvania. The name of that school may have added weight to their testimony in the estimation of some persons; but in the cross-examination the fact was elicited that they occupied the position of auxiliary professors only. With the records that they have made for themselves in their testimony upon the stand, and in their subsequent comments upon the trials, the ancient Institution with which they are connected may well disclaim such assistants:

Non tali auxilio, nec defensoribus istis.

In the number of *Lippincott's Magazine* for April, 1873, an article appeared from the pen of Dr. Wood, entitled "Medical Expert Evidence." Its title would suggest the discussion of an abstract topic; had it been such, it would have been perfectly legitimate, and no exception could rightfully have been taken to its publication in the pages in which it appeared.

But when, under cover of this name, Dr. Wood ventilated medical questions and attacked the opinions of medical men before the general public, his course of action can be characterized only as unethical and unprofessional.

Dr. Wood should have known that no right-minded physician would stoop to follow him into the arena of controversy which he had chosen. There he might safely have remained to enjoy the cheap plaudits won from those who, while incapable of weighing medical arguments, are readily impressed by false assertions and garbled facts. Now, however, that he has ventured into the fair field of medical discussion, an opportunity is afforded for commenting upon his conduct, and for vindicating the truth.

The New York Medical Record for April 15, 1873, contains a "Review of the Medical Testimony in the Trial of Mrs. E. G. Wharton," by Dr. Wood, which, in the interest of truth, and as a matter of simple justice to my professional friends and to myself, I feel constrained to examine. If in doing so my words shall be thought by any to be harsh or unmeasured, I would call attention to the following terms in which my colleagues and myself have been assailed by Dr. Wood:—

On page 172 of the Medical Record, our evidence in the trial is spoken of as "the *most extraordinary, ignorant*, or *biassed* and *untrue* expert testimony given by the medical gentlemen *engaged in the prosecution*," etc.

Again, on the same page it is stated that the trial "had its origin, as had also the judicial proceedings, in the *blundering of Dr. Aikin and his colleagues*;" and in the same connection, "the whole faculty of the University appeared in support of their colleague Dr. Aikin, until they were *all compromised* equally with him, and their *reputations equally involved* with his."

In view of the spirit shown by such utterances, let it be judged whether justice and propriety call for smoothness of speech in reply. That which is rather needed and deserved is stern rebuke for deliberate wrong-doing.

I do not propose to burden these pages with a detailed statement of all the circumstances of the case which gave origin to the trial held in January, 1873, but shall mention its clinical features and the facts in its history which are necessary to establish its diagnosis. My object in writing this paper is to give a true account of the case from my own personal observation. I shall show in addition, 1st, that Dr. Wood's opinions are invalidated by eager partisanship; 2dly, that he has misrepresented the facts of the case; and 3dly, that he has displayed a want of professional information in regard to the subjects upon which he writes.

I would call attention at the outset to the widely different relations held to this case in a legal point of view by the various medical witnesses called by the State, on the one hand; and by Dr. Wood and his colleague, Dr. Reese, on the other.

Dr. Williams and myself, as citizens of Maryland, were compelled by process of law to be present at the trials in Annapolis as witnesses to facts which had come under our own personal observation, and were also required to give our professional opinions as medical experts. From this there was no escape; our presence and the delivery of our testimony were compulsory. That we discharged this duty entirely free from passion or prejudice is incontestably proved by the fact that previously to the trials each of us had given to the defence a written statement of what we had observed. In doing this we were under no compulsion whatever; it was purely a free-will offering, designed for no other end than to aid the counsel for the defence in the work they had undertaken.

Our course was certainly open and liberal, and neither sophistry nor malignity could impute it to an unworthy motive. So far then as it was voluntary, our action was in aid of the defence, while our testimony as witnesses for the State, as well as that of all my colleagues in the University of Maryland, was given under a constraint which no citizen can resist; for the strong arm of the law was upon us.

What, on the other hand, were Dr. Wood's relations to this case? Living in the city of Philadelphia, where no process of a Maryland court could reach him; knowing nothing of the history or merits of the case, and therefore not inspired with the desire to enter the lists in the cause of injured innocence, for he distinctly asserts that "until after the recent trial he had never read any medical or other account of the first trial;"* he bargained with the senior counsel for the defence, and received a fee to "aid," as he says, "in bringing out the facts of the case, and to give privately a professional opinion thereon." In other words, he voluntarily assumed the position of paid counsel to the counsel. These were the circumstances under which Dr. Wood came to a conclusion different from that expressed by the witnesses for the State. He deems it necessary, however, to insist that "*as far as possible* his opinion was formed without bias;" but the reason he adduces in support of this position is certainly a little curious, and will hardly be considered very cogent.

"My agreement with Mr. Thomas, the senior counsel," he says, "was that my duties should be to aid in bringing out the facts of the case, and to give privately a professional opinion thereon; for this and this only was a fee to be received. *It was to be left to Mr. Thomas whether this opinion should also be promulgated from the witness-stand, but for going on the stand no further reward was to be given or taken.* I had, therefore, no possible interest to serve in this matter, and whatever the profession may judge of my opinion, I do insist that, as far as possible, it was formed without bias."

Now it is plain from this statement that, by Dr. Wood's own showing, the compact under which he received his fee contained several specifications, one of which was, that if required by the counsel employing him, he should give his opinion from the witness-stand; yet, while admitting payment for the opinion

* Med. Record, April 15th, 1873, p. 172.

as one item, he denies receiving any remuneration for another, viz., its enunciation from the stand.

And this statement he expects to be taken as proof of freedom from bias! Truly a remarkable argument, and one which may serve to show Dr. Wood's power of lucid reasoning. To what class of persons does he address himself?

Again, he freely charges those whose opinions he impugns with partisanship and bias, forgetting that his own record in the late trial was such that he, of all the witnesses examined, should have been most careful to avoid imputations of this kind.

However conscious Dr. Wood may have been of an effort to win in a contest, it might have been supposed that prudence at least would have deterred him from the public reference to his "*side*," which called down upon him in open court a merited rebuke from the learned and dignified Chief-Justice. "It would be well," said Judge Miller, "that the witness should not speak of his side. The only parties in this case are the State of Maryland and the accused, and their interests must not be imperilled by a witness taking a side." Charity might have drawn a veil over this portion of the proceedings in which Dr. Wood appeared in so very unenviable a light, had he not flouted others with a charge which was fixed upon himself alone. After this unfortunate betrayal of his partisan position, he left the stand, the object of derision to the jury and the spectators, and of sincere pity (for the *esprit de corps* will assert itself) on the part of all the medical men present, even of those whom he was employed to attack.

And yet this is the witness who charges the Faculty of the University of Maryland with giving "biassed and untrue testimony;" with being "all compromised," and having "their reputations equally involved." Such charges betray an endeavor to accomplish by abuse what could not be effected by argument.

I mention with reluctance any statements having a personal reference to myself; but having been assured by all three of the counsel for the defence, Messrs. Steele, Thomas, and Hagner, that my testimony as a witness for the State in these trials was free from every indication of bias or passion, it will easily be believed that I regard Dr. Wood's imputations as infinitely insignificant.

From what has been stated, it is obvious that Dr. Wood's opinions must be received with great caution, from his avowed position as the maintainer of a "*side*," while his qualifications as a critic of the views of others cannot be admitted at all.

Some men, however, are partisan by nature, and are consequently unable to discern that aspect of a case which is counter to their own preconceived views; and to a certain extent those who are thus constituted are perhaps excusable for the errors into which they fall. But no faulty construction of temper or of mind can excuse such misrepresentation of facts as is to be found in the papers now under notice. In the account given by Dr. Wood of Mr. Van Ness's illness, and of the management of the case by the physicians in attendance, the misstatements are of such nature that they can only be regarded as deliberate, and made for the purpose of giving factitious support to his "*side*."

I shall not enumerate all of these misstatements; a few examples will be sufficient to show the second reason for which Dr. Wood's report of the case must be set aside as wholly unreliable.

A brief statement of the principal facts of Mr. Van Ness's sickness as they really occurred and were testified to is here necessary, in order to expose the erroneous account given of them by Dr. Wood.

On the 24th of June, 1871, about four o'clock in the afternoon, Mr. Van Ness was invited to partake of lager-beer, into which a small quantity of what was stated to be gentian bitters had been poured. This he found so excessively bitter that after taking four or five sips of it, he could drink no more. A few moments after swallowing this, his vision became obscured, and on attempting to rise he felt so weak that he grasped at the window-frame to avoid falling.* Very quickly a feeling of stiffness in the back was experienced, extending to the arms and fingers, and thence to the legs, which "straightened out in a direct line from the body." In his struggles he fell upon the floor, his jaws became rigid, and a convulsion occurred in which he felt as though there were "a crushing in of the backbone."

A second paroxysm followed, more violent than the first, and accompanied with a feeling of suffocation. Convulsions of this tetanic character, amounting to complete opisthotonos, frequently recurred, the head being thrown back and the countenance growing dusky. In the height of the paroxysms consciousness was several times lost, returning, however, when their severity abated. Dr. P. C. Williams arriving at this time, administered an emetic of sulphate of zinc, which caused free vomiting, and then gave chloroform by inhalation, which controlled the condition, and prevented the full development of the convulsions. Rigidity of the body continued, however, with extreme sensitiveness and spasmodic contractions of the limbs, especially when anything came in contact with him. At this time I saw him, and, on conference with Dr. Williams, we determined to administer hydrate of chloral, under which the tendency to convulsions gradually passed away, and sleep came on. After all convulsive manifestations had ceased, the patient was occasionally fanned, as the weather was very warm.

It is to be observed that Mr. Van Ness has never at any time before or since the events described experienced a convulsion of any kind, nor has there ever been any recurrence of the sensations he then felt.

On the following day he awoke, "feeling bright," as he said; but after eating a piece of dry toast and drinking a cup of tea, he became nauseated, and felt a sensation of burning in the stomach.

Nausea and vomiting continued nearly the whole day, and were supposed, in the absence of a better explanation, to be possibly due to the use of chloroform and chloral; though this explanation was not satisfactory, since many hours had elapsed between the last administration of these remedies and the first occurrence of the vomiting.

For these symptoms he was treated with small quantities of brandy and water, creasote and lime-water, and finally with hydrocyanic acid. Gradually they abated, and in the morning of the following day, Monday, he was again better, and by my direction took two-thirds of a cup of beef-tea, which had been brought from his sister's house, and which proved grateful and refreshing. In less than an hour afterwards he expressed a desire for more, and it was accordingly brought from the cellar, where it had been placed after the first dose was taken, in order to be warmed by the kitchen fire. Before the second dose was given, some extract of celery-seed was brought by an inmate of the house, and poured into the beef-tea. After swallowing this, nausea again came

* Within the last few days a case has been brought to my notice, of a gentleman, who, when under the influence of strychnia, which had been administered in gradually increasing doses for disease of the retina and optic nerve, experienced a sensation of confusion in the head, and in endeavoring to stand was observed to catch at the tables and chairs in the room to avoid falling.

on, and he was unwilling to take more; but about 11 P.M. it was, against his wish, given to him again, when he fell asleep, but soon awoke with great oppression in the chest, intense nausea, constant vomiting, a sharp burning pain in the throat extending to the stomach, a metallic taste in the mouth, and irritability of the bowels. Such was the condition after taking the beef-tea.

Dr. Williams, who resides in the immediate neighborhood, was summoned, and arriving about one o'clock in the morning of Tuesday, found Mr. Van Ness prostrated and pale, his surface cool and covered with a profuse perspiration, his voice almost inaudible, and his pulse scarcely, if at all, perceptible. Under the free administration of brandy, he gradually recovered from this perilous state, and later in the day was much improved, though still greatly debilitated. It must be mentioned, as a very important part of the history of the case, that on the following day, June 28th, milk-punch was prepared for the patient by his wife, and administered by her. This was well borne by the stomach; but after part of it was taken, the tumbler with the residue was placed in a refrigerator, and on being brought out was found to contain a sediment, on which account no more of it was given. This sediment proved on chemical analysis to be tartar-emetic.

The above is a sketch of the prominent features of Mr. Van Ness's case. In drawing it I have scrupulously avoided reference to any collateral circumstances except those which serve to throw light on the history and diagnosis of the case.

The medical witnesses called by the State expressed the opinion that the symptoms of the attack of the 24th of June were due to strychnia. The grounds for this opinion were: 1st, the suddenness of the attack; 2dly, the speedy occurrence of tetanic spasms of the muscles of the neck, back, limbs, and jaws; 3dly, the sensation as of a crushing blow upon the back at the occurrence of each paroxysm; 4thly, the extreme sensitiveness and irritability, which occasioned convulsive contractions upon the slightest touch or shock; 5thly, the results produced by the medical means employed; 6thly, the clearness of mind during the intervals between the convulsions; and, 7thly, as a corroborative reason, the intensely bitter taste of the very small quantity of liquid swallowed immediately before the seizure; strychnia being the most intensely bitter substance in nature.

We maintained further that the action of strychnia is so peculiar and characteristic that a conclusion as to its being the cause of symptoms observed, may be reached independently of chemical evidence.

In this opinion we were supported by numerous medical authorities, who speak of tetanus as the only condition liable to be confounded with strychnia poisoning, from which, however, it may readily be distinguished with proper care.*

The possibility of the case being due to tetanus was absolutely excluded by its history, as shown in the suddenness of the attack immediately after drinking an intensely bitter fluid, and in the entire cessation of the symptoms in a few hours. Such a history belongs neither to traumatic nor to idiopathic tetanus, while it is perfectly characteristic of non-fatal cases of strychnia poisoning. The supposition that the case was hysterical or "*hysteroidal*" in nature, as maintained by Dr. Wood, is so utterly absurd that its refutation seems almost an unwarrantable trespass upon patience.

A gentleman of calm and unexcitable temperament, who had never in his life experienced a spasmodic or nervous attack of any sort, partakes when "perfectly well in mind and body" of an excessively bitter drink, and is suddenly stricken down with tetanic convulsions of such violence as to produce perfect opisthotonos and threaten asphyxia; and this condition is pronounced by a physician who had never seen the patient, and knew nothing of his constitution, to be simply "*hysteroidal*"! It is really hard to conceive the force of folly going further. The avowal of such an opinion would seem to tax to the utmost the resources of effrontery; and the assurance shown in the diagnosis might well provoke a smile, were not the means used to give it a show of plausibility such as to cause a feeling more akin to indignation than to amusement.

Dr. Wood asserts that "none of the characteristic symptoms of strychnia poisoning were present in the case of Mr. Van Ness;" a bold statement in view of the account given in the testimony, and as I have narrated it above. In his report of the case he makes no mention of the intense sensitiveness and irritability which induced convulsions on a slight touch or shock, and which are so highly characteristic of the effects of strychnia.

Knowing, however, that they are thus characteristic, he refers to Mr. Van Ness's desire to be fanned as disproving the action of strychnia; whereas, there was not one word of evidence that the fanning was desired or practised until after the convulsive tendency had ceased.

Again, Dr. Wood avoids mentioning the striking symptoms of the respiration being much embarrassed by the contraction of the muscles of the chest, and the consequent dusky hue of the complexion. These, taken in connection with the other symptoms, are too strongly indicative of strychnia to be allowed a place in his description of the case.

The attempt to disprove the influence of strychnia by showing that the spasmodic symptoms did not occur in a regular sequence, and that certain sets of muscles were not affected in a special order or degree, is a very fallacious sort of reasoning; for, though in many cases the usual order may be observed, yet when a large dose of strychnia is taken, so rapid and general is the influence, that all the voluntary muscles may be almost simultaneously affected. This is admitted by Dr. Wood to be true in some cases of strychnia poisoning; it was true in Mr. Van Ness's case; for, though he spoke of the "stiffening sensation gradually extending" from his arms to his legs, yet he did not use the word *gradually* in the sense of *slowly*, since only a few moments elapsed from the first sensation of uneasiness to the full development of the attack.

The symptoms of Sunday and Monday, the 25th and 26th of June, were ascribed by the medical witnesses for the State to the action of an irritant poison. This opinion was based, 1st, upon the repeated occurrence of gastric or gastro-intestinal irritation after taking different articles of food and drink, some of which produced a sedation of burning in the stomach;

* See Gross's Surgery; Da Costa on Diagnosis; Hammond on Diseases of the Nervous System. The opinion expressed above was controverted by Dr. J. J. Reese, who stated in his testimony that "there is not a single poison that can be exclusively determined by the symptoms; if you could not distinguish by the symptoms, there would be only one other means of distinguishing; that would be a chemical analysis of the food." It is somewhat noteworthy that in a report of a case of strychnia poisoning published by Dr. Reese in the *Amer. Journal of the Med. Sciences* for Oct., 1861, a precisely opposite opinion is expressed. He states that he conducted the chemical examination with scrupulous care and "entirely failed to detect any evidence of the presence of strychnia;" yet "all the moral circumstances connected with the case (as elicited in the subsequent trial) as well as the *symptoms attending the woman's death*, clearly pointed to poisoning by strychnia."

and 2dly, upon the profound sedation which occurred after the swallowing of the beef-tea in the evening of the 26th of June.

I expressed the opinion in regard to these symptoms that they were "due to some irritant poison taken with the food, but apart from a chemical analysis I would not say what the specific substance was."

With the light thrown upon them by chemistry, I stated without hesitation that I believed them to be due to tartar-emetic. I shall refer to this analysis hereafter, and show how absolutely certain its results were.

Dr. Wood, from his vantage-posts in Philadelphia and at the trial-table for forming an accurate diagnosis, attributed the condition to "overcrowding the stomach with beef-tea;" and in order to get rid of a circumstance so prejudicial to his view of the case as the "sharp burning pain in the throat extending to the stomach," of which Mr. Van Ness complained to Dr. Williams, he adopts the easy course of omitting this part of the description.

According to Dr. Wood's account, Mr. Van Ness felt, after the second dose of beef-tea, a "sensation resembling heartburn," whereas these words were really used not to describe the effect of the beef-tea, but that experienced in the early morning after taking a cup of tea for breakfast.

In still another case has Dr. Wood misrepresented the testimony that he criticises, in order to make occasion for censuring the State's witnesses. On page 170 of the MEDICAL RECORD he affirms that Dr. Williams and Dr. Chew "stated that they recognized the case as poisoning at the time of its occurrence." No such statement was anywhere made, or is to be found in the testimony. Dr. Williams and myself were both struck with the resemblance between Mr. Van Ness's symptoms and those of strychnia poisoning; but in the urgent necessity of giving relief we did not immediately form the definite opinion that the condition was certainly due to strychnia. The circumstances in which we encountered the case were such as to render it almost inconceivable that poison had been given; and so far from being reprehensible, it is creditable to a physician's humanity that he does not too suddenly arrive at the conclusion to which we were ultimately forced. In such circumstances opinions do not immediately crystallize into definite shape.

Let it be remembered, however, as a very important fact, that the treatment adopted at this stage of the case, viz., the administration, first of an emetic and afterwards of chloroform and chloral, was precisely what we would have used had we known with the most perfect certainty that strychnia had been taken. It was precisely the treatment which in a number of reported cases of undoubted strychnia poisoning has been the means of saving life.

In another place Dr. Wood asserts that "Dr. Chew went so far as to testify that the proper treatment of tartar-emetic poisoning was the free exhibition of prussic acid."

I regret to be compelled to say of this statement that it is deliberately untrue, and is a manifest perversion of my words, made with the intent of invalidating my opinion and placing me in a false position. In answer to a question, I had stated that prussic acid might be serviceable in allaying the irritation of the stomach caused by tartar-emetic, an opinion which can be supported by the highest authority. But this assertion is utterly different from that which Dr. Wood attributes to me.

I shall refer to this matter again in connection with the evidences of Dr. Wood's imperfect information upon professional subjects.

Again, on page 170 of the MEDICAL RECORD, the following passage occurs: "The reasons these gentlemen (Drs. Williams and Chew) gave for their opinion did not possess much clearness of detail, and have passed, to a great extent, from my memory." It is scarcely necessary to comment on the utter worthlessness of a criticism, the data for which the critic has forgotten at the very time of writing it; but I must call attention to a more serious fault shown in this passage than a defective memory. He goes on to say: "Dr. Chew, however, gave as one of the mainstays of his opinion, "*the loss of consciousness during the convulsions.*" Here again the perversion of my words is "gross as a mountain, open, palpable."

What I had in truth said was, that among other indications of strychnia poisoning the clearness of the patient's mind was noticeable, *consciousness being lost only during the convulsions.* A more egregious misrepresentation could not have been devised. With such manipulation of testimony, and such separation of words from their context, any sentiment, however absurd, may be put in the mouth of a witness.

The foregoing illustrations must be abundantly sufficient to prove the assertion that Dr. Wood's account of the case is utterly unreliable.

It remains to show that it is invalidated still further by his want of acquaintance with the subjects upon which he writes; and it is to be observed that this ignorance is displayed in matters about which, as a professed toxicologist, he might have been expected to be informed.

Dr. Wood is evidently wholly unaware of the application of prussic acid for the relief of gastric irritation caused by tartar-emetic. He has apparently never read the well-known articles upon pneumonia by Dr. C. J. B. Williams in the Library of Practical Medicine, and in the Cyclopædia of Practical Medicine; or perhaps his confessedly unretentive memory has forgotten them.

In the former article the following passage occurs:—

"The first dose of tartarized antimony commonly causes vomiting; if this should not cease, two or three drops of the diluted hydrocyanic acid will generally stop it."* And in the Cyclopædia of Practical Medicine the same author thus writes: "Where the vomiting from tartarized antimony becomes obstinate and urgent, we can confidently recommend the addition of a drop or two of hydrocyanic acid to each dose of the medicine."†

It would be well for Dr. Wood to ponder these passages.

Let it be observed that it was simply as against gastric irritation that the prussic acid was given to Mr. Van Ness, and as thus employed it was very beneficial.

On the following day, when great sedation occurred, its use was not thought of.

Dr. Wood's reading is very limited, it would seem, even in the literature of the subject which he professes to make a specialty. "Every medical man knows, or ought to know," he says, "that there is a universally recognized antidote to tartar-emetic." His reference is no doubt to tannic acid, and he seems wholly unaware that the claims of this agent to be an effective antidote to tartar-emetic have been much controverted; as, for instance, by that distinguished teacher Prof. Stillé, who, in his work upon Therapeutics, thus writes: "In poisoning by tartar-emetic it is recommended to give infusions of vegetable astringents, such as cinchona, galls, green tea, etc. But the best authorities deny the efficacy of these astringent substances."†

* Lib. Pract. Med., vol. iii., p. 233. † Cyclop. Pract. Med., vol. iii., p. 628.

† Stillé's Therapeutics and Materia Medica, 2d edit., vol. ii., p. 386.

Inasmuch, however, as Dr. Wood refused to recognize the authority of Prof. George B. Wood in questions of toxicology, when it was quoted on the stand against his opinions, he may equally disregard that of the present incumbent of the Chair of Theory and Practice of Medicine in the University of Pennsylvania. Possibly these eminent medical men may share, in his estimation, the common fate of prophets in their own country.

I would refer him, therefore, to the following passage from Pereira, a most weighty authority on any subject connected with the chemistry of drugs: "Nutgalls are recommended as an antidote in cases of poisoning by emetic tartar, *but I very much doubt their efficacy.*" *

The prominent clinical facts of this noted case have now been sufficiently set forth; as also the opinions pronounced upon those facts by the State's medical witnesses, and the grounds for those opinions.

It remains to say a few words in regard to the chemical analysis which resulted in the discovery of tartar-emetic in the tumbler of milk-punch prepared for Mr. Van Ness. This analysis must stand or fall with that which was made of the remains of Gen. Ketchum, the results of which were brought forward in the former trial.

The substances to be analyzed were put into Prof. Aikin's hands at the same time; the methods pursued in the two examinations were substantially the same, and the results identical. Not one word was said to suggest a suspicion of the presence of tartar-emetic; and so, guided by a brief sketch of the case, Prof. Aikin was led to search for strychnia and arsenious acid. These he did not find, but in his search he detected antimony in both the materials submitted to him.

His conclusions were ratified and confirmed by Prof. Mallet, of the University of Virginia; by Dr. Craig, the chemist in charge of the laboratory of the Surgeon-General's office in Washington, and by Prof. Tonry, of the Maryland Institute in this city.

The chemical experts for the defence professed to dissent from Prof. Aikin's conclusions on two grounds; 1st, because the same results as to color reaction could be gotten, as they alleged, from material known not to contain antimony; and 2dly, because antimony in the metallic form was not produced.

As to the former objection, I have elsewhere shown its utter fallacy, and shall not again discuss the question here.† Suffice it to say, that while professing to follow the same processes as those used by Prof. Aikin, these chemists deliberately omitted to apply what he regarded as a crucial test.‡

As to the second objection, let the following letter be its sufficient and final answer:—

MARYLAND INSTITUTE, CHEMICAL DEPARTMENT,
BALTIMORE, *June* 24, 1873.

PROF. S. C. CHEW:

DEAR SIR,—I still retain in my possession the metallic antimony which I obtained from the viscera of General Ketchum, and which I carried to Annapolis in January, 1872, and held ready for exhibition to the jury and chemical experts for the defence in the first trial of Mrs. E. G. Wharton. This antimony I am ready to submit to an examination to be made in my presence by any chemist of known integrity and standing in his profession. I have also specimens of crystals of tartar-emetic gotten from the same material as that from which I obtained the metallic antimony, and hold them ready for a similar examination. I would add that during the trial I offered to one of the counsel for the defence, to be examined by their chemical experts, a portion of the viscera, which I had retained, but my offer was not accepted.

Very truly yours,

WM. P. TONRY,

Prof. Anal. and Applt. Chemistry, Md. Institute.

I have myself examined with the microscope the specimens of tartar-emetic obtained by Prof. Tonry, and have found them to correspond with the rhombic crystals of the salt, delineated in Prof. Wormley's work on the Micro-Chemistry of Poisons. Prof. Tonry's analysis was not finished within the time allowed by the court, and therefore its complete results were, from a technicality, not admitted as evidence. They were, however, brought into court, and offered for exhibition, though in the absence of the jury; hence they belong to the scientific record of the case. It is, of course, evident that they supplement, and at the same time fully corroborate, Prof. Aikin's analysis.

In concluding this portion of the subject, I assert that no proposition in chemistry is more conclusively demonstrated than that the viscera of Gen. Ketchum contained antimony. It challenges the detection of a flaw, and to deny it, in the face of the proof by which it is substantiated, is to court the reputation of being either hopelessly ignorant or shamelessly dishonest.

I repeat that the milk-punch prepared for Mr. Van Ness was subjected to the same analysis as the viscera above mentioned, yielded the same results, and was thus perfectly proved to contain antimony.

Dr. Wood quotes in both of his papers, apparently with great satisfaction, an extract from the new edition of Dr. Taylor's work upon Medical Jurisprudence, which requires a brief notice. The case of Gen. Ketchum is mentioned in this extract, and the extraordinary statement is made in it, that "but for the alleged discovery after death of tartar-emetic, no suspicion of poison would probably have arisen."

Now it is certain that Dr. Taylor has received a report of the first trial of Mrs. Wharton. In that report it is made perfectly clear that, so far from the discovery of tartar-emetic having given rise to the suspicion of poison, it was the suspicion founded upon the symptoms and history of the case that led to the chemical examination. The medical opinion was not the consequence, but the *cause* of the chemical analysis.

This dilemma is therefore presented; either Dr. Taylor had not read the report of the trial in his hands, when he wrote the sentence quoted above, or he had read it. If he had not read it, he expressed an opinion, involving the professional reputation of medical men, upon a subject about which he had not used the means at his command to inform himself.

If, on the other hand, he had read it, then his opinion is in direct contravention of a fact within his own knowledge; for it is distinctly stated in the report of the trial, that the suspicion of poison *antedated the chemical analysis*, and therefore could not have taken its origin from it.

If, as a third supposition, Dr. Taylor, having read the trial, has forgotten or overlooked the fact referred to, then he owes it to justice, and to the physicians

* Mat. Med., vol. ii., p. 525. The same passage occurs in an abridged edition of Pereira, edited by Dr. H. C. Wood himself, page 410.

† *Richmond and Louisville Medical Journal*, July, 1872.

‡ Dr. Reese, when on the witness-stand, said in response to a question from the Court, "I remember that Dr. Aikin and Prof. Mallet testified that the solution should be kept acid; I do not remember whether I kept mine acidulated."

Court.—"Was the solution you treated with sulphide of ammonium an acid or alkaline solution?"

Witness.—"I don't know." That is, while professing to follow Prof. Aikin, he could not say whether in the crucial test of the experiment he had followed him or not!

whom by implication he has censured, to acknowledge his error. Apart, moreover, from considerations of justice, the credit of Dr. Taylor's work is concerned; for if so signal a mistake has been made in the report of one case, what value can be attached to that of any other in the book?

The eminent authority of Dr. Taylor is fully conceded, but it seems clear that upon this subject his opinion has been formed hastily, and upon one-sided evidence, and gives no valid support whatever to Dr. Wood's statements.*

In his article in *Lippincott's Magazine*, Dr. Wood speaks of certain evils in the prevalent system of medical expert evidence in this country. That evils exist is undoubtedly true; and no more forcible illustration of them could be found than is presented by the trial under consideration. The true explanation of them, which Dr. Wood is perhaps scarcely prepared to admit, is set forth in the following very pointed terms in a new edition of Wharton and Stillé's Medical Jurisprudence.

It is commended to his very careful consideration when he is next asked to assume the part of volunteer medical expert, paid to sustain a "*side*."

"The radical defect," says this book, "of our present Anglo-American practice, in this respect, is the volunteer position of experts, which makes them, to a large measure, the mouthpieces of a party who often only selects them because their preascertained views suit his purposes; or who only presents them with such materials as subserve his interests. In what way this defect can be removed is one of the most important questions to which social science can now be addressed."

I have now completed my task, and have discharged what I believed to be a duty binding upon me by reason of the opportunities I have had for knowing the whole history of this remarkable case. I have examined it solely from a medical point of view, and have not discussed the issues of guilt or innocence, which can have no place in medical questions. So far as these are concerned, the position of the medical witnesses for the State would be wholly unaffected, whether the patient's condition were due to accident or design.

I have felt that it would be wrong, with my knowledge of the case, to allow a misrepresentation of the facts to go upon record as an undisputed narrative, and to suffer erroneous medical opinions upon these facts to remain unexposed.

If my words have seemed unduly harsh, I regret the necessity of speaking plainly; and I would plead in their defence the dictum of one who is equally an authority in logic and in morals:

"Sharpness of speech," says Dr. Isaac Barrow, "may sometimes be used in defence of truth, and impugning errors of bad consequence; especially when it concerneth the interest of truth that the reputation and authority of its adversaries should somewhat be abased."

BALTIMORE, *June* 25th, 1873.

KEMPSTER.—Dr. Walter Kempster, second assistant physician for six years of the N. Y. State Lunatic Asylum, at Utica, has been elected Superintendent of the Northern Wisconsin Hospital for the Insane, located at Oshkosh, Wis.

* How Dr. Taylor may have received a one-sided account of the testimony in the trial is perhaps explained by the fact that the new edition of his work on Medical Jurisprudence is edited in America by Dr. J. J. Reese.

Progress of Medical Science.

ATROPIZED CASTOR-OIL AS AN APPLICATION IN SOME CORNEAL AFFECTIONS.—Dr. D. C. L. Owen writes to the *Br. Med. Jour.* of May 10, that in the treatment of irritable ulcer of the cornea, and of abrasion of the epithelium, it is generally advisable to use some application of a viscid nature which may fill up the inequality of surface and reduce the irritation caused by the movements of the eyelid to a minimum. For this purpose no remedy is so fit as castor-oil; and if to the oil be added sulphate of atropia, in the proportion of from one to four grains to the ounce, the effects of the latter may be obtained. Castor-oil is to be preferred to glycerine and gelatine, since it is not, like the former, painful when applied to the eye, nor like both, easily washed away by the tears.

A NEW SUBSTITUTE FOR QUININE.—*The British Med. Jour.* says that among the specimens of drugs exhibited in the Vienna Exposition is the *Echisess echolaris*, a plant of the natural order of *Apocynæ*. It is especially abundant at Luzon, in the province of Batangar, in the Philippine Islands; and its bark has long been used by the natives under the name of *dita*, as a remedy in all kinds of fever. Herr Gruppe, an apothecary in Manila, has found in it an uncrystallizable, very hygroscopic, bitter substance, to which he has given the name of *ditaür*. The principal Spanish physician in Manila, Dr. Miguel Zina, has given it to numerous hospital patients under his care, and has found that ditaür is not only a perfect substitute for quinine, but that its use is not followed by the disagreeable results which often attend the use of quinine. It is given in the same doses and in the same way as quinine. Its activity as a tonic was well marked in several cases. Ditaür is prepared from the bark in the same way as quinine from cinchona. 100 *grammes* of the bark giving 2 *grammes* of ditaür, 0.85 *gramme* of sulphate of lime, and 10 *grammes* of a perfectly inert extractive matter. A single tree yields a large quantity of bark without injuring its growth. Its price in Europe is estimated at about 160 *francs* per kilog.

OLEATE OF MERCURY IN SYPHILIS.—Mr. Berkley Hill says he has employed the oleate of mercury in a large number of cases with the following results: In the first place, if continuously applied, it quickly produces the usual effects of mercury on the system, and if used in sufficient quantity causes salivation. Secondly, it is apt, in delicate, fair-skinned persons, to excite violent smarting pain, which, though rarely lasting more than half an hour, if so much, is enough to disgust them with the remedy. The irritation may soon cause erythema and slight vesication, these being the most serious local effects noticed by Mr. Hill. To avoid these undesirable occurrences Mr. Marshall, who first suggested the remedy, has devised three preparations of different strengths, containing twenty, ten, and five *per cent.* of peroxide of mercury respectively: to the weakest dilution ten per cent. of morphia is added. With one or the other of these preparations the application of this form of mercury can be continued on even very sensitive skins. When used for inunction, about a scruple or half a drachm of the twenty per cent. jelly should be rubbed gently into the flank till it is absorbed by the skin, which occurs in about eight or ten minutes, leaving the skin almost dry and not greasy. This may be repeated once or twice in twenty-four hours, of course changing the site of the inunction

each time. The anointed part may be washed next day without fear. This quantity usually causes swelling and slight soreness of the gums in a week, if anointed once a day, or in four days, if employed twice daily. He has found the ten per cent. preparation most useful as an adjuvant to the ordinary treatment by iodide of potassium internally or for persons whose stomachs do not bear mercury.

The great advantage of the oleate over other forms of mercury, when externally applied, lies in the rapidity of its absorption. When the twenty per cent. form is smeared as a cosmetic over syphilitic papules or stains it is remarkable how rapidly the papules sink down and grow pale.

Again, it is of great service in fissures of the fingers about the nails or palms, the weaker preparations being employed at night and the hands covered with wash-leather gloves. Gloves should also be worn out of doors, the cracks being closed with court-plaster and collodion.

As a paraciticide the oleate has proved exceedingly valuable. In the hands of Mr. Hill success has not followed the use of the oleate in non-syphilitic affections, diseases of the joints, or inflammatory affections.

The formula for the preparation of this substance is given as follows:

For the 20 *per cent.* solution, stir ten drachms of oleic acid in a mortar, while two drachms of precipitated peroxide of mercury are gradually sprinkled into it, and triturated frequently during twenty-four hours, until the peroxide is dissolved, and a gelatinous solution formed.—*The Practitioner.*

Clinical Illustrations of the Value of Phosphorus in certain Forms of Disease of the Nervous System.—Under this heading, Dr. W. H. Broadbent, of London, relates cases of epileptiform vertigo, severe neuralgia with gastric complications, nervous break-down from overwork, and atonic dyspepsia. He thinks the failure on the part of phosphorus to answer the expectations of those who thought a few years since they had in it a powerful remedy in this class of affections, is to be explained by the difficulty of administering it without destruction, or, at any rate, impairment of its activity by oxidation. He says, that instead of giving it as formerly, dissolved in almond or olive oil, and suspended in mucilage, in which form oxidation takes place slowly, but which forms a nauseating mixture, he has administered it dissolved in oil or lard and inclosed in a gelatine capsule; the dose is about $\frac{1}{10}$ of a grain, and it may be taken two or three times a day, always after food. When dissolved in cod-liver oil phosphorus appears to undergo oxidation more rapidly than in any other medium by which it has been administered, and in the form of pill its deterioration is but little less rapid. Dr. Broadbent thinks it as absurd to substitute phosphoric acid for phosphorus as it would be to expect sulphuric acid to give us the therapeutical effects of sulphur.—*The Practitioner.*

Therapeutical Effect of Liquor Sodæ Chloratæ.—Dr. Cooper advocates the use of Labarraque's solution in relaxed states of the uterine and periuterine tissues, and thinks that it gives tone to the weakened utero-sacral ligaments, increases vaginal contractions, removes the bearing down and tendency to prolapse, diminishes congestion of the neck of the womb, thereby lessening very considerably leucorrhœal and menorrhagic discharges; and these effects are followed by the entire subsidence of sympathetic disturbances, the sacral, rectal and ovarian distress, the hypochondrial tumefaction, the gastric and precordial sinking, the sub-mammary stitch, and chest pains and headache. He recommends two or three drops of the ordinary commercial solution to be placed in half a tumblerful of water, and directs that a dessert-spoonful of this be taken occasionally. Should disagreeable symptoms be produced by the medicine,—*e. g.*, rapid emaciation and influenza-like debility, which is its most uniformly unfavorable symptoms,—it should be discontinued for some time. As an ingredient of vaginal douches in ulceration of the neck of the womb, hypochlorite of soda gives great relief.—*Dub. Jour. of Med. Sci.*, April.

Treatment of Chloroform Narcosis by Ice in the Rectum.—Dr. Baillée thinks there is no readier or more effectual mode of combating the narcosis of chloroform than that of introducing a small piece of ice into the rectum. But little force is required to pass it through the anus; it melts immediately and causes by its presence a deep reflex inspiration, which leads to respiratory movement and re-establishment of the cardiac function. The method is also recommended to be pursued in the treatment of apparent death in the newly born.—*Bul. Gén. de Thérap.*, April 15.

Neuriasis is a name given by Dr. C. B. Radcliffe to the condition of a class heretofore known as "nervous, hysterical, or hypochondriacal" people. For the most part, people of this class are easily tired, easily become faint from want of food, and are easily overcome by sleep. They are more the slaves of involuntary, irrational impulse, more wanting in composure, than is consistent with a well-balanced mind. They are more frequently women than men, and are never the robust and strong-minded of either sex. In them the feminine qualities of body and mind predominate. Certain peculiarities of body and mind are more or less constant in this condition—*e. g.*, proneness to pass large quantities of pale, limpid, neutral urine, under any emotion or excitement, or after it, with a frequently irresistible *besoin d'uriner;* proneness to abdominal flatulence, *pneumatose intestinale;* proneness to fits of laughing and crying, without sufficient reason for them; proneness to globus; proneness to overflow of saliva; proneness to constipation; together with tenderness on pressure, with more or less uneasiness or actual pain apart from pressure, in one or other part of the abdomen, or under the left nipple, or somewhere in the course of the spine; with a marked disposition to spasm; and with as marked a disposition to periodicity in one form or another. Among the latter, or mental peculiarities, undue sensitiveness; overpowering craving for sympathy; quick and perverse likes and dislikes; feebleness of will, showing itself in impulsiveness and in many other different ways; fancifulness; imitativeness; unbalanced spirits, the inclination being commonly towards despondency; and, lastly, a comparatively feeble sense of moral obligation.

Few at the present day will be prepared to contend that the womb has any special connection with hysteria, or the liver, or any other abdominal viscus with hypochondriasis; or to doubt the correctness of the view which regards both hysteria and hypochondriasis as disorders, closely allied, of the nervous system. Still it may be doubted whether, practically at least, this latter view is as clearly realized as it ought to be—whether the words hysteria and hypochondriasis do not still retain a good deal of their old meaning, and not unfrequently mislead effectually in practice. At all events, hysteria and hypochondriasis can be no fitting names for that general derangement of mind and body of which we have been speaking. Another name, he thinks, is evidently desirable, which will point away from the womb or liver, or other abdominal vis-

cus, to the nervous system; and hence his excuse for proposing the term *neuriasis*. He hopes that the time will come when it will be possible to get a step further than this, and choose a name which will include the mental as well as the nervous half of the disorder in question; for he cannot help but think that the *nervous* trouble is the effect rather than the cause of the *mental* trouble; and is even sanguine enough to hope that eventually, by the institution of a sound discipline, in which the mind is taught—chiefly through wise mothers acting upon it in the morning of life—to know and exercise its high powers of subjecting the feelings and thoughts, as well as actions, to sound reason and will, that mankind may be delivered, not only from the evils of neuriasis, but even from the still graver evils of actual insanity.—*Br. Med. Jour.*, April 5.

Section of the Orbicular Muscle and Integument at the Outer Canthus, as a Prelude to the Extraction of Cataract.—Edw. Chessire writes to the *British Med. Jour.* of April 5, that he has recently been making a section at the outer canthus through the fibres of the orbicular muscle and the integument, before operating, and has found much advantage therefrom. The advantages attending this method are: the more extensive exposure of the globe, enabling the operator to manipulate his instruments and make his section through the cornea with greater ease. The spasmodic contraction of the orbicular muscle being overcome, the surgeon is left to complete his operation at leisure; while all risk of sudden protrusion of the lens, followed, as it sometimes is, by prolapse of the iris and escape of the vitreous, is almost entirely avoided; and the contraction of the lids on the globe, which is sometimes a troublesome symptom in the after-treatment of cataract extraction, is prevented.

With division of the orbicular muscle, the wire speculum, which greatly facilitates each step of the operation, may be used without injury or annoyance to the patient. No sutures are required, as the divided surfaces readily unite, and scarcely leave a trace behind them. All that is necessary to be done is to keep the eyelids nicely in a position for a few days after the operation by means of strips of court-plaster. All bandages and other covering after extraction are, to his mind, objectionable. Where great neatness is desired the section of the muscle can be made subcutaneously.

Oxide of Zinc in the Diarrhœa of Infants and Young Children.—Dr. Brakenridge, of Edinburgh, whose experience is very extensive, and who has employed all the remedies in use for infantile diarrhœa, gives the preference to the oxide of zinc. He says 1. Diarrhœa in these cases arises from a condition of debility and great susceptibility of the nervous centres, which prevent proper secretion from the alimentary tract. 2. It is intimately associated with convulsions and convulsive affections. 3. It is accompanied by congestion of the secreting surface of the digestive passages.

To meet these conditions requires a remedy which is at once tonic, antispasmodic, and astringent. These properties he believes to be united in the oxide of zinc. It is a tonic for the nervous system, just as iron is for the blood. As an antispasmodic and astringent it has already gained a reputation founded on clinical experience. He has employed it in twelve cases, four of them girls and eight of them boys, and varying in age from four months to one and a half years. The form was usually that of the powder, but it was also given in a solution of gum-arabic, with a slight addition of glycerine. The general results observed were—1. That it moderated the diarrhœa quickly. 2. That vomiting stopped. 3. That digestion improved. 4. That intestinal hemorrhage was frequently arrested. 5. Teething was favored rather than otherwise. 6. That even where no change was made in diet, and the other conditions remained the same, the treatment progressed favorably. 7. When, however, diet and regimen were carefully regulated, success was more rapid and decided. *Med. Times and Gazette—Allg. Med. Central-Zeit.*, 47, 1873.

Intra-vaginal Auscultation in the Diagnosis of Pregnancy.—An interesting paper on this method of auscultation was recently read before the Academy of Bologna, by Dr. Verardini. He concludes as follows:—

1. Internal or intra-vaginal auscultation is of the greatest importance for detecting pregnancy during the first months. A characteristic bruit may then be heard, if the instrument be pressed against the cervix uteri.

2. This method was first announced by Meygrier in 1825, and four years later was employed by Nauke, but latterly has been brought into frequent use, in England, by Routh, who, in conjunction with the author, found that he was possessed of the means of recognizing both early pregnancy and placenta prævia.

3. If it be impossible to make a satisfactory diagnosis of placenta prævia during the early months of pregnancy, it can always be determined during the later stages, from the continuous bruit.

4. The utero-placental bruit, the indication that the fœtus is pressing against the uterus, is soft and prolonged, similar to that heard in aneurismal tumors when the stethoscope is pressed upon arteries. When once heard it can always be detected a second time.

5. It is important always to be sure that there is no pulsating tumor or artery in the neighborhood of the cervix.

6. The prolonged utero-placental bruit, which is distinctly appreciated during the first months, ceases at the commencement of the sixth or seventh month.

7. If other symptoms of pregnancy are present, and this characteristic is absent, the diagnosis will remain in doubt. It is, then, most probable that there is uterine disease; certainly, if there have been symptoms that pregnancy has at some time taken place, there must have been disease of the ovum, followed by death of the embryo or fœtus.

8. In making the examination the patient may lie upon the back or the side; but if in this position the accoucheur fails to hear any bruit, then let him place the patient in the knee-elbow position, and he will succeed without difficulty.

9. Internal auscultation is of great importance in practical and forensic medicine and in surgery. Early pregnancy can thus be diagnosticated, and many possible errors avoided.

10. The name given to the instrument employed is the vagina-uteroscope. It can be made of various shapes, and is usually of gutta-percha, to render it as light as possible.—*Gaz. Med. Ital.*, 17, 1873.—*Allg. Med. Central-Zeit.*, 47, 1873.

Thudicum's Douche.—Dr. Frederick P. Henry (*Phila. Med. Times*, May 17, 1873) mentions the case of a girl, two years old, who had introduced a large-sized shirt-button into her nose, and was quickly relieved by the aid of Thudicum's douche. The child's cries, which were comprised in one prolonged expiratory effort, seemed to have aided the operation by raising the velum and thereby preventing escape of water into the mouth, which any one who has used the instrument on his own person knows is so liable to occur.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month, by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, July 15, 1873.

THE EVILS OF CARELESS PRESCRIBING.

From the time when there were no physicians, and when it was customary to ask the nearest neighbor what could be given to relieve the sick one, up to the present, there have always been a class more willing to take the advice of an outsider than the counsel of a physician. It is amusing to see with what respect any invalid will listen to the suggestion of a friend as to the cause of his malady, the course he shall pursue to gain health, and with what persistency he will keep up a plan of treatment founded upon such suggestion. It is vain to hope for any radical change in this respect, and so long as the ordinary domestic remedies are employed, no particular harm can come of its practice. Castor-oil, catnip-tea, peppermint cordial, epsom salts, boneset, an occasional foot-bath, and the application of a mustard-plaster, are generally used with a discretion sanctioned by the experience of our great-grandmothers, and with an ordinary understanding of the effects to be expected of each. The community, however, are enlarging their list of remedies to such an extent that it is no easy task to separate them from most of those used by the profession. The articles of the materia medica which were at no distant time the exclusive property of the educated physician, have their respective merits discussed by the laymen with an impudent assurance that is astonishing and humiliating. The consequence is, that very many apparently intelligent people do not hesitate to urge the use of potent drugs, not a few are willing to accept their assertions as authoritative and act upon them accordingly, and still a greater number prescribe them for themselves.

Every one of ordinary observation must be prepared to accept these assertions as facts. In view of such an acceptance, it is interesting to inquire into the causes of such a state of affairs. As a profession, we alone are accountable for all this dangerous knowledge of potent drugs. There are no objections to informing the people on matters connected with the preservation of health, and the means to be employed to prevent disease. This, as a profession, is our duty; but in doing our whole duty it is not only unnecessary, but unwise, to strive to educate them beyond their point of comprehension. By so doing, we tempt their presumption and stimulate their assurance.

The information has not been imparted through medical works, nor through medical pamphlets, as the technicalities of expression in such productions offer a barrier to the laymen which even an extraordinary desire for acquiring a knowledge of the strange things in medicine cannot usually overcome. The lessons are in the vast majority of instances given in the sick-room. The physician, in the desire to impress upon his patient his knowledge of his case, and his skill in its treatment, is too apt to give short clinical lectures for the benefit of the bystanders, to name the medicines used, and to explain his idea of their *modus operandi*. We see no harm in satisfying the patient as to the nature of his malady so far as it may be necessary to inspire confidence and calm unnecessary fears. This is, in fact, a plain matter of obligation; but when we go farther than this, we take upon ourselves a grave and unwarrantable responsibility. The patient is nothing but a patient, and not a medical student. If we view him as the latter, and inform him that he is taking this or that article in the materia medica, we give him the best possible excuse for using his own judgment and employing all the arguments which his ignorance or his conceit may dictate.

But we not unfrequently go still farther, especially in chronic cases—we not only inform them of the name and nature of the drug, but, to save ourselves trouble in giving minute directions, we leave it to the patient's judgment how, when, and in what doses to take it. How often is this done with the very fashionable stimulant whiskey, the valuable anti-periodic quinine, the powerful drug opium or its compounds! On a previous occasion we pointed out the results of such carelessness in the ultimate creation of hundreds of habitual tipplers and thousands of opium-eaters. What may be said of these articles may with equal force be said of others which are being used by such patients literally at their own discretion, the physician not unfrequently continuing the prescription so long as the patient is pleased with the medicine, or so long as he imagines it is doing him good.

Often in conversation with patients we have been surprised to learn that the ingredients of each prescription are named to them by their medical attendant. One will say that he has been taking quinine in such a dose; such a preparation of iron in such a dose, etc., etc. Another will say that he does not wish to take quinine, because it "gets into his system:"

another, that he will not take calomel; another, that aloes must not be prescribed, and so on *ad infinitum*. We repeat that the profession is accountable for such a state of things, and for the good of the patient and for the good of medicine it should be discontinued.

If we want to break up the practice among patients of arguing their cases, of actually prescribing for themselves, of taking whiskey, quinine, opium, chloral, etc., almost at their option, we should never tell them what medicine they are taking when really sick, and especially should we not leave the dose to their judgment. By neglect of these precautions we must force the patient to the conclusion that the science of therapeutics is nothing but the merest empiricism, and create in their minds a suspicion that the science of medicine is a myth, and its practice a farce.

Even in unimportant matters, in prescribing domestic remedies, it is best to be exact and positive as to quantity; aside from every other consideration, the moral effect is excellent. This should be especially so with mineral waters, the names and a certain knowledge of which we cannot prevent our patients from obtaining. It is frightful to contemplate how many gallons of these waters are drunk by these self-prescribers, because they imagine that they have a right to judge when they are required.

We call the attention of the profession to this subject, because we believe it to be a growing evil which, if not checked, will react upon us in many disagreeable ways.

THE HEALTH DEPARTMENT AND THE CELLAR POPULATION.

In every large city there is always a certain proportion of the population who from force of circumstances are compelled to live in hovels, cellars, and in crowded tenements. As the demand for such quarters increases, the supply is equalized by the gradual abandonment of particular localities by the more respectable inhabitants. This fact has been strikingly evident in the lower wards of New York, especially such as border the East and Hudson rivers. For years this tenement and cellar population have gone on steadily increasing, and have been one of the most serious bugbears to the enforcement of any of the ordinary sanitary regulations. Every means have been employed to counteract the pernicious influences which such habitations have upon the tenants themselves and upon surrounding localities, and although much has been accomplished in compelling landlords to make improvements, there were many habitations in which such improvements were impossible. In such cases, the obvious remedy was to make such premises vacant. The fear, however, of trampling upon what the meanest citizen claims as his individual right, has, until lately, prevented the Health Department from taking the requisite steps. We are happy to say that the Sanitary Bureau of our present Health Board have proved themselves equal to the emergencies of the hour. Too much credit cannot be given to Dr. James, the present Assistant Sanitary Inspector, for the manner in which he has conceived and matured the plans necessary to the accomplishment of such necessary measures. Under his direction, many of the inhabited cellars of the city have been carefully inspected, and such as have been proved to be unfit for human habitation have been ordered to be vacated. In a certain proportion of these cases the orders were obeyed with reluctance and remonstrance, it is true, but still without the necessity of using force. In certain other instances compliance with orders was effected only by the aid of a police force, who caused the furniture and effects to be summarily deposited upon the sidewalk.

Every sanitarian must be convinced that radical as is this measure, it is after all the only one which can result in the greatest good to all. These cellars not only directly increased the mortality of a district even in healthful times, but during epidemics they were the hotbeds for the spread of contagion and disease. Thus far the work has been well done, and we hope to see it continued.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 9, 1873.

DR. ERSKINE MASON in Chair.

VILLOUS CANCER OF BLADDER.

DR. HALL presented the kidneys and bladder removed from a patient who died Feb. 21, in Bellevue Hospital, a day after admission. The patient was 55 years of age, large, stout and muscular, and said that he had had trouble with his urine for six or eight months. The urine was described as thick and milky, and its passage was attended with some difficulty. About six weeks before admission the urine of a sudden stopped, and after much effort was voided with several clots of blood. From that time until his admission he could not urinate with ease, and when admitted he was in a very exhausted condition, and all efforts to rally him were useless.

Autopsy.—Brain not examined, lungs œdematous and congested. Large quantity of fat over the heart. Other organs healthy except kidneys and bladder. The latter was occupied by a large clot, the result of hæmorrhage from villous pedunculated growths upon the posterior and lateral surfaces of the mucous coat. Dr. H. thought the specimen was one of villous cancer. The third lobe of the prostate was much enlarged, the ureters were dilated and filled with milky urine. The kidneys presented well-marked evidences of fatty degeneration, and weighed two pounds and six ounces.

OVARIAN TUMOR.

DR. MARY C. PUTNAM presented a large polycystic ovarian tumor. The patient from whose body it was removed stated that she first noticed an enlargement of her abdomen last July, but, from the appearance of things at the time of her first examination in November, it is probable that the tumor began to grow before that time. At this examination she measured sixty inches

in circumference. There was then no difficulty in diagnosticating an ovarian tumor, with which diagnosis Dr. Weir (who subsequently saw the patient) concurred. The patient was then in pretty good health, suffering no inconveniences except such as were attendant upon dyspnœa from pressure. As an indication of an unhealthy condition of the lower extremities caused by pressure upon the iliac veins, it may be mentioned, that a year before she had had her foot crushed, and as a result one or two toes had been amputated, and the wound had not yet healed. The heart was carefully auscultated, but there was no murmur, nor anything abnormal detected. Dr. Weir thought that the patient might be operated upon, as did also Prof. Thomas; but as the circumstances were such as to preclude the possibility of her remaining in hospital (N. Y. Infirmary for Women and Children), she was simply tapped. She was tapped with Dieulafoy's Aspirator and three gallons of a coffee-colored fluid were drawn off. Although there was no perceptible diminution in the size of the abdomen, the dyspnœa and other effects of pressure were much relieved. From that time Dr. P. never saw the patient alive. She did not present herself again to the Infirmary until three weeks before her death, when it was found that her abdomen had increased very much in size, her dyspnœa was more urgent, and her œdema more considerable. She was then tapped again, and about the same quantity of fluid as at the first operation was drawn off. Three days after she was tapped again, when, after a gallon having been evacuated, the canula met with a resistance and the tapping was discontinued. For that day she was perfectly well, but the following day she complained of feeling sick. The temperature was then found to have suddenly risen to 104°, and the day following it ran up to 105°. No distinct symptoms of peritonitis, however, were found to account for this rise in temperature. From that time she grew better and had no more pain nor rise in temperature. The urine was examined and no albumen nor casts found, but two days before her death she began to suffer from nausea and vomiting. After a violent attack of the latter she was seized with a convulsive attack. Whether it was from syncope or serous apoplexy cannot be determined, as no one was present at the time except an attendant. She seemed to recover somewhat from this attack, but soon after commenced to sink and died in four hours.

The autopsy was performed with the assistance of Dr. Adler. Before opening the trunk the body was so warm that several tests for apparent death were made.

The tumor was found adherent at different portions, but not sufficiently so to interfere with the results of an operation. There was no effusion in the peritoneum of any kind, but in several places, especially in the pelvic and iliac regions, there were patches of very intense injection. The tumor was removed entire; the pedicle was quite small, and was attached to the left ovary. The right ovary was perfectly healthy, but there was a small cyst in the right Fallopian tube. The tumor was remarkable for the multiplicity of the cysts. There were two principal cysts in the centre, the walls of which were lined with smaller cysts, and these in their turn contained still smaller ones. In a few places, where the walls were not covered with cysts, they were found to be quite thin, but these spaces were few and far between. Some cysts contained fluid material, and others were filled with a semi-solid substance.

The immediate cause of death, which it was of importance to take into account in connection with an operation which might have been performed, was in an altogether different part of the body. In the first place, the heart was dilated and very flabby, and filled with small clots entangled in the trabeculæ. In one place, in the right ventricle, a clot had by pressure produced a localized fatty degeneration. Both kidneys were the seats of extensive diffused nephritis. In one of the organs there was a large cyst, with no communication between it and the pelvis. This condition of the kidney must have been produced three or four weeks previous to the death of the patient, and yet the only symptom of renal disease was the vomiting, which occurred only three days before death, and the convulsion, which apparently depended upon cerebral œdema.

Dr. Weir exhibited and described an instrument which has been devised by Trendelenberg, of Berlin, for the purpose of preventing the usual complications and accompaniments of tracheotomy, and other injuries and operations about the throat.

STRANGULATED HERNIA TREATED BY THE ASPIRATOR.

Dr. Erskine Mason exhibited a portion of intestine removed from a patient of Charity Hospital, for the purpose of placing on record a case of strangulated hernia where the aspirator was used, but without accomplishing a reduction. This patient was a man seventy years of age, who stated that he had a hernia of only fourteen days' duration, and that he had been able to reduce it until eight days before he entered the hospital. He had all the symptoms of strangulated hernia on the night that he entered. At that time a careful attempt was first made with taxis, and afterwards, the patient being under ether and thoroughly relaxed, a needle attached to an hypodermic syringe was first introduced into the intestine, and half a drachm of yellow fluid was withdrawn. Immediately after that a large needle (No. 2) was attached to the aspirator, when two ounces and a half of the same kind of fluid was withdrawn, reducing the tumor very considerably. Another attempt was then made with taxis, but without success. He was then seen the following morning by Dr. Hewit, who was prepared to operate. Dr. Mason asked to try the aspirator once more. A No. 2 needle was introduced, and only a few drops were drawn off, but a considerable quantity of gas escaped. The patient being thoroughly under the influence of ether, another unsuccessful attempt at taxis was made. The man's condition was one of great exhaustion, and he was suffering from the symptoms of general peritonitis. Dr. Hewit made up his mind to operate without opening the sac. He exposed the sac and there was no appearance of gangrene; the stricture was found to be at the external ring, and being nicked slightly the strangulation was readily relieved. The patient died some hours after from general peritonitis and exhaustion.

At the autopsy there was no fluid in the sac and no evidences of any perforation of the gut. In conclusion, he remarked that this, with the cases reported by the French surgeons, was the fifth in which the aspirator had been used, but the only one in which the operation had been unsuccessful. The specimen illustrated the fact that the intestine could be perforated without any evil effects resulting.

The Society then went into executive session.

Stated Meeting, April 23, 1873.

Dr. Erskine Mason, President, in the Chair.

CANCER OF BREAST, ETC.

Dr. Finnell presented several specimens. The

first was one of cancer of the breast, removed by Dr. Chas. Phelps from a female, age 55, a patient of St. Vincent's Hospital. The disease was of a year's duration, and the specimen was interesting as exhibiting the cystic variety of cancer.

BRIGHT'S DISEASE AND ANEURISM.

A second set of specimens consisted of the heart and kidneys removed from a male patient, aged 45, who entered St. Vincent's Hospital with the symptoms of Bright's kidney. He lived but a short time. Both kidneys were found extensively diseased, the right being hypertrophied and weighing ten ounces, the left atrophied and weighing but four ounces. Both organs were the seats of advanced granular degeneration. The heart was also markedly hypertrophied, and there was besides an aneurismal dilatation of the ascending aorta, which would probably have ruptured had life been prolonged for any considerable period.

PRIMARY CANCER OF PANCREAS.

A third specimen consisted of a pancreas, interesting as the seat of extensive and primary cancer. He was indebted to Dr. Morton for the opportunity of exhibiting it. The patient was a woman, aged 50, who during the last years of her life suffered from dyspeptic symptoms. A diagnosis of cancer of the stomach was made, the mistake in which was only discovered at the autopsy, the pancreas alone being affected.

In regard to some questions asked by Dr. Garrish in reference to the propriety of operating in cases of cancer of the breast, Dr. Finnell remarked that Dr. Markoe had given all the information of value upon the subject in a published paper; and Dr. J. C. Peters stated that it was the practice in the London Cancer Hospital not to use the knife when the disease was in its active stage. The violation of the latter rule explained in a great measure the speedy reappearance of the disease.

On motion of Dr. KNAPP, the specimen of Dr. Finnell was referred to the committee on microscopy.

ONE OF THE CAUSES OF SUDDEN DEATH.

DR. DRAKE exhibited a specimen showing one of the causes of sudden death. It was removed from a man aged 75, who was admitted into Charity Hospital in October last. On admission, nothing was elicited except that he was very feeble and very cold. He was examined by the house-physician, but no diagnosis was made. The next day, while sitting on the end of the bed, he fell over and suddenly expired.

On opening the chest, the pericardium was found distended with fluid blood. The heart was hypertrophied and the aorta atheromatous. About half an inch above the valves there was a rupture extending almost entirely around the aorta through the internal coat of the artery, thence the blood found its way through the middle coat a little lower down and by a longitudinal rupture, and, lastly, through the external coat, the final rupture occurring at the base of the aorta. There was considerable serum at the base of the brain. The ventricles of the heart were distended with fluid blood; the other organs were healthy, with the exception of the kidneys, which were fatty.

DR. FINNELL remarked that in cases of rapid death the ventricles were always filled with fluid blood, and in cases where death was gradual there were always clots.

DR. PETERS referred to a paper by Dr. Markoe, contributed to the Society in the earliest years of its existence, upon ruptures of aneurisms just above the valves. In that article about fifty cases were collected.

DISSECTING ANEURISM OF THE AORTA.

DR. JANEWAY presented a specimen of dissecting aneurism of the aorta which differed from the one exhibited by Dr. Drake in the position of the rupture and the time of its occurrence previous to the death of the patient.

There was a large laceration of inner coat and part of middle of aorta a little above valves, partially transverse, partly vertical. The edges of this rupture were turned under and slightly adherent to subjacent coats; from this point the blood had formed a channel between layers of middle coat as far as a point a little below opening of left subclavian artery, where a rupture of middle and inner coats about three-fourths of an inch wide allowed the blood to return into cavity of aorta. By gently passing finger into sac it was found that the openings of left carotid and subclavian were nearly closed. The opening of innominate must also have been partly obstructed. The channel was situated along the posterior wall of arch. By this means, undoubtedly, during life, a part, perhaps a third of the blood, travelled through a course, so that it did not reach the upper part of the body, and at same time, by the pressure, the current was also interrupted in the left carotid and subclavian.

The fatal rupture was due to a perforation from the channel described through pericardium, between aorta and pulmonary artery, into pericardiac sac.

The hemiplegia must have been due, as there was no brain-disease, to anæmia due to interrupted circulation on left side, and also to want of blood in main aorta.

AN OLD FRACTURE OF THE HEAD OF THE HUMERUS.

DR. JANEWAY also exhibited a case of old fracture of the head of the humerus with dislocation into the axilla. It was removed from a dissecting-room subject, and was of course without a history. The glenoid cavity was partly filled with fibro-cellular substance, and was occupied by the greater tuberosity; the head of the bone lay on the inner surface of the scapula, just back of the glenoid cavity and below the coracoid process. There was a well-formed false joint just below the glenoid cavity. Dr. J. thought that the head of the bone had probably been fractured in the attempt to reduce the dislocation.

DR. MASON thought it probable that if such a thing had occurred it was during the early life of the patient, when a separation of the epiphysis was possible. He had never heard of fracture of head of bone being produced by careful attempts at reduction.

DR. JANEWAY stated that he had a recollection of two such cases while an interne in Bellevue, but further than this he could give no particulars of age or circumstance.

MUSKET-BALL IN BLADDER, ETC.

DR. JANEWAY lastly presented an interesting specimen, with the following history:—

Joseph Hassenfratz, æt. 51, ad. Dec. 21, 1872. No hereditary tendency. Nineteen years ago accidentally shot in gluteal region, ball entering bladder. Difficulty of urination ever since while standing—only able to do so in sitting or lying position. Thinks he can feel ball rolling in bladder when standing. No bloody urine since injury. Had a number of abscesses in different parts of body when 14 years of age.

Patient anæmic—skin of an earthy color. Increased number of white blood globules. A movable tumor of some size found above left clavicle, evidently enlarged glands. Found faint click by sound in bladder once only.

For ten months has been growing weak; loss of appe-

tite and strength; 3 months ago first noticed tumor in epigastrium; some vomiting at times for ten months and occasional diarrhœa.

Urine, sp. gr. 1012, quantity, over 24 oz. in 24 hours; albuminous; afterwards patient took milk and gruel; vomited occasionally; sank into a dull, sleepy condition, and died of asthma January 5th.

Autopsy, Jan'y 6th, 1873.—Exterior, pale, yellowish color of surface; marked emaciation; moderate œdema of lower extremities. Brain normal. Lungs—slight vesicular emphysema. Heart normal. Liver somewhat enlarged; fatty; a few small carcinomatous nodules in right and left lobes. Spleen normal.

Stomach.—Pyloric extremity the seat of a cylindrical epithelioma involving entire circumference of organ for two inches. The surface of the tumor is unbroken, but depressed slightly in the centre. The edges are raised one-quarter of an inch above surrounding surface and overlapping it. Carcinoma of glands in gastro-hepatic omentum, along aorta back of this, and a few at root of neck on the right side. These latter are some of them as large as a hen's egg.

Kidneys.—Small, atrophied.

Bladder.—Muscular coat slightly hypertrophied—mucous membrane normal. There are three small pouches capable of admitting the end of little finger situated in the posterior wall of bladder, a little above and back of orifice of ureters; a round bullet was lodged in one of these a little deeper than the rest. It was easily displaced and capable of fitting in any of the others. It was of a dull color and only slightly incrusted by urates at one small place. It is somewhat flattened in several places. No signs of the opening by which ball entered bladder could be found. On the hip, over wing of iliac bone, was a cicatrix with loss of muscular tissue, and through this undoubtedly the ball had passed.

PIGMENTAL CHOROIDAL SARCOMA.

Dr. H. Knapp exhibited a specimen with the following history:—The specimen I have here was presented by me some weeks ago at this Society. It is a *pigmented choroidal sarcoma* which had perforated the sclerotic, proliferated in the orbit, was removed by Dr. E. Williams, of Cincinnati, but the patient died, some months later, from a large local relapse and general exhaustion. I recently made an extensive microscopic examination of the specimen, which yielded some very remarkable results—one heretofore undescribed. The elementary parts of the growth were round and spindle-shaped sarcoma-cells, partly pigmented, the pigment evidently derived from the blood, as many of the pigmented cells contained blood-corpuscles. The large primary choroidal tumor presented nothing new. The ciliary processes and the ciliary muscle were transformed into sarcoma tissue. The peculiar elementary parts of the retina were wholly replaced by sarcoma cells. The most interesting feature of the specimen consisted in miliary white deposits, with which the inner surface of the choroid was studded. They were accumulations of round sarcoma cells between the choroidal epithelium and the chorio-capillaris. In some places there were small nests of three or four cells only, crowded between the pigment cells; in others they were larger, and raised or perforated the epithelium, their apices forming those white projecting nodules to which I have called your special attention. They had no connection with one another, but were strewn on otherwise healthy chorond, nor were they in connection with the primary choroidal sarcoma or with the detached, corrugated, and nodular retina. What was [illegible] I have only one explanation for it, viz.: from the small exulcerating nodules of the sarcomatous retina young cells became detached, fell through the liquid in the vitreous chamber upon the choroid, and developed in the new soil into secondary growths. It is *an example of dissemination from a seminium* as elegant as you can wish to see. Virchow has, you know, dwelt upon this mode of propagation of tumors. In the eyeball I have first described it in retinal glioma; for intraocular sarcoma this is the first instance. The propagation of the pseudoplasm from the original choroidal sarcoma to the retina which it encompassed, was by contact, but from the retina to the isolated clusters on the healthy choroid it could only have been by detached seeds *strewn out* upon the choroid.

Stated Meeting, May 14th, 1873.

Dr. Erskine Mason, President, in the Chair.

INTRACAPSULAR FRACTURE OF THE NECK OF THE FEMUR.

Dr. White presented the right femur of a patient in which fracture had taken place at the neck and within the capsule. The patient from whom the specimen was taken was a married woman, American, and about 74 years of age. She was the mother of a large family, and her general health had always been good up to Nov. 30th, 1871, when she had a slight apoplectic attack, followed by a hemiplegia of the left side. Restoration was as good as usually takes place in such cases. The following summer she was able to travel considerably by public conveyance.

Nov. 13th, 1872, she was found lying upon her right side, with the lower extremity of that side under her, and she was perfectly helpless. It was supposed that she had tripped upon the carpet and fallen. She was perfectly rational. The patient was placed in bed, and when I was called to see her the following day, it was found that she still had motion preserved in the left side of the body, the side which had formerly been paralyzed, but that she was perfectly helpless in the right lower extremity. The right foot was everted, there was considerable swelling about the upper portion of the thigh, but she complained more particularly of her back. The right limb appeared to be shortened, but several measurements at the time of the first visit, and subsequently, proved that there was no real shortening. The patient was a woman of large frame, and very fleshy. Such treatment as was thought proper was instituted, without any special treatment being directed towards the fracture. After a few days, she began to suffer from incontinence of urine and fæces; she was unable to use a bed-pan, and although cared for with the greatest faithfulness, bed-sores made their appearance. The patient went on from bad to worse, sank into a typhoid condition, and died from exhaustion at the end of eighty days. Post-mortem was limited to the specimen, and that will show for itself. The fracture was plainly intracapsular.

Dr. Mason inquired whether any ecchymoses were seen on the upper portion of the thigh, or over the ileum, and received the answer from Dr. White that there was something of the usual appearance of the skin after fractures, but not very well marked.

EPITHELIOMA.

Dr. Knapp first presented a patient, from whom he had presented a specimen several months before. The case was one of epithelioma, involving the inner portions of the orbit and its surroundings. The operation which had been performed in this case necessitated the removal of the eyeball, all of the lids, and a

considerable portion of the adjacent skin from the root of the nose, extending about two lines beyond the median line. Nearly all of the inner wall of the orbit, and a greater part of the floor of the orbit were removed. The wound was dressed with a simple bandage, and syringed with lukewarm water. The wound was nearly closed, and the point of interest in the case was, to notice how kindly such an extensive operation might heal. Nothing was used as a dressing except warm water. This case exhibited how plastic covering may be trusted to nature. As soon as no eyeball remains to be protected, plastic operations are unnecessary; but when the eyeball is to be protected, the contrary is the case.

FIBROMA VASCULARE.

Dr. Knapp also presented a tumor which had been removed from the orbit of a child two months old. He first saw the child about three weeks ago, and the parents of the child then said that they had noticed the tumor, or swelling, some two or three weeks. It first began as a small intumescence in the inner portion of the upper lid. It was of a bluish color. The intumescence grew. An oculist was consulted, who decided that it was not of a serious nature, and thought it not advisable to institute any treatment before the child was one year old. When the tumor was seen the first time, the skin of the upper lid was not found involved in the intumescence, but simply pervaded with dilated and tortuous veins. Upon touch, a softish tumor could be felt occupying the inner part of the corner of the orbit. The tumor yielded somewhat to the touch, but it was not possible to empty it by pressure. It had sufficient consistence, that its limits could be easily defined. It was found to extend farther back into the orbit than could be penetrated by the finger.

When the child cried, the tumor was somewhat increased in size, but not very essentially. The same result was also obtained by placing the child suspended by the feet. The eyelid could not be raised at its inner half, the eyeball being visible only at the outer corner of the eye. The tumor was about the size of a filbert. The tumor had been pronounced to be a nevus, but nevus is a too general expression. My diagnosis was *fibroma vasculare*, that is, a tumor made up as orbital cellular tissue is made up, with an undue amount of fat. It was not regarded as being of a cancerous character, because cancer in this region is almost exclusively confined to the retina. It was not regarded as sarcomatous, because sarcomas of the orbit have not been observed in so young children.

Dr. Guldenberg saw the case in consultation and concurred in my diagnosis. The operation was performed yesterday, Drs. Pooley and Turnbull being present. A curved incision was made in the upper lid, following the curve of the fibres of the orbicularis muscle. The hemorrhage which followed the incision through these dilated and tortuous veins was very profuse, but was controlled by lifting the tumor up from below, and making pressure towards the bony wall of the orbit. This elevation of the tumor also gave the secondary advantage of bringing the tumor more prominently to view. An effort was then made to secure the tumor within a clamp, but it being an orbital growth the effort was unsuccessful. The tumor was circumcized by an incision through the healthy cellular tissue, and the hemorrhage which followed was comparatively trifling. The portion now removed consisted of the roundish portion upon the plate. Further examination of the orbit, however, revealed a small tumor in the innermost portion of the wound, and projecting into the orbit. This tumor was perfectly red. It was seized with a pair of tooth forceps, dragged forward, was easily compressed—evidently a more vascular portion of the tumor—and was removed by taking the index finger for a guide, and cutting over it with a pair of scissors, cutting the pedicle, which was composed of hard fibrous tissue containing the afferent and efferent vessels, and stretched deeply into the orbit. The hemorrhage which followed the cutting of the pedicle was profuse, but was easily controlled by the use of the hot iron. After all bleeding had ceased, the cavity of the orbit was cleansed, and the roof of the orbit and about the lachrymal sac were found studded with small lenticular portions of the tumor. These were snipped away, and the surface left perfectly clean and shining like a tendon. Sutures were applied, leaving the inner corner of the wound open, to permit the free escape of all after-secretions. The eye was covered with lint, and a simple flannel bandage applied, which was removed about six hours after the operation, or as soon as it was found that no hemorrhage had occurred. To-day the wound is doing well. The bluish appearance of the skin of the lid has entirely disappeared, which may be regarded as a certain indication that the tumor has all been removed. The nature of the tumor confirmed the diagnosis in all its details—that is, it is a tumor made up of blood-vessels, connective tissue and fat, and nothing else. The front portion of the tumor is made up chiefly of fat, small round cells, and small blood-vessels. The cells were evidently young cells, sometimes were seen with large nuclei and small cell-body, sometimes nothing but nuclei, and then they were seen elongated into spindle-shaped cells, and then into fibres. The back portion of the tumor was made up almost entirely of fibres, and filled with large blood-vessels. In the front portion of the tumor there is, in some places, an immense amount of fat, and this can be seen more particularly in the cells themselves. It is recognized by its lustre and its peculiar appearance. This tumor would be called by some a vascular fibro-lipoma, on account of the quantity of fat which is present, and it may not be improper to retain the term lipoma for this reason. The nature of the tumor is benign. The location of the tumor is not to be regarded as a perfect argument against its malignancy, since cancerous tumors containing all the epitheloid elements may develop upon mucous membranes and upon the skin, but connective tissue and fat is not seen as constituting the elements of a malignant tumor. With regard to the future of the patient, the rapid growth of the tumor indicated a very dangerous condition, and this dangerous condition is confirmed by the histology of the tumor. The large amount of vascularity, the presence of young cell elements in abundance, which are not encapsulated, but are thrown out into neighboring tissues, indicated the elements of rapid growth; so that within the next month, perhaps, the tumor would have protruded the eyeball, encroached upon the outer half of the lid, and, by the formation of new blood-vessels, formed a vascular growth which would have extended into neighboring cavities, and been no longer accessible to an operation. The last resort in such a case, then, would be ligature of the common carotid, and the result of that operation is well known. It was believed that the nature of the tumor and the clinical history justified the early removal of the growth delay of three months, it was thought, would have dangered the child's eye, and perhaps its life. The doctor felt certain that the [illegible]

because its consistence was such as to permit its complete removal without the escape of any portion.

Dr. Janeway exhibited the bullet which was spoken of as being present in a bladder, which he had presented to the Society at one of its former meetings.

The Society then went into Executive Session.

ARTICLES IN OUR EXCHANGES.

SURGERY.

On Colles' fracture of the radius and its treatment. MacDonald, J. A. *Br. Med. Jour.*, March 1.

Removal of a needle from the heart; recovery of the patient. Callender, G. W. *Ibid.*

On the good effects of hydrate of chloral in puerperal eclampsia. BOURDON, M. *Jour. de Méd. et de Chir. Prat.*, March.

Rupture of the cord in precipitate labors, from a medico-legal point of view. *Ibid.*

Case of vaginal enterocele treated successfully with a water-bag. *Ibid.*

Description of a new cephalotribe (illustrated). BAILLY. *Ibid. & Le Mouvement Méd.*, March 26.

Forcing in of the skull during a normal labor. CHABOUX. *Lyon Méd.*, March 30.

Causes of the first respiratory movements of the fœtus. PREVOST. *Gaz. Méd. de Paris*, March 8.

The effect of travelling after marriage in producing

abortion and endometritis. GALLARD. *Gaz. des Hôp.*, March 18.

Case of vaginismus treated by forced dilatation.

Case of fibro-cystic tumor of ovary; operation; recovery. BARRAULT. *La Tribune Méd.*, March 9.

Influence of uterine cancer upon gestation. MONTMEJA. *La France Méd.*, March 5.

Prolapsus uteri. MONTMÉJA. *Ibid.*, March 12.

The action of opium on the gravid uterus. GALICIER. *Ibid.*, March 29.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from June 19, 1873, to July 3, 1873.

MAGRUDER, D. L., Surgeon.—Granted leave of absence for 60 days, with permission to apply at Headquarters of the Army for an extension of 30 days. S. O. 55, Military Division of the Missouri, June 17, 1873.

HARTSUFF, ALBERT, Assistant Surgeon.—Assigned to duty at Sidney Barracks, Nebraska. S. O. 107, Department of the Platte, June 21, 1873.

WOODHULL, ALFRED A., Assistant Surgeon.—Granted leave of absence for twenty days. S. O. 124, A. G. O., June 20, 1873.

MILLER, GEO. McC., Assistant Surgeon.—When relieved by Assistant Surgeon Delany, to comply with S. O. 113, c. s., A. G. O. S. O. 117, Department of the South, June 25, 1873.

AZPELL, THOS. F., Assistant Surgeon.—Granted leave of absence for six months, on Surgeon's certificate of disability, with permission to go beyond sea. S. O. 124, A. G. O., June 20, 1873.

DELANY, ALFRED, Assistant Surgeon.—Assigned to duty at St. Augustine, Florida. S. O. 117, c. s., Department of the South.

EWEN, C., Assistant Surgeon.—Assigned to duty at Baton Rouge, La. S. O. 95, Department of the Gulf, June 14, 1873.

Medical Items and News.

THE ANDERSON SCHOOL OF NATURAL HISTORY was formally opened by an address, by Professor Louis Agassiz, on Penikese Island, on July 8th. The number of students has been limited to fifty-six, which is but a small proportion of the whole number of applicants. There is scarcely a State in the Union which is not represented, most of the pupils being professors and teachers in normal and high schools and colleges. The building, which is being erected under the direction of Mr. Robert H. Slack, of Boston, and has been framed on the mainland, is to consist of two wings, each 120 feet long by 25 feet wide, united by a large lecture and dining hall. The wings will be two stories in height, the upper floors consisting of dormitories. The lower stories are arranged as laboratories, each wing containing twenty-eight aquariums and working tables, one for each student, who is responsible for their care and good condition. The want of intelligence sufficient to keep his or her aquarium in working order will forfeit the privilege of remaining in the school.

The island is about sixteen miles south of New Bedford, and is about three-fourths of a mile long, by half a mile broad. It comprises about one hundred acres, and is the most fertile of the group of Elizabeth Islands, to which it belongs, and is valued at $100,000.

Mr. C. W. Galloupe, of Boston, has presented the school with a yacht of eighty tons, worth $30,000. The following scientists will assist Professor Agassiz in his project: Dr. Burt G. Wilder, of Cornell Univ.; Dr. A. S. Packard, of Peabody Academy of Science, Salem; Count Pourtales, of the Coast Survey; Prof. Waterhouse Hawkins, of England; Paulus Roetter, artist of the Museum at Cambridge; Prof. Mitchell, of the Coast Survey; Prof. J. S. Lovering, of Harvard University; Prof. F. W. Putnam, of Peabody Acad. of Sci.; Prof. N. S. Shaler, of Harvard, who was the first proposer of this scheme, and who is at present in Europe; Prof. Arnold Guyot, of Princeton College, N. J.; and Prof. Brown-Séquard, of this city.

We take from the *New York Tribune* the above facts, and the following extract from a circular addressed by Prof. Agassiz for applicants admission to the school.

"I must make hard work a condition of continued connection with the School, and I desire particularly to impress it upon the applicants for admission, that Penikese Island is not to be regarded as a summer resort for relaxation. I do not propose to give much instruction in matters which may be learned from books; nor do I wish books to be read during the summer session of the school on Penikese Island. I want, on the contrary, to prepare those who attend *to observe for themselves*, that they may hereafter be able to make the most of their opportunities for study in nature, in whatever part of the country they may reside, as there are hardly two adjoining school-districts in which the same objects may be collected for examination.

"It will no doubt appear to many a wearisome process to sit for hours before a specimen, without any but a very general direction what to do with it. I would therefore advise all those who wish only to be taught natural history in the way in which it is generally taught, to give up their intention of joining the Anderson School.

"My plan will further imply the obligation, on the part of all present, of making special collections to carry home and use as a basis for teaching others; in the same way I propose to teach myself with the assistance of many of my scientific friends. My object in adopting this course is not only to give what I consider to be the best instruction, but also to show how teaching should be conducted by competent teachers."

PROFESSOR D. WARREN BRICKELL, formerly of the University of Louisiana, has been appointed one of the Professors of Obstetrics and Diseases of Women and Children, and Clinical Midwifery, in the Bellevue Hospital Medical College.

THE YELLOW FEVER is abating at Rio Janeiro, but becoming more virulent at West India ports. In Matanzas it was especially fatal during the past week: the first cases appearing on the schooner James M. Riley, on which eight deaths occurred, including Captain Coffin. The brig Mabel (from Matanzas for England) was spoken at sea with the captain dead on board. It is somewhat less in Havana, though still occurring. Of other parts there are still cases at Montevideo, Para, and Bahia. No cholera, as yet, has appeared in New York harbor or city.

RECORD OF SCHOONER JAMES M. RILEY.—Arrived in Havana with cargo of hay and paving stones, May 6th, and lay at the quay. May 18th, Frank M. Kelly was taken sick, and died on the 22d, with yellow fever. She left Havana June 2d, with steward, Geo. M. Ficket, sick, who died at sea, June 4th, as also did Chas. Winters,

seaman. The mate, Mr. Eaton, who was in charge of the vessel on her arrival here, was left in hospital at Havana, with yellow fever. Arrived in Matanzas June 5th. June 18th, Captain Alphonso S. Coffin was taken sick, and died the 21st. June 18th, O. Simmonson, a seaman, was taken to hospital, and died the 22d. June 20th, Daniel Pinkham was taken sick, and died 25th. Left Matanzas for New York, June 26th. July 1st, T. Bordel, a Dane, seaman, was taken sick, and died July 3d. All well on arrival.

The late Dr. Robert Nelson.—The late Dr. Nelson, of Staten Island, in 1829 was the first surgeon in Canada to ligature the carotid artery. Before he left Montreal, and while a young man, he operated sixty-five times for urinary calculi very successfully. He translated "Hufeland's System of Medicine," also published a treatise, in pamphlet form, on "Ovariotomy."

The Pennsylvania College of Dentistry will not, in future, receive any female students.

Statistics show that hydrophobia is periodic in character.

Society for Relief of the Ruptured and Crippled, N. Y.—The annual meeting of this Society was held May 7, 1873, at the Hospital, corner Forty-second street and Lexington avenue. During the past year 4,023 patients were treated, of whom 290 were in-patients. Officers were elected for the ensuing year.

New York Medical Societies.—The officers of the N. Y. Medical Union for 1873 are as follows: *President*, Dr. J. E. Janvrin; *Vice-President*, Dr. A. H. Smith; *Secretary*, Dr. Wm. H. Hall; *Treasurer*, Dr. Ellsworth Eliot.

The officers of the Harlem Medical Association for 1873 are: *President*, Dr. John Shrady; *Vice-President*, Dr. Malcolm McLean; *Secretary*, Dr. Henry G. Forbes; *Treasurer*, Henry T. Peirce; *Trustees*, Drs. H. H. Gregory, H. L. Sheldon, and Henry F. Patch.

The Yonkers Medical Association has elected the following officers for 1873: *President*, Dr. H. M. Sprague, of Fordham; *Vice-President*, Dr. George F. Jackson, of Carmansville; *Secretary*, Dr. T. R. Pooley, of N. Y.; *Treasurer*, Dr. S. G. Perry, of Yonkers; *Trustees*, Drs. Reinfelder, Jenkins and Varian. The Society has twenty active and six honorary members.

Faxton.—The Hon. T. S. Faxton, of Utica, has given fifty thousand dollars for founding a hospital within the limits of that city, to be called "The Utica Faxton Hospital." Probably about $100,000 will be added to the original amount.

Insane Retreat, Hartford, Conn.—Dr. James H. Denny, for many years assistant physician at the Retreat, has been made Superintendent of this flourishing institution.

The Meteor.—The patients in the Alabama Insane Asylum edit and print a paper called *The Meteor*. The editor of the *American Journal of Insanity* remarks that the patients of the Vermont State Asylum published the first periodical of the kind in this country. This was soon followed by the *Opal*, edited and printed by the patients of the N. Y. State Asylum, at Utica, which was continued for nine years.

Leprosy.—Shocking forms of leprosy are met with all over Palestine, as of old. One street is especially assigned the lepers in Jerusalem. There are two institutions for their reception in Damascus, one for each sex. Through the day they wander about without restraint, but are required to be home at night. Even in their horrible condition they intermarry among themselves, and some live to an advanced old age. The same disease has been carried to the West India Islands and Newfoundland, requiring special legislation to keep it from being propagated.

Among the 11,000 cases of skin-disease recorded by McCall Anderson, only three cases of Elephantiasis Græcorum (true leprosy) were noted, one of which occurred among the hospital and two among the private patients. One was a young Scotch Highlander, one a boy from India, and the other, a young lady of fifteen, came from Jamaica.

The Process of Taking Cold.—Daily experience teaches the medical practitioner that persons who guard most anxiously against every possible chance of taking cold are most frequently its victims. Geiger, in an article on the mortality of children at Würtzburg, Germany, translated by Ch. Rauschenberg, M.D., Atlanta, Ga., shows that diseases of the respiratory organs cause, in the first year of life, the death of relatively many more legitimate than illegitimate children; while the contrary is true of diseases of nutrition, proving that the too great care of fond mothers to their offspring frequently produces what it is intended to prevent.

Science as Known to the Ancients.—In Egypt mummies have been found with teeth filled with gold, and in Quito a skeleton has been discovered with false teeth secured to the cheekbone by gold wire. In the museum at Naples, among some of the surgical instruments discovered at Pompeii, there is a fac-simile of Sims's speculum. In the ruins of Nineveh, Layard found several magnifying glasses.

Manhattan Eye and Ear Hospital, N. Y.—The third annual report of this Institution, for 1873, gives the following particulars:—Since the Hospital was opened, Oct. 15, 1869, 6,069 patients have been treated, of whom 4,323 were suffering from diseases of the eye, 1,484 from diseases of the ear, and 31 from diseases of the throat; 231 cases not diagnosticated. During the same period 1,158 operations have been performed upon the eye, and 116 upon the ear; total, 1,274. During the past year 2,394 cases of diseases of the eye, ear, and throat have been treated. Number of surgical operations performed, 508. Of the 2,394 cases 1,272 were males and 1,122 females; 1,344 were born in United States, 779 in Ireland, 97 in England, 95 in Germany, 29 in Scotland, and 50 were of 15 other nationalities. *Cataract Operations*:—In the 7 corneal flap extractions, 6 were successes and one a total loss. Three cases were operated upon by Graefe's method modified, and the result was as follows: In the first case, $V=\frac{5}{40}$; in the second, $V=\frac{4}{100}$; in the third, $V=\frac{2}{40}$. In 9 cases the cataract was extracted by Liebreich's Extraction. The first two cases were total losses; the vision in the remaining 7 resulted as follows: 1st case, $V=\frac{2}{40}$; 2d case, $V=\frac{2}{20}$; 3d case, $V=\frac{2}{40}$; 4th case, good recovery, will need secondary operation; 5th case, $V=\frac{2}{40}$; 6th case, $V=\frac{1}{20}$; 7th case, $V=\frac{1}{50}$, and still improving. In 21 cases of extraction, 18 were successful, and three were total failures.

Dr. Edward Curtis has resigned the office of Microscopist, and Dr. Henry C. Eno has been elected to fill his place, with the title of Pathologist. The Directors have secured the services of Mrs. Bertram Thorpe as Matron, who has had the benefit of instruction in nursing in the University College and Queen Charlotte's Lying in Hospitals, London. *Medical Officers*:—Drs. C. R. Agnew, E. G. Loring, Jr., D. B. St. John Roosa, O. D. Pomeroy, C. I. Pardee, F. R. Sturgis, A. H. Smith, and David Webster, the latter being House-Surgeon.

A New Physiological Institute in Berlin.—On the 1st of April the foundation-stone of a new physiological institute was laid at Berlin. It is to consist of a large amphitheatre, several smaller lecture-rooms, a library, dwellings for the assistants and servants, and five laboratories, viz.: one for physiological chemistry, one for physical physiology, one for vivisections, one for microscopy and embryology, and one for the private use of the professors. There are also to be dark rooms for optical experiments, an aviary, and places for keeping animals for experiment. In addition there will be a dwelling and laboratory for Helmholtz, a laboratory of inorganic chemistry, and one for pharmacology, under the direction of Liebreich. The building is to stand in a garden, thus being free from the noise of the streets and well supplied with light and air.

Education of Midwives in Russia.—The Russian government has established the following course of study for midwives:—

First year.—Normal anatomy, including histology of the normal tissues; physics, expounded in their application to the physiology of health and disease, and the hygiene of women and children; botany, with reference to materia medica and pharmacy; and anatomy, especially with reference to women and children.

Second year.—Physiology, medicine, chemistry, pathology, methods of investigating disease, pharmacy, and dispensing. Physiology and pathology shall have special reference to the organization of women and children, pregnancy, and the history of development. Pharmacy is to have special attention devoted to it, as female students will be under the necessity of mixing their own medicines in villages where only small druggists exist.

Third year.—Pathological anatomy, histology, midwifery, the teaching of diseases of women and children will be taught clinically from the beginning. Clinical instruction is confined to the most frequent forms of disease. In the surgical *clinique*, the pupils ought to make themselves acquainted with fractures and dislocations, wounds, and the art of bandaging. The study of nervous diseases and those of the eyes is important; the first with regard to the ailments of women (gynæcology), and the last to those of children.

Fourth year.—Operations in midwifery. General practice in midwifery, hygiene, clinical instruction in diseases of women and children, syphilitic and skin diseases. Operative midwifery must include the use of forceps, turning, etc., with practical training of the students. The duty of an expert in midwifery is confined to the explanation of forensic medicine, referring to the female sex and their offspring: *e.g.*, questions relating to virginity, seduction, pregnancy, miscarriage, the capacity of life of the fœtus, the viability of the child at time of birth, etc. Hygiene is to be studied principally with regard to the health of the child after birth, and of the woman during the periods of development, pregnancy and parturition, and after the cessation of the menses.

Each yearly course lasts eight months, beginning in September and ending in May. The number of lectures may not consist of less than three a day.

From the establishment of this course of instruction the Russian government anticipate the following results: 1. The lives of many women in childbirth will be saved which are lost in Russia from inadequate medical attendance; 2. The lives of many children and people of all ages will be preserved among the lower orders, which are lost through superstition and prejudice; 3. An efficient number of properly constituted midwives will be spread over the country; 4. Such a training will make women very useful as nurses in war, where they are needed, not merely for wounds, but the various disorders which a life in camp engenders; 5. If women are properly educated in medicine, they will be useful in druggists' shops, etc., and thus the services of many men will be at the disposal of the state, whose places they could fill.—*British Medical Journal*, April 12.

Insanity in the State of New York.—Dr. Charles S. Hoyt, Secretary of the Board of Public Charities of New York State, at a late meeting of the Medical Society of the County of Albany, stated that in 1871 the total number of insane in this State was 6,775. Of these 1,582 were in the custody of friends, 1,093 in State institutions, 312 in private institutions, 3,552 in city and county poor-houses, and 161 in institutions in other States. During the year 1872, 1,678 new cases of insanity occurred, or 1 to every 2,612 of population. In the same time there were 761 recoveries and 502 deaths among the insane of the State.

Medical Library and Journal Association of New York.—At the stated reunion, held April 11, 1873, Dr. J. C. Peters, President, in the chair, Dr. Paul Munde read a paper on the craniocast, and Dr. E. R. Pulling on respiration; and at the meeting May 16, 1873, Dr. D. B. St. John Roosa read a paper on "The Consequences of Chronic Suppuration of the Middle Ear." Drs. Pomeroy, Post, and Hackley participated in the discussion.

A Prize in Materia Medica.—The Society of Medicine, Surgery, and Pharmacy of Toulouse offers a gold medal of the value of 300 francs, as the prize of 1874, for the best essay on the following subject: "The Purity of the Chemical Medical Agents most frequently employed; the most certain and easy Methods of Recognizing their Purity."

Galvanic Ecraseur.—According to the London correspondent of the *Canada Medical and Surgical Journal*, Mr. Erichsen says that the galvanic écraseur is the most beautiful adaptation of science to surgery of late years. He has removed several tongues with it, and the penis also, and always with the most satisfactory results as an operation.

Royal College of Surgeons.—One of the examiners of this institution is reported to have said that those candidates who recently went up for their primary examination of the M.R.C.S. were the worst he ever remembered. Out of 105 who presented themselves, 46 were sent back to their studies, and only a few got first-class marks.

Success in Ovariotomy.—Dr. Lewis Rogers (*Am. Practitioner*, April, 1873), in a paper on "Facts and Reminiscences of the Medical History of Kentucky," calls attention to the fact that Dr. Taylor Bradford, of Augusta, Ky., has already attained in his cases of ovariotomy the 90 per cent. success which Spencer Wells thinks *may be* ultimately attained.

The First Operation of Lithotripsy in America.—Dr. Alban Goldsmith, the first assistant to Dr. McDowell in many of his ovariotomies, made the first operation of lithotripsy ever performed in Kentucky or in the United States. It occurred in 1829.

Rothschild.—Baron Adolphe de Rothschild proposes to build and endow, at Geneva, Switzerland, a hospital for eye-diseases, at a cost of $100,000.

THE FIRST ENGLISH OBSTETRICAL WRITER.—The first English midwife who appeared as an obstetrical writer was Mrs. Jane Sharp, of London, whose work was published in 1671, under the name of the "Midwives' Book"—a duodecimo of 418 pages.

EXCISION OF THE ANKLE-JOINT.—The first English surgeon who performed the difficult operation of excision of the ankle-joint was Henry Hancock, senior surgeon of Charing Cross Hospital, and President of the Royal College of Surgeons, London.

LIFE-SAVING SOCIETY OF NEW YORK.—A society of this character has recently been inaugurated in New York city, to promote the rescue of persons in peril from drowning, from fire, and from other accidents. The medical officers are as follows: *Vice-President*, Dr. E. R. Peaslee; *Corresponding Secretary*, Dr. Benjamin Howard; *Executive Committee*, Drs. Frank H. Hamilton and Alfred C. Post; *Board of Directors*, Drs. B. Howard, A. C. Post, T. G. Thomas, E. R. Peaslee, Marion Sims, C. R. Agnew, Wm. A. Hammond, A. Flint, Jr., F. H. Hamilton, and Fordyce Barker. Prof. Theo. W. Dwight, *President*.

TAYLOR.—Rev. W. G. Taylor, M.D., late of Camden, New Jersey, has been appointed by the Board of Foreign Missions as physician to the Gaboon Mission, on the western coast of Africa.

UNIVERSITY HOSPITAL, PHILADELPHIA.—The trustees of this new hospital have nearly six acres of ground, free from all incumbrance, and a building fund, given by the State, of about $200,000. A contribution of $350,000 will also, probably, be raised. The structure will be 220 feet in length.

REFRACTION AND ACCOMMODATION.—"A Treatise on the Diseases of Refraction and Accommodation," is the title of an interesting *résumé* by H. S. Fenner, M.D., of Louisville, Ky., published in the May number of the *Richmond and Louisville Medical Journal*, and reprinted in pamphlet form.

MEDICAL EDUCATION.—Prof. Alfred Stillé, in his address before the Society of the Alumni of the Medical Department of the University of Pennsylvania, at its annual meeting, March 12, 1873, gives a practical view of "Medical Education: What it is, and what it might be made," and strongly favors the necessity of providing endowments for its professors' chairs. Eight, he remarks, would be a minimum number of professors; but that number should include a Professor of General Pathology and Morbid Anatomy. This brochure of 34 pages contains much that is interesting to medical men who are desirous of elevating the standard of medical teaching in this country.

LOGIC OF MEDICINE.—The learned essay on "The Logic of Medicine," by Edward S. Dunster, M.D., which was originally delivered before the New York Academy of Medicine, and published in full in the *N. Y. Medical Journal*, reappears in the form of a brochure, by order of the Academy.

THE OBSTETRICAL JOURNAL OF GREAT BRITAIN AND IRELAND.—The first number of this new monthly obstetrical journal, which appeared April 1st, is dedicated to William Harvey, the father of obstetrics, and contains original papers by Drs. Robert Barnes, Gustavus C. P. Murray, Andrew Inglis, Thomas Chambers, and J. H. Aveling; reports of hospital practice, notices and reviews of books, abstracts of societies' proceedings, and obstetrical summary, etc., comprising 72 pages. An American supplement of 16 pages, edited by William F. Jenks, M.D., Obstetric Physician to the Philadelphia Dispensary, is appended. James H. Aveling, M.D., and Alfred Wiltshire, M.D., are the English editors. Henry C. Lea, of Philadelphia, is the American publisher.

SOCIAL SCIENCE ASSOCIATION.—Dr. Edward Jarvis, at a late meeting of this Association, held in Boston, Mass., read a paper on the "Influence of Crime," in which he drew from statistics the deduction that, while the crimes of males are against persons and property in two instances out of three, the crimes of females were sensual and against themselves in the ratio of 70 per cent.

DEPILATORY MIXTURE.—A new depilatory mixture is recommended by Prof. Boettger, consisting of one part of crystallized sulphydrate of sodium, and three parts of prepared chalk. Mixed with water, and applied to the skin, it effects the easy removal of hair.—*Med. and Surg. Reporter*.

EMOTIONAL INSANITY.—At a recent meting of the New York Medico-Legal Society, David Dudley Field Esq., in discoursing upon "Emotional Insanity," concluded as follows:—

Children under the age of discretion, idiots and imbeciles are not within the discipline of criminal law.

The mental unsoundness of other persons, commonly designated as insanity or mania, is in itself, or is attended by, disease of the brain, so that no heat of mere passion, and no degree of mere frenzy, can in any just sense be pronounced insanity by either of the professions.

That neither perceptional nor emotional insanity by itself, nor both together, can be accepted as excuse for criminal responsibility.

That intellectual or volitional insanity absolves from criminal responsibility when, and only when, the reason has lost either the power of choice or the power of controlling the will.

That in every case of acquittal on the ground of insanity, the defendant should be forthwith placed in a lunatic asylum, and there kept until it is proved that he is restored to such a state of sanity as to remove all apprehension of a recurrence of the disease.

That the present gradation of punishments is unsuited to the present condition of medical learning, and a change is required which shall make the law punish not only according to the harmfulness of the outward act, but according to the quality of the inward spring of action.

New Publications.

BOOKS RECEIVED.

CHEMISTRY, MEDICAL AND PHARMACEUTICAL, including Chemistry of the U. S. Pharmacopœia, &c. &c. By JOHN ATTFIELD, Ph. D., F.C.S., Prof. Pract. Chem. to Pharm. Soc. Great Britain. Fifth ed. Phila.: H. C. Lea. 1873.

INTRODUCTION TO THE STUDY OF CLINICAL MEDICINE, &c. By OCTAVIUS STURGES, M.D., Cantab. Phila.: H. C. Lea. 1873.

ON THE TREATMENT OF DISEASES OF THE SKIN, &c. By Dr. MCCALL ANDERSON, Prof. Pract. Med., Anderson University. Phila.: H. C. Lea. 1873.

CLINICAL REPORTS FROM PRIVATE PRACTICE. By JOHN CLAIBORNE, A.M., M.D., etc. Petersburg, Va. 1873.

CONTRIBUTIONS TO PRACTICAL SURGERY. By GEO. W. NORRIS, M.D., late Surg. to Penn. Hosp. Phila.: Lindsay & Blakiston. 1873.

PHARMACEUTICAL LEXICON. A Dictionary of Pharmaceutical Science, &c. By H. V. SWERINGEN. Phila.: Lindsay & Blakiston. 1873.

Medical Department of Life Insurance.

LONGEVITY;

OR, THE RELATIVE VIABILITY OF THE SEXES: PARTICULARLY WITH REGARD TO THE RELATIVE LIABILITY TO THE INHERITANCE OF CERTAIN TRANSMITTED DISEASES.—CONSIDERED IN RELATION TO THE SELECTION OF LIFE-INSURANCE RISKS, WITH A VIEW OF EXHIBITING THE UNJUSTNESS OF THE PRACTICE OF CHARGING HIGHER RATES FOR WOMEN. ILLUSTRATED, IN PART, BY THE STATISTICS OF PHILADELPHIA, FOR THE ELEVEN YEARS ENDING 1871.*

By JOHN STOCKTON HOUGH, M.D.

Part II.

"Feminæ præ Viris Longeviores."†

It is useful, in this connection, to inquire whether men are more likely to have hereditary diseases engrafted on their constitution than women, and it is for this purpose that I have made careful calculations of the proportion of males to females dying of the various affections named in the table.

OLD AGE.

Of the persons dying of "old age" (60 to 110 years) 65.17 per cent. were women, and only 34.83 per cent. men. In the free white population of the United States, there were, in 1830, 2,041 males and 2,523 females living from 90 to 100 years of age, or in the proportion of 80.88 to 100. In 1840 there were of the same ages, 2,143 males and 3,145 females, or in the proportion of 76.72 to 100. In 1850, 5,183 males and 6,512 females attained these ages, or 79.57 males to 100 females. In 1860, 5,854 males and 7,924 females, or as 73.86 males to 100 females. In 1870, 6,922 males and 9,731 females, or 71.13 males to 100 females attained these ages. It is curious to note that of the persons aged 100 years and above in 1830, 301 were males, and 238 females, or in the proportion of 126.47 to 100. In 1840 the proportion for the same ages was (432 to 285) 151.59 to 100. It would appear from this, that although the mean average duration of life from 90 years up is greater for women than men, yet in extreme ages (above 100) the men exceed the women. Of 46 persons whose names appear on the records of extreme longevity (from 130 to 176 years) only 10 were women, though the one who attained the greatest age (176 years) was a woman.

In the United States, in 1850, 1,077 males and 1,478 females attained to 100 years and above. In 1860, 1,233 males and 1,720 females. In 1870, 1,286 males and 2,236 females. Both of these decades of ages show a growing increase in the proportion of females attaining extreme ages.

Of 1,712 persons attaining 100 years and above, 670 were females and 1,042 males, or in the proportion of 1,000 males to 642 females. ‡

In the city of Providence§ for the 15 years ending 1870, 202 men and 445 women died from old age, or 45.37 men to 100 women. In England, 1857, 11,323 males and 15,524 females died of old age, or 728 men to 1,000 women, the proportion of sexes in the living population being 966 males to 1,000 females.

ZYMOTIC DISEASES.

Zymotic diseases are generally more fatal among males than females; in England, 1856, 1,248 males and 1,029 females died of small-pox, or in the proportion of 1,212 males to 1,000 females. In Philadelphia (1871), 1,016 males and 863 females died of this disease, or in the proportion of 1,176 males to 1,000 females; under 20 years of age, there were 578 males and 581 females; above 20 years of age, 438 males to 282 females, or 1,553 males to 1,000 females. In England (1856), 137 males and 90 females died of purpura and scurvy; 599 men and 477 females died of rheumatic fever; 4 males and 1 female of hydrophobia; 61 males and 33 females of mumps; 7 males and 1 female of glanders. Two men to one woman died of cholera maligna in Philadelphia, in 1834.

SUDDEN DEATHS.

Devergie* says the difference in the proportion in the sexes of those dying suddenly is enormous, there being but 5 women out of 44 cases, or 100 females to 780 men.

In England, 1851, there were 1,917 males and 1,486 females who died suddenly from unascertained causes, in the proportion of 1,289 to 1,000.

MURDER, VIOLENCE, AND SUICIDE.

Nearly 4½ times as many males as females meet a violent death, either at their own hands or by an assassin. In France from 1835 to 1849, on an average, 3 men to 1 woman committed suicide, the proportion being very nearly the same for each year. The U. S. census of 1870 gives 17,517 male and 5,223 female decedents from accidents and injuries. Of these 1,080 men and 285 women committed suicide, or 395 males to 100 females. 1,907 men were murdered, and only 150 women, while 31 men were executed.

INTEMPERANCE.

A much larger proportion of deaths from intemperance occur among the male sex, 136.84 to 100, or taking the proportion of the sexes in the population into consideration, there are probably two men to one woman among the decedents from this cause.

WOUNDS.

Seventeen men died from the effects of wounds to every woman dead from the same cause.

APOPLEXY.

1.20 per cent. of all the deaths were ascribed to apoplexy; of these, there were 123.25 males to every 100 females, or taking the proportion of the sexes in the adult population into account, more than 3 men to 2 women. This is in keeping with the fact of a more frequent sanguine temperament among men than among women; men also have a larger quantity of blood, having a higher specific gravity, and a larger proportion of red corpuscles and other solid constituents, as determined by Dennis, Foedisch, and Le Canu. These facts taken in connection with the function of menstruation in the woman, and greater exposure of men to the elements, would appear to be sufficient to explain the difference in the mortality from this cause.

GOUT.

Although Hippocrates and other sages have said that women, children, and eunuchs do not have

* The writer, in the course of this article, has enunciated theories, some of which are novel and original, and while he fully believes them to be true, he desires it to be distinctly understood that they are not *necessarily* recognized by scientists generally; and further, the scope of this article gives him no opportunity to prove his position, which he hopes to do at some future time.

§ Dr. E. M. Snow's Reports to the Board of Health.

* Annales D' Hygiene Pub., etc., t. XX., 1838, p. 177

gout, yet we find in our reports a few deaths of females from this cause, in the proportion of about 1 female to 3 males. In England (1856), 221 males and 39 females died of this disease. Of other constitutional diseases, 825 males and 634 females died of abscess; 60 males and 13 females died of fistula.

LOCAL DISEASES.

In England (1856), 78,152 males and 71,759 females died of local diseases, or 1,084 males to 1,000 females.

DISEASES OF URINARY ORGANS.

In England (1856), 3,161 males and 1,166 females died of these affections, or 271 males to 100 females; of diabetes, 271 men to 159 women.

HYDROCEPHALUS.

In England (1856), 4,161 males and 3,138 females died of this disease.

WHOOPING-COUGH.

This affection is uniformly more fatal among females than males, but as the decedents from this cause are nearly always minors, it does not affect the question under consideration.

AFFECTIONS OF THE HEART.

The deaths reported from "diseases," "inflammation," and "congestion" of the heart, constitute 2.66 per cent. of the total number of deaths from all causes whatever. By far the larger proportion, 2.15 per cent., of these were adults above 20 years of age. Among those dying before the 20th year of age, there were about 3 boys to 2 girls; while of those dying at 20 years and above there were 95.55 men to 100 women; and when we take into consideration the fact that there are probably not more than 85 men to every 100 women above 20 years of age in the general population, we find that there is actually an excess of 5.4 per cent. of males over females among the adults dying from these affections. It is worthy of observation, however, that the percentage of excess of male deaths among the adults of this class is smaller than that for any of the other affections under consideration, except cancer. Dr. Geo. H. Norris, in his article on Aneurism of the Subclavian Artery, gives 59 cases in which the subjects were males, and only 7 females. (*Amer. Jour. Med. Sci.*, July, 1845.) In England (1856), 254 men and 84 women died of aneurism.

AFFECTIONS OF THE BRAIN.

5.21 per cent. of all the deaths reported were from "diseases," "inflammation," and "congestion" of the brain. About two-fifths of the number were under twenty years of age, and the proportion of males to females was as 132.13 to 100, for all ages, 118.45 to 100 for those dying under 20 years, and 324.50 to 100 for those 20 years and above. This proportion of 13 men to every 4 women dying of these affections after the 20th year, is certainly very large, and would seem to indicate some other causes than greater exposure to the elements, and dangerous and difficult occupation. Notwithstanding this much larger proportion of adult males among the decedents from affections of the brain, yet there are more women insane than men. Though there be more of genius among men, there are also more idiots, deaf, blind and dumb, than among women.

SCROFULA.

This hereditary malady is much more frequently fatal among males than females, even after they have reached their 20th year. In England (1857), 1,552 males and 1,229 females died from this cause, or 1,262 males to 1,000 females.

PARALYSIS.

1.26 per cent. of all the deaths were ascribed to this malady; of these, 122.92 were males to every 100 females. Nearly all of those cases were above 20 years, most of them far advanced in life, yet the proportion of males is very large, the excess amounting to about 17 per cent.

INFLAMMATORY AFFECTIONS OF ORGANS OF RESPIRATION.

In England (1856), 28,400 males and 24,508 females, or as 1,158 males to 1,000 females, died from these affections.

PULMONARY CONSUMPTION.

Every inquiry about this very fatal disease must be both interesting and useful, for a very large proportion of life-risks die of this malady, and every addition to our knowledge of the laws of transmission and exhibition of its effects must be exceedingly valuable. 12.78 per cent. of all the deaths occurring in Philadelphia during the period named were from this cause; of these, 99.15 were males to every 100 females. Comparatively few (1.78 per cent.) die under 20 years; but the proportion of females among the decedents below this age is very large (4 to 3), as compared with the proportion after the 20th year, when the males have an excess of 9.7 per cent. For the years 1832–3–4, the excess of female decedents amounted to 17.3 per cent. 11 per cent. of all the deaths from whatever cause are persons above 20 years of age, from consumption of the lungs. The deaths from pulmonary consumption in the city of Paris,* for the ten years ending 1848, numbered 20,723, of which 63.67 were males to every 100 females. Of the 19,409 deaths from pulmonary catarrh in the same city during this decade, 76.65 were males to 100 females. These proportions are for all ages, and we have seen in the deaths occurring in Philadelphia, that the proportion of females was much greater for ages below 20 years than for those above that age, and then the proportion of females in the adult population of Paris is much greater than in Philadelphia, which would, I think, finally give an excess in the proportion of males in the deaths from this affection. In the State of Michigan,† in the year 1870, there were 3,000 deaths from consumption, 86.79 of which were of males to every 100 females. Where an entire State is included in the returns, the greater mortality of women from all causes in country districts, is probably not without its effect on consumptives. In the city of Providence, R. I.,‡ for the 15 years ending 1870, there were 2,957 deaths from pulmonary consumption, or 18.70 per cent. of the total mortality from all specified causes; of these 45.56 per cent. were males, and 54.44 per cent. females, or 83.66 males to 100 females; there being 89.44 males to 100 females in the population.

The following table I have elaborated from the Registrar's (Mr. Chambers's) report:—

Age and percentage of decedents from consumption of the lungs, in Philadelphia, for the 11 years from January 1st, 1861, to December 31st, 1871:—

Average age of all decedents from consumption	35.57 years
Average age of all decedents from consumption dying after the 20th year	39.41 "

* M. Trébuchet, in Annales D'Hygiène Pub., etc., v. xlvi., p. 6-12.
† Dr. Baker's compilation of the Statistics of Michigan, 1870, p. 342.
‡ Dr E. M. Snow's Regst. Rept., 1870, p. 46.

Average age of all decedents from consumption dying after the 30th year	46.77	"
Average age of all decedents from consumption dying after the 40th year	51.73	"
Average age of all decedents from consumption dying after the 50th year	58.51	"

The percentage dying at different ages was as follows:—

Under 1 year.	1 to 2.	2 to 5.	5 to 10.	10 to 15.	15 to 20.	20 to 30.
1.73.	1.06.	1.34.	.99.	1.29.	6.90.	30.39.
30 to 40.	40 to 50.	50 to 60.	60 to 70.	70 to 80.	80 to 90.	90 to 100.
24.21.	16.94.	8.95.	5.28.	2.19.	.34.	.019.

In England and Wales, according to Dr. Farr,* consumption (phthisis) is most fatal to women, the difference being greatest between the ages of 15 and 55 years. For the 7 years ending 1854, 166,741 males and 187,801 females died, or 2.70 males died annually, to every 1,000 living, and 2.92 females, being an excess of .22 for females.

From	0–5	years	there	was	an	excess	of	.08 for males.
"	5–10	"	"	"	"	"	"	.08 " females.
"	10–15	"	"	"	"	"	"	.57 " "
"	15–25	"	"	"	"	"	"	.72 " "
"	25–35	"	"	"	"	"	"	.67 " "
"	35–45	"	"	"	"	"	"	.23 " "
"	45–55	"	"	"	"	"	"	.70 " males.
"	55–65	"	"	"	"	"	"	.88 " "
"	65–75	"	"	"	"	"	"	.74 " "
"	75–85	"	"	"	"	"	"	.18 " "
"	85–95	"	"	"	"	"	"	.07 " "
"	95 and upw.	"	"	"	"	"	"	.20 " females.

This table indicates that females are more likely to die of consumption than males, from puberty to the menopause, but after the 45th year, more males succumb to this cause than females; until 95 years is reached, when it is again more fatal among females. For all ages there is an excess of female decedents in the proportion of 1,000 females to 887 males, but it must not be forgotten that there is an excess of females in the population of all ages (1,000 females to 966 males), and of the ages of decedents from this cause the proportion is probably in favor of females, so that of the *adults* dying of this affection, as indicated by the above table, there is a larger proportion of males than females; for the excess of females, among the decedents from the 20th to the 45th year, is more than counterbalanced by the excess of males above the 45th year.

Dr. J. V. C. Smith says that "females in cities are more prone to consumption than those in the country." In the State of New York, 1865, 3,042 males and 2,999 females died of pulmonary consumption, or 16.19 per cent. of all the deaths were from this cause. This mortality is 4 per cent. greater than that of Philadelphia for the last 11 years. In New York State, 1850, 3,257 males and 3,434 females died from this disease, and in 1860, 4,014 males and 4,185 females; for these 3 years the proportion of males to females was as 97 males to 100 females. In 1865, there were 96 males to every 100 females living of all ages in the population of the State.†

Dr. Snow says: "Of the decedents from consumption a large majority of those of American parentage have been females, but until 1868 there were usually more males than females among those of foreign parentage."

In the New England States, according to the census of 1870, of the decedents from consumption 84.58 were males to every 100 females, which is probably not much above the proportionate excess of females in the population.

* Registrar-Gen.'s Rept., 1854.

† Census of State, 1865, compiled by Dr. Franklin B. Hough.

Some authorities say that "consumption is more likely to be transmitted by a mother than a father." We may find a reason for this in the following:—

The egg from which a male is derived, being for a longer time under the sole influence of the mother (before impregnation), acquires more of her physical constitution and peculiarities, resembles her more, or inherits more of her physical defects and tendencies, and this egg is impregnated by a weaker element on the father's part, than his female issue;—while the egg from which a female is derived is a shorter time under the sole influence of the mother, being impregnated earlier in its course of development; and besides this it requires the highest power of the male element to communicate the impregnating influence to it. Hence we have less hereditary disease *exhibited* in the female, yet she may *transmit* it with greater facility than the male, though it may not have developed in her.*

An *increasing or high rate of mortality* is accompanied by greater fecundity, larger proportion of male births, and *greater mortality among males than females of all ages.* This rule holds in cities or parts of cities as compared with other cities, but may not hold when cities are compared with country districts. With very rare exceptions the males usually exceed the females in births, from 2 to 6 per cent.; yet in no country, were the influence of emigration and immigration excluded, are the number of males living equal to the number of females, particularly in old and highly "civilized" countries. Throughout the world there are millions more females than males; especially is this true among adults. As there are from 2 to 6 per cent. more males born than females, yet there are at least 6 per cent. more females in the living population,† and as the proportion is steadily increasing it is evident that females are longer-lived than males.

I have been contented to bring together these facts and arrange them with a view of showing the greater longevity of females in general, and in particular in regard to the effects of hereditary disease, which are the great source of loss to life-companies. It is scarcely necessary for me to draw the inferences from these facts and figures, for they are so plain that it is unnecessary; one can easily see, by examining the table, that a woman whose parents died of brain-disease, is a much better risk than her brother, so far as the likelihood of her dying of the same affection is concerned.

2003 WALNUT ST., PHILADELPHIA, May, 1873.

THE MEDICAL EXAMINERS.

TO THE EDITOR OF THE MEDICAL RECORD.

As one deeply interested in the subject of Life Insurance, and having a high opinion of the benefits conferred by the institution, when rightly managed, upon society, I most heartily welcome the effort you are making to increase the safety of the companies and the security of the insured by improving the medical examinations. There is great need of improvement in many respects. Yet, if you will allow me the liberty of saying so, the *tone* of the articles in your first number conveys the impression that the fault lies chiefly, if not entirely, with the medical profession. That the companies have not as yet done all they might do to secure faithful and reliable reports

* For a more full explanation of this theory, see the author's next paper on "The Laws of Transmission of Resemblance from Parents to their Children."

† The U. S. census of 1870 gives only 99.89 males to 100 females in the native-born population, while in the foreign-born population there were 117.01 males to every 100 females. The large excess of males in the latter case is due to the greater number of male immigrants as well as the larger proportion of male births among them than among the native-born parents.

as to the health and eligibility of candidates for insurance is to me perfectly plain, and the object of this communication is to very briefly present for their consideration two propositions, the adoption of which would, I believe, be very great improvements upon the present plan of doing business.

First: Let there be appointed a State or district supervisor of medical examiners. Let him be a medical man, acquainted with the profession generally, and let him appoint examiners from considerations of age, experience, character, etc. Such an officer would render valuable services to the company, and would deserve pay for his services. Under such administration, we should not see the examinership given to the first medical acquaintance made in the town by the agent, or to one who has just graduated, when there are many who have served in the capacity for years and made the subject a study. Further, and far more important, the examiner would then never be, as he never should be, the creature of the agent, or in any way dependent upon him.

Second: Whether the former plan be followed or not, let the blank for the medical examiner be invariably separate from the application, with directions to mail it direct to the home-office and not allow it to pass through the agent's hands, to be seen by him or by any one else. Generally, in small towns, and sometimes in large cities, the examiner finds it difficult to make an honest report upon an applicant without injuring himself. Frequently he is obliged to resort to some subterfuge to enable him to do his duty honestly by his employer, the company, and by his other employer and neighbor, the applicant. All this would be avoided by the plan suggested, were it followed by the companies generally, and made invariable as to individuals.

The value of these suggestions may not appear as great to others as to myself; I have learned it from an experience extending over many years as examiner for several companies, and I present them in your columns for the consideration of those interested. J. C. R.

DAYTON, OHIO.

TO THE EDITOR OF THE MEDICAL RECORD.

I AM in receipt of the Special Edition of the MEDICAL RECORD, May 15, 1873, with the notice that the ..... Life Insurance Co., of Hartford, Conn., has paid the subscription price and directed the RECORD to be sent to me for one year from May 15, 1873.

While I tender, through you, my sincere thanks to that company for so doing, I wish to take notice of the article written by the Secretary of a Life Insurance Company—on the relation of the Medical Examiner to the business of Life Insurance.

The writer of that article says, "It is undoubtedly the fact that by all life-underwriters the medical examination is considered the *weak spot* in conducting the business of life insurance," and as he proceeds we are led to feel that this weak spot comes less from a want of professional skill than from a want of honesty and *moral* qualifications in the medical examiner.

Now this is putting the matter in a strong light, and casting a reflection upon the medical profession which, I think, is not fully deserved. The author of the article evidently does not write through any feelings of malice, and probably not without reason for so doing, but I think he lays the cause to the wrong source, and makes the examiner bear the guilt which often belongs and should be laid to other causes.

Without going into an argument, I will state two facts which came to my notice and bear on this point. An agent for whom I had made several examinations presented one man who, to appearance, was a good subject, but knowing something of his history I declined to examine him, feeling sure I should not pass him, and supposed the matter stopped there; but, instead, the applicant was taken to a neighboring town, passed examination, and received into a company.

The other instance was an applicant whose examination was good, but the family history given by the applicant caused me to send him to the headquarters of the company; he was admitted. Some two or three years after that, this person made another application through an agent to this company, and his examination being good I recommended his insurance, knowing he had been admitted at headquarters on previous application. The company, however, rejected the application with considerable spirit, gave the agent a lecture, telling him that he must pay the examining fee.

I am glad you have added a department of Life Assurance to the RECORD, and think that good will come out of it.

Companies cannot be too particular in taking risks, nor physicians too thorough in examinations, but agents can be too persistent in getting applicants.

Yours truly,

JEROME WILMARTH, M.D.

UPTON, MASS., June 9, 1873.

THE RELATIONS OF THE LIFE-INSURANCE COMPANIES TO THE MEDICAL PROFESSION.

BY A MEDICAL DIRECTOR.

No one who is conversant with the business of life insurance will deny that the mutual relations between the companies on the one hand, and the medical profession on the other, are at the present time eminently unsatisfactory to both parties, and fraught with danger to the best interests of the community. The executive officers complain that "the medical examination of applicants does not afford that protection against the intrusion of unsound lives which it is designed to effect;" in other words, they consider the medical examination as "the *weak spot* in conducting the business of life insurance." This evil they attribute not so much to a lack of professional skill in the medical examiner as to the "absence, too frequently observable, of a certain *moral* qualification, not less essential in the exercise of his responsible duties." *

This is, in brief, the ground of complaint on the part of the companies; and, we regret to add, it rests on a foundation of fact.

On the other hand, the medical examiners complain that the companies do not treat them fairly; that they are quietly allowed to make room for some more lenient physician, the moment the exercise of their duty to the company conflicts with the interests of the agent. They say, furthermore, that their fees are too small in proportion to the responsibility which they are made to assume.

While both sides, then, seem to have just cause for complaint, the question still remains, Who is primarily to blame for this condition of things? Is it because there is a widespread and growing lack of moral responsibility among the members of the medical fraternity, or have the companies enlisted in their service

* See MEDICAL RECORD of May 15th, 1873; article, "On the Relation of the Medical Examiner to the business of Life Insurance." By the Secretary of a Life-Insurance Company.

a large percentage of the irresponsible men in our profession? Are physicians deteriorating as a class, or have the companies been negligent in their efforts to secure the coöperation of the best medical men in the towns where they insure lives? "Secretary," viewing the question from his stand-point, throws the blame upon the medical profession, or, rather, he dwells upon the fact that a very large percentage of the medical examiners fall short of their duty to the companies, and says nothing about the shortcomings of the companies themselves. His communication, which is made in the friendliest spirit, is an appeal to the medical profession to co-operate with the executive branch of the business in affording to the insured community that protection to their interests which they have a right to expect. It is in this spirit, and with this end in view, that we would offer the following criticism on the course pursued by the companies toward the medical profession.

It has been and still is the custom of a large proportion of the life-insurance companies, to entrust the appointment of medical examiners to the local agent. They instruct him to select the best physician he can find in the place and to forward his credentials to the home-office, where, if it is found that his references are good and that he is a graduate from a regular medical school, the appointment is confirmed. This pernicious method is the chief source, we believe, of the whole trouble, and we therefore beg leave to follow out its workings more in detail.

In the first place, is it likely that, even under favorable circumstances, the agent will select the most capable and trustworthy physician in the town? Does not the choice of a doctor in this case affect the pecuniary interest of the agent too deeply to render him a competent person to make the selection? So very many cases are on record of collusion between the examiner and the agent, that we are amazed that a majority of the companies should still tolerate a system under which such things are possible.

While most agents would undoubtedly scorn to recommend a bad risk to their companies, yet very many of them, as stated by a correspondent,* will "purposely avoid giving business to a man they know to be competent and independent, preferring a more *compliant* examiner." These men want an examiner who will not be over-particular, who will "let their candidates off easily"—in a word, who will help them in their business.

Another of the bad effects of this system may be seen in the frequent change of examiners in one and the same town. The agent, finding that he has not received from Dr. A. all the assistance he expected in the way of introductions to friends, or that he is a trifle too rigid in his examinations, writes to the home-office that it will be necessary for him hereafter to employ Dr. B., as Dr. A. has too large a practice to attend to the business of examining applicants. Dr. B.'s credentials are satisfactory to the company, and he becomes the new examiner. In the same way, Drs. C. and D. in turn are appointed. Dr. A. in course of time discovers that his place has quietly been filled by Dr. B., for what reason he is unable to discover. In all probability the same performance will be gone through with by the agent of another company, and then Dr. A., who is a straightforward man and possesses some self-respect, determines in the future to make no more examinations. Is it astonishing that the better class of physicians are disgusted with life insurance, and look with distrust upon companies that knowingly allow their business to be conducted on such loose principles? They see, better than any one else, how this branch of medicine, in many parts of the country, has gravitated into the hands of the incompetent, inexperienced and unscrupulous; and their conclusion is, that "the companies are indifferent about the matter," that they do not care to secure the services of the best men in the profession.

The real reason why the companies have perpetuated this method of appointing medical examiners lies, we believe, in the fact that they are *afraid* of losing their agents; they fear that the adoption of a system which would practically ignore the agent in the appointment of medical examiners, would cause him to revolt to the service of another and more pliable company.

The medical profession, like all the other professions, has its share of unworthy members, and we believe that the evil of which "Secretary" complains is in great measure due to the fact that the companies have widely enlisted these unworthy professional men in their employ. We certainly prefer to believe this rather than to assume that the standard of professional morality and skill is being lowered.

The second ground of complaint on the part of the medical examiners relates to the question of fees.

We recognize the difficulty of offering any satisfactory solution to this knotty question, and shall be glad to receive additional light upon it from any quarter. The following remarks, however, are offered as bearing upon the subject.

The general demand is that the companies should pay a uniform fee of five dollars for every examination, and in some sections of the country the county medical societies have passed a vote making it an offence for any of their members to examine for less than that sum. This surely is not the right way to accomplish the object in view, and, besides, it is likely in certain instances to prove oppressive to younger but competent and trustworthy members of the profession, who would be glad to examine for a smaller fee. Another effect of such a resolution is to place the services of inferior men at the same value with those whose opinion, in a moneyed point of view, is really worth the fee demanded.

There is still another aspect to the question. If the examiners in the country and in the smaller towns and cities receive five dollars for an examination, the examiners in the larger cities—New York, Boston, and Philadelphia—would then have a right to demand at least eight or nine dollars for similar services, as the purchasing value of a dollar in the country is nearly equal to that of two in the three larger cities. With perhaps one or two exceptions, the companies could not afford to pay such fees, without at the same time charging higher rates for insurance.

On the other hand, if the companies could secure the services of competent and trustworthy physicians, who at the same time would take a reasonable degree of interest in the prosperity of their employers—the company—and would feel how serious is their responsibility to the insured community, it would be found a positive economy to pay five dollars, or even more, for every examination. At present, however, the companies feel that they are not receiving a fair equivalent for their outlay, and are consequently not disposed to raise the fees.

The last point to be considered—and it undoubtedly is the most important of all—is, how may satisfactory relations be restored between the medical examiners and the companies, and how may the latter secure the valuable protection to their interests—and their inter-

* See MEDICAL RECORD of June 15, 1873. Letter from a "Medical Examiner."

ests are the interests of the community — which the medical profession alone can give.

In answer to this question we would say, in the first place: Leave the appointment of medical examiners to physicians of the highest character and standing in their respective States or sections of country. They can have no possible motive for appointing any but competent and trustworthy men, and their facilities for ascertaining the real character and professional ability of the physicians in their vicinity are unquestionably greater than those possessed by any non-professional person. Let the examiner so appointed understand that his position is a permanent one; that, if he performs his duties faithfully, the agent will be powerless to remove him. According to this method the positions will seek the men, because of their fitness, and not the reverse, as has hitherto been the case to a very great extent. This course, too, will tend to win back the respect of the medical profession for the business management of the life-companies, and open the way for a closer union between the great body of examiners and the home-offices. A few of the companies have already tested this mode of appointing medical examiners, and have found it a decided improvement over the old system.

In the next place, there should be but one examiner in every town. If in certain places it is thought desirable to have a second or substitute examiner, the agent should be instructed that he is not to employ the two indifferently, but to use all possible efforts to have the applicant examined by the official representative of the company.

A correspondent lays stress on the importance of having the medical examiner's report kept separate from the application, the physician being instructed to send it direct to the home-office. He believes that by this means the examiner will be able to conceal the results of the examination from everybody except the company, and so avoid injuring his interests in the town where he practises. It is difficult to see what material advantage this plan would have over the one now generally followed, for the applicant would very soon hear of his rejection, and would of course know upon whom to throw the blame. It appears to us that there are but two ways of managing this difficulty, namely, either to face the responsibility boldly and conscientiously, or to refuse to assume the duties of an examiner.

Finally, the home-offices should do everything in their power to interest the examiners in the work of excluding all who are not justly entitled to the benefits of life-insurance. So far as is possible, these physicians should be induced to take a personal pride in the mortuary report of the company which they represent. Exactly how this should be done is a difficult question to answer. At least two companies, to our certain knowledge, have for more than two years spared no pains to cultivate friendly relations between the examiners and the home-office. The medical directors of these companies have availed themselves of every opportunity for becoming personally acquainted with the examiners. Efforts like these must go far toward solving the question of how to enlist the profession more earnestly in behalf of the life-companies.

ASSOCIATION OF LIFE-INSURANCE EXAMINERS FOR BOSTON AND VICINITY.

We give below the full text of the circular note issued by the "Association of Life-Insurance Examiners for Boston and Vicinity," to the Presidents and Directors of the companies doing business in that city.

We are glad to welcome any movement looking to a more uniform action on the part of the medical examiners for life-insurance companies. At present every company has its own peculiar notions and ways of conducting the medical part of their business. If the examiners of these companies would meet from time to time, as proposed by the Boston Association, and compare views on some of the important subjects which constantly come before them, good would undoubtedly result from their deliberations. We can see no reason, for instance, why the question of family history should not be estimated at a more uniform value in all the offices. If every medical director would carefully investigate the experience of his own company in this particular, and then, armed with these facts, meet his brother physicians of the Association for the purpose of discussing the question and comparing experiences, it is not improbable that a decision would be reached which would from that time forth govern all the companies. At present, the widest difference prevails among the different offices in regard to this particular question. It is a source, too, of great annoyance to the agents, who are constantly writing:—"How is it that your doctor rejects this application, while such and such a company's physician considers the man a first-class risk?"

The question of family history is not the only one; rheumatism, gout, fistula, spitting of blood, amputations, etc., might all be assigned a more uniform value by the intelligent discussions of an organization like that of the Boston examiners.

At first sight, it appears rather anomalous that a body of medical examiners should recommend to their respective companies "the acceptance of a moderate number of unexceptionable, rather than of a large number of doubtful risks," and yet the present tendency of many of the companies fully justifies these physicians in thus urging greater caution in the selection of lives.

The plan of notifying rejections would undoubtedly give greater security to the business of all the companies. It would also stimulate the examiner who first sees the applicant to use great caution, for fear that, at a subsequent examination by another physician the risk might be declined on just grounds. We are told, however, that there are legal objections to such a plan, and that the companies are not willing to officially sanction it. As the proposition was made purely for the good of the companies themselves, the withholding of their sanction must necessarily result in the abandonment of the plan, as of course the examiners would not assume the responsibility.

The request that there should be a uniform fee of five dollars for every examination in Boston and vicinity appears to us reasonable and just, and we trust it will meet with a favorable response from the companies that still continue to pay a smaller fee.

The subjoined is a copy of the circular recently issued by the Association:—

To the Presidents and Directors of Life Insurance Companies doing business in Boston and vicinity.

GENTLEMEN.—The undersigned, Medical Examiners of many of the Life Insurance Companies having home or branch offices in Boston, respectfully represent that they have recently united themselves into an organization, to be known as the "Association of Life Insurance Examiners for Boston and Vicinity."

The special objects contemplated in this movement embrace not only a full understanding of the duties and responsibilities of Medical Examiners, and in a

general way an assurance of mutual support and co-operation in the performance of those duties, but also the consideration of subjects important to the companies we individually represent, and to whose interests we feel ourselves pledged. We trust that the views which we express in this letter will meet with your approval, and that you will be induced to give us your co-operation.

We believe the examination of applicants for insurance to be a subject of the utmost importance; that the due performance of his duties in making such examinations should call forth the highest ability and the most conscientious action on the part of the Examiner; and that upon such performance of duty by the corps of Examiners depends the very life of a company. We are confident we subserve the best interests of the companies we represent in recommending a judicious selection of risks,—the acceptance of a moderate number of unexceptionable rather than of a large number of doubtful risks. To this end we ask that the companies will aid us by appointing none but men standing honorably in the profession, of undoubted ability and unimpeachable integrity.

From our knowledge of the fact that in some cases applications are presented to the home-offices by persons other than the general agents, and that examinations for such risks are occasionally made by irresponsible physicians, we beg respectfully to suggest that *all* applications made in Boston and vicinity be presented for approval to the Examiners at the general agencies; it being understood that all examinations, and all business relating to the medical department, shall be transacted through the regular Examiners of the companies, unless for manifest reasons to the contrary.

We request that the sanction of the companies be given to an arrangement by which Medical Examiners shall communicate to the members of the Association the names and causes of disability of rejected applicants. We ask this privilege in order that cases presenting obscure or latent symptoms may be brought clearly to the notice of the Examiners. It is well known to us that unscrupulous canvassers frequently attempt to pass applicants in one company, who have been, either virtually or actually, rejected in another, without stating such fact, and even denying it. Such persons apparently do not consider an applicant rejected until his papers have been passed upon by the home-office. It will readily be seen that a plan of notifying rejections, while it would not injure the company which has declined an applicant, will act reciprocally in his favor.

Several of the companies represented in Boston pay their Examiners salaries, or a uniform fee of five dollars for each examination. We respectfully request companies who do not follow either of these plans to take into consideration more ample remuneration of their Examiners for the time spent in the discharge of their duties. Many of the Examiners named below are expected to visit the offices of their companies at stated hours daily, and pass a certain portion of time there. The time thus devoted is usually the most important in the day to a physician; it often requires him to pass over a considerable distance from his home; it obliges him to give many hours at the office without any compensation whatever; and acts as a serious detriment to the transaction of his private business. In view of these considerations, we respectfully urge upon you either the payment of an annual salary, sufficient to compensate the medical officer for the time spent, or, where business does not warrant it, the uniform payment of five dollars for each examination made.

It is the hope of the undersigned that the suggestions thus made will meet with your approval. Without doubt other suggestions may present themselves, which will be of advantage to the companies, and we shall take the liberty of offering them to your notice from time to time.

Respectfully submitted by the undersigned, Medical Examiners of the companies named.

MISCELLANEOUS.

EXAMINATION OF APPLICANTS BY PHYSICIANS WHO DO NOT RESIDE IN THE SAME TOWN WITH THEM.

We have known of a few instances where an agent has succeeded in foisting an undesirable risk upon the company by having the applicant examined in a neighboring town, where little or nothing was known about his habits. To prevent this, as far as possible, the following order has recently been issued by one of the life-companies of this city:—

To our Agents: You are hereby notified that in the future we shall not accept the medical report of an examiner who does not reside in the same town with the applicant, or who has not been designated as the regular examiner for that town.

The knowledge possessed by a physician regarding the personal habits and general health of the individuals in his own town and vicinity is of great value to us. It is for this reason that we shall insist upon a strict adherence to the rule.

We are gratified to see by our exchanges, that Dr. Hough's able article on "Longevity and other Biostatic Peculiarities of the Jewish Race," (published in our number of May 15) has received from the Jewish newspapers the favorable criticism which it deserves. The "Hebrew Leader" republishes it entire in four consecutive numbers. We also notice its republication in the "Cincinnati Lancet and Observer."

TEMPERANCE AND INTEMPERANCE IN LIFE INSURANCE.

An English Life-Company, that issues life-policies to those who restrict themselves to the use of beverages not more ardent than tea or coffee, has published the re-

sult of its experience during the last year. We are not aware of a life-company in this country that has such a high opinion of severe temperance in drinks as to offer a premium for its practice; but perhaps the result of the experiment, as referred to in the following article extracted from the London *Commercial World*, may direct the attention of our companies to the subject:

"The Temperance and General Provident Institution has attained some distinction in one particular—it has added in a single year £125,528 to its assurance fund. The experience of the two sections, as brought out in the directors' report recently issued, shows very similar results to those which have appeared in former years, namely, that in the Temperance section, where the assurants practise abstinence from alcoholic liquors, the mortality is considerably below the expectancy, while in the General section it is above the expectancy.

"In the absence of precise information we are left to conjecture, to adopt a medical phrase, the predisposing and active causes of this divergence. That there are specific causes in operation, adequate to produce these different results, can admit of no question. What we require to discover is what those causes really are, and in what degree their philosophy—using the word in the sense of the reason of things—can be traced with anything like certainty. A mind of the right sort, dealing with the data open to the knowledge of the officials of the office, could, no doubt, construct a reliable theory of the causes actually at work. But hitherto, neither by Mr. Brown, the actuary, nor by any other person, so far as we are aware, has any such attempt been made. Year after year we have the same bare-bone facts submitted. In the present report we find it stated:—

"'The actuary, Mr. Samuel Brown, reports the mortality of whole-life policies to have been as follows, viz., expected claims in the Temperance section, 137 for £27,058; actual claims, 90 for £13,005. In the General section, 241 claims for £48,883 were expected; the actual have been 282 for £50,575.'

"It is observable that the business of the General section of the office is very much larger than the business of the Temperance section. That fact, however, standing alone, supplies no adequate clue to the discovery of the real reasons for the wide divergence in the mortality of the two sections. We want to have an actuarial and philosophical answer to the query, 'What are the probable reasons of this palpable difference in the mortality of two sections of the business?' We should like to know if, in a comparison of equal numbers, the ages of the assurants in both sections are the same, and, also, if the occupations are the same, or similar, and, if not, in what respects they differ. Are the differences favorable to the Temperance section, or against it?

"We submit these points to Mr. Brown, and invite him, as a matter in which the community is deeply interested, to give us the best answer which his science and philosophy can supply.'—*Ins. & Real Est. Jour.*

MORTALITY OF INSURED FEMALE LIVES.

An actuary of this city informs us that, according to all the tables not based upon the experience of life-insurance companies, female lives are unquestionably the best, except perhaps in the ages over 65; but that in the best-ascertained and most voluminous table, based upon the risks taken by companies, the female risks between the ages of 15 and 49 are the worst. (See H^m and H^f, New Actuaries, 1869, page 26, based on 16,604 female lives.) The following is the table referred to:—

H^m and H^f—Mortality per cent. of Male and Female Lives compared.

Ages.	Male. (1)	Female. (2)	Difference.
15 to 19	.47	.86	— .39
20 to 24	.69	.85	— .16
25 to 29	.69	1.18	— .49
30 to 34	.82	1.13	— .31
35 to 39	.95	1.21	— .26
40 to 44	1.07	1.28	— .21
45 to 49	1.36	1.39	— .03
50 to 54	1.74	1.57	+ .17
55 to 59	2.40	2.02	+ .38
60 to 64	3.48	2.86	+ .62
65 to 69	5.02	4.37	+ .65
70 to 74	7.33	6.84	+ .49
75 to 79	11.00	10.66	+ .34
80 to 84	16.52	12.51	+ 4.01
85 to 89	22.35	22.82	— .47
90 to 94	32.73	22.68	+10.05
95 to 99	54.55	33.33	+21.22

It will be noticed in this table that the excess of deaths among the female lives occurs between puberty and the menopause, and that it reaches its highest point between the ages of 25 and 30. This circumstance would suggest the idea that this higher mortality during this particular period of life is probably attributable to parturition, or to diseases of the female organs of generation. We have never seen a tabulated statement showing the actual experience of our companies in this particular, and so cannot say whether the facts corroborate this idea or point to other diseases as the cause.

IMPORTANCE OF VACCINATION.

Dr. Robert Grieve, in a paper recently read before the Epidemological Society of London, thus sums up the results derived from an experience of 6221 small-pox patients admitted to the Hampstead Hospital:—

"Of 6,221 patients admitted, 1,248 were without marks of vaccination, and of these 638, or 51.12 per cent., died; whilst among the 4,973 who showed proofs of being vaccinated, in only 567 instances did the disease prove fatal, giving a percentage of mortality of 11.40. From these numbers it is seen that, although the number of patients received into the hospital of the vaccinated class exceeded the number in the unvaccinated—a fact of which the anti-vaccination league has made vigorous use—the larger number of deaths occurred amongst the unvaccinated.

"In the 3,555 cases in which the number of marks was noted, it is found that the percentage of mortality in those showing one mark is 17.39, showing two 12.17, showing three 10.58, showing four 8.38, showing five and more 6.43—a scale in which the mortality is in inverse ratio to the number of marks seen. The practical deduction to be made from these numbers is, that the larger the number of places in which we vaccinate, the more protection is given. To obtain even a fair average of protection, at least three marks are required, but something is gained by exceeding that number."

In the blank-forms of most of the insurance companies the question of vaccination reads thus: "Have you ever been vaccinated?" In a few instances it reads:—"Have you been successfully vaccinated, and when last?"

The ideal insurance company of the future will probably have the question printed in these words: "How many vaccination marks have you on your body?"

Original Communications.

ACUTE URÆMIA.

By ALFRED L. LOOMIS, M.D.,

PROFESSOR OF INSTITUTES AND PRACTICE OF MEDICINE, MED. DEPT. UNIVERSITY OF THE CITY OF NEW YORK.

(Read before the New York Academy of Medicine.)

MR. PRESIDENT, at your request, and in compliance with your suggestion, I will, this evening, make a few remarks on the history and treatment of *Acute Uræmia*.

Under this term may be grouped two classes of symptoms, which differ in their mode of development and in their attendant phenomena.

In the one, nausea, vomiting, and headache usher in twitchings and epileptiform convulsions of the voluntary muscles, a state which has received the name of uræmic convulsions.

In the other, headache and drowsiness, or convulsions usher in a state of insensibility, which has received the name of uræmic coma.

The primary cause of both these conditions is always to be found in a failure of the kidneys to perform their normal function of elimination, and the consequent accumulation in the circulation of some or all of the poisonous elements of the urine. This condition may occur in the course of any disease in which suppression of the renal secretion takes place. Such arrest of the function of the kidneys most frequently occurs in scarlatina, in the different forms and stages of Bright's disease, in the puerperal state, and in connection with the surgery of the urethra.

Whatever the poisonous agent may be, it unquestionably acts directly upon the cerebro-spinal centres. In its action, it does not seem so much to directly excite convulsions or coma, as to increase the irritability of the nervous system, and the consequent liability to convulsions from causes which, under other circumstances, would produce no noticeable disturbance.

A number of theories have been advanced in regard to the exact element which acts as the poisonous agent.

The earliest accepted view is that which attributes the symptoms of uræmia to retained urea. This view, originally proposed by Willis, has been ably sustained by the experiments of Drs. Richardson and Hammond; and although at different times it has been discarded and apparently disproved by the experiments of distinguished observers, to-day it is the accepted view of most authorities.

Some years since, Frerichs made the statement that urea as urea is innocuous, and advanced the theory that the poisonous agent was carbonate of ammonia resulting from the decomposition in the blood of urea into carbonate of ammonia and water, which decomposition he ascribed to the action of a ferment in the blood. This theory has been entirely overthrown by other experimenters.

Still more recently, Traube has advanced a hypothesis which has attracted much attention (Stewart). "He points out that, as in Bright's disease, the blood serum being in an impoverished state, tends to transude, and in consequence of hypertrophy of the heart, the blood-pressure in the arterial system is increased; so when from any cause this blood-pressure is suddenly increased, or the density of the blood-serum is further diminished, serous fluid transudes through the small arteries, and œdema of the brain results. The result of this is, that the capillaries and veins are compressed, and the brain becomes correspondingly anæmic. The form of the uræmic attack varies according to the part of the brain which is so affected. If the cerebrum alone is involved, coma appears; if the pons varolii and medulla oblongata alone, convulsions; if both together be affected, the result is combination of coma with convulsions. This hypothesis is certainly well worthy of being carefully investigated, for the condition of the brain met with in fatal cases of uræmia often accords with it, at least in the chronic cases in which death occurs from uræmia. But I have some difficulty in accepting it as explaining uræmia in acute cases. It is to be remembered that its author does not claim for it any position higher than a mere hypothesis."

The experiments of Oppler and others go to show that urea is formed by the kidneys from the nitrogenous materials in the blood, and that the uræmic manifestation depends mainly upon the accumulation in the blood of creatin and creatinin. Oppler also found that there is a retention of muscle-waste in cases of uræmia, and conceived that there may be a similar retention of the products of nerve-waste; and to the deleterious influence of this substance he would ascribe the symptoms.

Dr. Grainger Stewart makes the statement that some forms of uræmia *may* be associated with structural changes in the brain, similar to those which occur in the retina in cases of neuro-retinitis.

The experiments and facts upon which these different theories are based lead to the following conclusions:—

1st. That uræmic toxæmia, acute and chronic, depends on a complete or partial arrest of the urinary secretion.

2d. A qualitative analysis of the constituents of the urine goes to show that urea is its only positive poisonous ingredient, and "that *it* is not the special product of any one particular tissue or organ, but the united product of all nitrogenized effete matter."

3d. Numerous experiments show that urea, when introduced into the blood of animals, acts as a narcotic poison, producing phenomena identical with those of uræmia.

4th. That urea is not decomposed into carbonate of ammonia and water in the blood, but that such decomposition may take place outside the blood-vessels in the bladder, pelvis of the kidney, and intestines; and if the products of the decomposition are retained in these cavities any length of time, they give rise to a condition of ammonæmia, which in many of its features resembles uræmia.

While, therefore, the question as to the exact poisonous agent in uræmia is still unsettled, it seems to me that the facts relative to urea warrant the assumption that urea is an irritant poison, and when in excess in the circulation acts primarily upon the cerebro-spinal centres, and through them interferes more or less with the functions of organic life,—and that œdema of the brain and other structural changes which occur in the course of uræmia are the results of the action of this poison.

An acute uræmic attack is usually preceded by certain premonitory signs, such as œdema in various parts of the body, restlessness, or an almost irresistible desire to sleep, vertigo, headache, delirium, nausea, vomiting, and impaired vision; the countenance has a pale, waxy or dingy appearance; the urine is scanty, high colored, bloody, albuminous, and contains casts. After the appearance of the premonitory symptoms the progress of the mischief will vary in different cases

according to the amount and cause of the retention of the urea.

Thus, if a large amount of urea is suddenly thrown into the circulation and retained by a continuance of the arrested elimination, or increased by a continuance of the producing cause, the body and extremities become violently convulsed, or the patient passes rapidly into a state of coma.

The convulsion may consist of a single paroxysm, or a succession of paroxysms may follow one another at intervals of a few minutes or several hours, the patient lying during the interval in a state of more or less profound insensibility. During the convulsion, the face becomes livid, eyes glassy, the pupils contracted or dilated. At the commencement of the convulsive attack they are generally contracted; frothy mucus, which is sometimes bloody, collects around the mouth, and there is a strong urinous odor emanating from the perspiration. The pulse is accelerated, and the temperature is raised in some instances as high as 107°.

Uræmic coma may come on gradually, twenty-four or forty-eight hours elapsing before the stupor is complete, or the patient may fall suddenly into a state of profound coma, its advent resembling an attack of cerebral apoplexy. There are periods when the coma is so profound that nothing arouses the patient; at other times he is easily aroused, or arouses himself, and attempts to speak and to sit up, swallowing fluids with little difficulty.

When urea is gradually introduced into the circulation, or is freely eliminated, as in cases where renal disease is slowly developed, the system becomes accustomed to the presence of the poison, and thus a considerable excess of urea may exist in the blood for a long period without giving rise to any but the premonitory symptoms of acute uræmia; but when once the balance is destroyed and a certain excess of urea in the blood is reached, the kidneys become embarrassed by the excessive demand made upon their excreting power, and rapid and intense renal congestion follows, the nerve-centres are overwhelmed and either convulsions and coma, or both, follow, and thus acute uræmia may be developed in the chronic as well as in the acute stage of renal disease.

Uræmic coma is always accompanied by a certain amount of stertor; the respirations are accelerated at first, but they soon become slow and labored. The pupils are dilated, but they are not irregular; the pulse is more rapid than natural and lacks firmness. The temperature at first is raised, but after a time falls below the normal standard. Acute uræmia simulates in some particulars so many diseases in which convulsions and coma are the leading symptoms, that it is difficult to give directions which shall enable one to always separate it from analogous disorders. I will name a few of the more prominent points in its differential diagnosis.

The phenomena of an epileptic seizure are almost identical with those of uræmia, and in some instances the task of distinguishing the one from the other would be exceedingly difficult unless the previous history was admitted.

If the patient's history is known, the chronic character of the epilepsy is sufficient to distinguish it from acute uræmia, and an examination of the urine positively determines the uræmic character of a convulsion. At the time of the paroxysm a distinction may also be drawn, for in epilepsy one side is convulsed more violently than the other, while in uræmia both sides of the body are equally affected by the convulsive movements. In epilepsy, although there is loss of consciousness, reflex sensibility continues from the beginning to the end of the paroxysm, which is not the case in uræmia. Immediately following uræmic paroxysms there is deep coma; following an epileptic seizure there is merely a deep sleep, from which the patient may be aroused.

In cerebral apoplexy, coma always precedes convulsions, and with the convulsions there is facial paralysis and hemiplegia; there is also clonic spasm of the paralyzed parts, and the urinary symptoms of uræmia are absent. In hysterical convulsions the patient falls into a convulsive, tetanic or cataleptic condition, with a scream. Close inspection shows that the patient is not unconscious, and the pupils are normal, as are also the pulse and temperature. The limbs are jerked irregularly,—the breathing is jerking and spasmodic, and is attended with a choking sensation. There is no lividity of the face or distention of the cervical blood-vessels, and the close of the paroxysm is usually accompanied by the discharge of a large quantity of pale urine.

Cholemic convulsions, or those that occur when the blood is overcharged with the constituents of the bile, in their phenomena very closely resemble uræmia, but may be distinguished from them by the jaundice which precedes or accompanies their development, and by the antecedent history of acute hepatic affections. Convulsions originating in meningitis and other cerebral affections are distinguished by the accompanying characteristic symptoms of these affections.

The main points in the differential diagnosis of uræmic coma are identical with those of uræmic convulsions. It may be distinguished from the coma of apoplexy by the absence of paralysis, from opium-poisoning by the rise in temperature (the temperature in uræmic coma being generally above 100°, while in the coma from opium it is below the normal). The slow and peculiar character of the respiration in opium-coma also distinguishes it from uræmia.

The condition of the pupils is not a safe guide, for not unfrequently in uræmia they are as contracted as in opium-poisoning.

It is distinguished from epileptic coma by the antecedent history, and from rum-coma by the alcoholic surroundings of alcoholismus.

In all cases of coma, an examination of the urine is necessary to complete the diagnosis.

Causes of Death in Acute Uræmia.—Apparently the primary cause of death in uræmia is the accumulation of urea in the circulation, which acts as a true narcotic poison, resembling in its *modus operandi* other narcotics, of which belladonna and opium are the best types. When introduced in so small quantities that its elimination can be accomplished in a short time, it produces a moderate sleep; but when the quantity is sufficiently large to overtax the eliminating powers, it causes death by arresting oxidization.

Dr. Watson remarks, that whatever may be the nature of the unknown and perhaps fugitive condition of the nervous centres in uræmia, which is capable of arresting or abolishing their function, it is important to keep in mind a distinct and clear conception of the fact that there must be some such physical condition.

Dr. Richardson claims that there is first a direct toxical effect of the urea, acting by depression on the muscular and nervous system, and that in acute uræmia, as a result, the blood undergoes physical modifications which render it incapable of supporting the changes which constitute natural life. These modified states of the blood, consisting of increase of water, diminution of red corpuscles, modifications in the physical construction of the remaining cells, and accu-

mulation in the mass of blood of a true toxic agent, tend to render that fluid incapable of undergoing normal chemical reconstruction in the pulmonic current. Such blood is incapable of combining with the oxygen of the air; the arterial blood consequently loses its active colorific life-sustaining properties, and the final result is secured by what may be most properly designated apnœa commencing in the circulation.

Dr. Moreland states that acute uræmia, marked by the occurrence of convulsions and coma, leaves the brain anæmic in appearance and probably somewhat softened.

From the many facts, experiments, and statements made by competent observers, as well as by the clinical history of uræmia, it is evident that the primary cause of death is a narcotic poison, the exact nature and action of which we do not understand; that the primary action of this poison is on the nerve-centres, producing certain changes in the blood, which interfere with or arrest oxygenation; and this is followed by certain structural changes taking place in the different tissues of the body, which make up the post-mortem history of the disease.

I have now come to the special object of this paper, viz.: to the consideration of the treatment of acute uræmia.

I shall first give a brief synopsis of the most prominent views of the present day—the views of standard authorities. All agree in this, that in the treatment of acute uræmia, to secure as rapidly as possible a free eliminative action either by the skin or bowels, or by both, or by the kidneys, is of the first importance.

Frierich is the only authority that proposes to neutralize the uræmic poison, which, he claims, is ammonia. To accomplish this he directs the inhalation of chlorine gas, or the internal administration of the vegetable acids.

With most authorities the favorite method is diaphoresis, accomplished by vapor or hot air. It is claimed that by a vicarious action of the skin, the excrementitious products which normally fall to the lot of the kidneys to excrete are removed from the system in the cutaneous perspiration.

In connection with the process of elimination, a vicarious action of the bowels is induced by the internal administration of drastic purgatives: elaterium and scammony are the favorites to accomplish this hydragogue catharsis; and it is also claimed that by this method the alimentary canal eliminates the products which should normally find their way out of the body by the urine.

The testimony of authors on the utility of diuretics in the treatment of acute uræmia is conflicting.

Dr. Roberts says that his experience has not given him a high opinion of their efficacy.

Dr. Harley says that it ought never to be forgotten, that in acute Bright's disease, as well as in the first stage of all inflammatory and congestive attacks occurring in the course of chronic kidney affections, diuretics are inadmissible; and he adds, that the reason why the employment of diuretics often does harm in acute kidney affections is readily understood when we recollect that they have always the tendency rather to increase than diminish the flow of blood to the already inflamed organs.

Dr. Geo. M. Johnston states that with our present knowledge of renal pathology, it is clear that the practice of giving diuretics in acute nephritis is most unjustifiable.

Dr. Richardson says that one of the greatest errors common to the inexperienced is to give diuretics to a badly-working kidney,—an error as unphilosophical as it is unpardonable, for the cessation of the secreting function of the kidney indicates a tendency to congestion of the renal organs. To relieve renal congestion, not the kidneys, but some other emunctory channels, must be freely opened, and the kidneys left to do as little labor as possible.

On the other hand, *Niemeyer* maintains that, whatever theoretical objection against the employment of diuretics there may be, in desperate cases recourse should always be had to them.

Dr. Stewart recommends diuretics in the acute stage of the inflammatory form of Bright's disease to remove the effete material from the uriniferous tubes.

The ground on which diuretics are objected to is, that it is contrary to the principles of medicine to stimulate an inflamed part,—that the first step towards the healing of an inflamed organ is rest.

Admitting that this view is sound, we have a class of diuretics that do not in any sense act as stimulants to the kidney. Digitalis ranks first in this list; although a very efficient diuretic, it never seems to irritate the kidneys. The *modus operandi* of this remedy is now well settled (Stewart). By increasing the power of the heart's action, and perhaps, also, contracting the capillaries, it materially increases the blood-pressure. As the normal secretion of urine depends upon that pressure being in the healthy state unopposed by any obstruction, and the diminished flow in this disease is due to obstruction within the tubules, the digitalis appears to supply such an increase of pressure as overcomes the obstruction, and, indeed, carries it away by the force of the current it originates.

Accepting this view of the diuretic action of digitalis, its administration is especially indicated in acute uræmia. To obtain its effects in the condition of the kidneys that attends acute uræmia, I am convinced that much larger doses are required than usually are administered. My rule of practice in these cases is to give ½ an ounce of the infusion of the English leaves every three hours for twenty-four hours—or at least until I produce the specific effect of the drug—and I do not remember in a single instance to have met with the overwhelming accumulative effects of digitalis of which so many writers warn us.

The experience of every one, I think, will sustain me in the statement that when acute uræmia is fully developed, and the patient is in convulsions or coma, that often (in the majority of cases) the skin and the bowels, as well as the kidneys, lose their excretory action, diaphoresis cannot be induced, or if induced is not eliminative, and the bowels do not respond to purgatives, although the patient may swallow them in large doses.

Under these circumstances, Dr. Richardson says that he is "convinced that in cases of acute uræmia there is one, and only one, remedy to be adopted; that remedy is none other than the free abstraction of blood."

On physiological grounds venesection, in extreme examples of uræmia, comes forward as a natural and effective remedy; for, as there is a soluble poison in the blood, we secure in blood-letting the readiest means by which to remove the poison directly. He adds, there is yet another advantage in blood-letting; by it we relieve congestion of the visceral organs, and specially of the kidneys,—hence it usually obtains that after a removal of blood, secretion takes place readily, and a response is offered to diaphoretic and purgative remedies which did not before present itself.

Dr. Harley (in his recent work on the urine and its

derangements) makes the statement that in some cases of acute uræmia, especially in uræmic eclampsia, venesection may sometimes be had recourse to with great advantage, but its indiscriminate use he regards as highly unphilosophical with our present knowledge of uræmic convulsions.

Dr. Bamn, in his monograph on uræmic eclampsia, states that since the days of Dewées, Burns, and Hamilton, it has been and still is the custom to find the only power against uræmic eclampsia in abundant general blood-letting often repeated—a proceeding which he believes can be justified as little by the present state of our theoretical knowledge in regard to this disease, as it is by the mortality which follows its employment.

By bleeding the hydræmia is increased, as well as the danger of puerperal thrombosis and pyæmia, and not unfrequently the paroxysms are aggravated. A very strong argument against venesection in acute uræmia is the fact that, after extensive trial by the profession, the practice has fallen into disuse.

The question then comes to us, if overwhelming the system by the uræmic poison (marked by convulsions and coma) shuts off for a time all avenues of elimination, what means have we to counteract the effects of this poison and open again the avenues of its elimination, or, at least, to hold the patient until the normal eliminating process shall be re-established?

Our first efforts must be directed to diminish reflex sensibility, and subdue spasmodic muscular paroxysms, for these, if continued, either will directly terminate life or end in an equally fatal insensibility.

The remedy which for some years has been employed for the accomplishment of this object is chloroform. It has been extensively used, and is, I believe, regarded as the readiest and safest means for controlling uræmic convulsions.

Dr. Bamn says, in regard to it, that chloroform narcotism should be induced instantly when indications of an impending paroxysm show themselves, but that the administration of chloroform must not be kept up during the convulsive attack or the state of coma.

Dr. Roberts says that during the convulsive paroxysm chloroform inhalation is the most prompt and ready means of controlling the spasm; when, however, uræmic paroxysms begin with drowsiness and gradually pass on to insensibility, or when convulsions occur as breaks in a continuously comatose condition, chloroform affords no prospect of relief.

Dr. Harley, although he recommends some form of anæsthetic in uræmic eclampsia, makes the statement that if medical men were more intimately acquainted with the powerful chemical changes which chloroform exerts on the constituents of the blood, even when taken into the system by the lungs, they would probably employ it with more reserve than at present they do.

Sir James Simpson says that although the direct action of chloroform upon uræmia is doubtful, yet it is certain that in eclampsia chloroform is the best palliative, inasmuch as it moderates the paroxysms.

Although many authorities recommend the use of chloroform in uræmic eclampsia, few make mention of its employment in acute uræmia independent of the puerperal state. Its only known clinical effect is to control muscular spasm, and in a large proportion of cases it fails to give more than temporary relief to those patients who pass from one convulsion to another into a state of complete coma, and die without any apparent neutralizing or eliminating effect from the chloroform.

In the few cases in which I have administered chloroform in non-puerperal uræmic convulsions, it has seemed to me to have no other effect than to arrest convulsive movements by rapidly hastening my patient into a state of insensibility. In no instance have I known its administration to be immediately followed by diaphoresis, or a return of the urinary secretion; and it has seemed to me to be more difficult to establish diaphoresis or diuresis by diaphoretics or diuretics in patients with uræmia to whom chloroform had been administered, than in those who had not taken it. I believe, therefore, that while it temporarily controls muscular spasm, it prejudices the chances of ultimate recovery, by the changes its inhalation produces in the blood, which changes increase rather than retard the uræmic toxæmia.

With these impressions, one naturally seeks an agent that not only has power to control muscular spasm, but at the same time by its action shall tend to reopen the avenues of elimination, either by counteracting the effects of the uræmic poison on the nerve-centres, and thus facilitate the action of diuretics and diaphoretics, or itself act directly as an eliminator.

I believe morphine administered hypodermically to be such an agent.

This brings me to the question which has led me to this discussion this evening, viz.:

1. Can morphine, in full doses, be hypodermically administered to patients in acute uræmia without danger?

2. What are the effects which follow such administration?

If we turn to acknowledged authorities for an answer to the first of these inquiries, we find that nearly all make mention of opium only to warn us of the danger attending its administration. I will quote from a few of them. Dr. Harley states "that although Dover's powder may be given with impunity, opium can seldom be employed in kidney affections in any other form without a certain amount of risk. More than one example of its deleterious effects in such cases has come under my notice. In cases where there is a tendency to convulsion, even Dover's powder must be cautiously used."

Dr. Geo. Johnston states that Dover's powder may be given in Bright's disease, "when the bowels are freely open, the urine not scanty, and there is no headache or drowsiness. In other cases, opium, in any form, would probably be injurious, on account of its tendency to check secretion and aggravate the symptoms of cerebral oppression. . . . In no circumstances is an opiate so likely to produce dangerous and unmanageable stupor, as when its influence is added to that of urea in the blood."

Dr. Geo. T. Elliot, in a paper on albuminuria in pregnancy, states that in uræmic eclampsia he has always used narcotics very sparingly,—codea and McMunn's Elixir of Opium being his choice. He had resorted to a hypodermic injection of morphine.

Dr. Alonso Clark in the most positive terms warns against the use of opium in uræmia.

Dr. Austin Flint, in his Practice of Medicine, states that opium should be given with circumspection, and adds that observation has shown that in moderate doses it is liable to produce marked and even fatal narcotism if the blood is surcharged with urea. In the same connection he alludes to the case of an opium-eater with Bright's disease who took a bottle of McMunn's Elixir daily, without any apparent ill effect.

It is hardly necessary to multiply quotations to show that the profession has almost unanimously lifted its voice in warning against the use of opium either in acute or chronic uræmia.

During the first years of my professional life, I regarded opium as one of the most dangerous remedial agents that could be administered to uræmic patients, rarely daring to give more than five grains of Dover's powder to a patient with albuminous urine, and if convulsions and fatal coma happened to follow such administration, more than once do I remember to have felt that a Dover's powder which I had administered might have been the cause of the fatal coma.

I will now read from the recorded histories of a number of cases of acute uræmia, which it seems to me go to show that the dangers attending the administration of opium in acute uræmia have been overrated.

These histories will also, I believe, enable us to judge to some extent of the effects of morphine administered hypodermically to patients suffering with uræmic intoxication. I shall detain you with only so much of these histories as bear upon the two questions before us.

Case I.—In the early part of March, 1868, a gentleman, 58 years of age, who for two or three years had known from his physician that he had Bright's disease of the kidneys, came under my care in a condition of general anasarca, suffering almost constantly with headache, inability to sleep, and a restlessness which compelled his attendants to be constantly moving him from one position to another.

On examination I found cardiac hypertrophy, slight pulmonary œdema, general anasarca, albuminous urine of low specific gravity, which contained finely granular and hyaline casts. The quantity of urine passed on the first day of my attendance was 44 ozs. He suffered somewhat from dyspnœa, but it was not extreme. On the third day of my attendance, his urine became markedly diminished in quantity,—his headache, restlessness and dyspnœa were greatly increased, muscular twitchings were present, his pulse became accelerated and irritable in character, beating 120 in a minute, his surface dry and hot (the temperature was not taken). Fearing convulsions, I had dry cups applied over his kidneys and plied him with diaphoretics and hydragogue cathartics without any apparent relief. Death becoming imminent, I asked Dr. Metcalf to see him with me. At Dr. Metcalf's suggestion, and under his direction, I administered to him my first hypodermic injection of morphine to a patient with uræmia, expecting to see its administration followed by a fatal coma. To my astonishment my patient soon after its administration passed into a quiet sleep, from which he was easily aroused, during which he perspired freely. On the following day he reported himself as greatly relieved; his urinary secretion was re-established, and he was able to take and retain large quantities of milk. For six weeks I administered daily to this patient from 20 to 30 drops of Mag. sol. morphine hypodermically, with ½ oz. of infusion of digitalis twice a day. During this time, not only was he relieved of most of his distressing symptoms, but his improvement was so decided that he was able to walk about his rooms and go out to ride. In about two months he went into the country, and I only heard from him occasionally. His dropsy entirely disappeared. Whether the plan of treatment mentioned was continued or not I do not know. He died the following August, so far as I could learn, in a state of collapse following an attack of what seemed to be cholera morbus. This case taught me that in some cases of Bright's disease with marked uræmic symptoms morphine could be administered hypodermically not only with safety, but with apparent advantage. Since that time I have occasionally used hypodermics of morphine in the treatment of patients with Bright's disease, especially when the premonitory symptoms of acute uræmia were present, as well as during the active manifestations of uræmic intoxication, and, so far as I am able to judge, its administration has been uniformly followed by good results. In no instance am I aware that I have caused a fatal narcotism.

The following history shows the effects of a hypodermic of morphine in uræmic intoxication, coming on during the acute stage of parenchymatous nephritis:—

Case II.—J. B., a young man, 23 years of age, of temperate habits, free from hereditary or acquired tendency to disease, early in February, 1869, came under my care with acute Bright's disease. Three week previous he had been thoroughly chilled after an exposure of two or three hours on one of the docks on a damp, chilly day.

From that time he did not feel well, suffered more or less from headache, loss of appetite and nausea. Ten days before I first saw him, he had noticed his face swollen on rising; at the same time he noticed that his urine was scanty and darker than usual. He had sent for me to relieve the pain in his head, which he described as terrible.

On examination I found his feet and legs, as well as his face, slightly œdematous; his pulse was 110, and irritable in character; skin hot and dry. He said that he had passed no urine since the previous night, but at my request voided about four ounces of smoky-looking urine which was highly albuminous; it was not examined microscopically. I ordered him to be dry-cupped over the lumbar region, a hot-air bath, and a large saline cathartic.

When I next visited him, twenty-four hours after, all his previous symptoms were aggravated. The œdema was increased; he had passed little urine, none for ten or twelve hours, and his bladder was empty; pulse 120, headache still severe, vision imperfect, was restless and at times delirious; dyspnœa not severe.

As the hot-air bath had produced very little diaphoresis, and his bowels had not moved, I ordered him one grain of elaterium, to be followed by an enema in four hours, and half an ounce of the infusion of digitalis every two hours.

At four o'clock the next morning, six hours after, I was summoned to him with the statement that he was in a convulsion. When I reached him he was semi-comatose; his friends said his convulsion lasted twenty minutes. His bowels had not been moved. I immediately administered a large enema of spirits of turpentine and oil, which was soon returned without any fæcal discharge. His muscles began to twitch, he became restless, his skin was dry and hot; pulse 130 and small. Fearing another convulsion, I administered hypodermically fifteen drops Mag. sol. morphine. Gradually the muscular twitchings ceased, he became quiet, and passed into a heavy sleep. I remained with him. In about two hours after the administration of the hypodermic, his surface was covered with a profuse perspiration, and his breathing became more natural. He could be aroused, and would swallow when fluid was placed in his mouth; four hours after with a catheter I drew off five or six ounces of highly albuminous urine, which contained blood and granular casts. Six hours after, I commenced the administration of the infusion of digitalis, a tablespoonful every two hours; he was sleeping quietly, perspiring freely, could be easily aroused. I then left him.

At my next visit, ten hours after the administration of the hypodermic, I found him sleeping,—skin moist

pulse 100, could be easily aroused and drank freely of milk. At my request he passed six or eight ounces of urine; his bowels had moved freely twice.

From this time, under the daily administration of digitalis and mur. tinct. ferri, and a milk diet, he went on to complete convalescence.

This was a somewhat rare case of acute parenchymatous nephritis occurring independent of any known blood-poison.

It shows in a striking manner how difficult it is to get the action of diaphoretics, diuretics, and cathartics, when the symptoms of acute uræmia are present in such cases, as well as their failure to prevent the occurrence of convulsions. The administration of a full dose of morphine, at apparently the most unpromising period in the history of the case, not only seemed to prevent an impending convulsion, but aided in the establishment of a saving diaphoresis and diuresis.

The two following histories have been furnished me by Dr. H. B. Millikin, late House-Physician to Bellevue Hospital.

Case III.—J. C., a German dyer, 70 years of age, was admitted into Bellevue Hospital, April 22d, at 6 P.M.

He was brought to the hospital in a state of uræmic coma. Body of large size, well nourished, surface cold and cyanotic. Extremities and thoracic walls œdematous. Head rolled back, mouth open, tongue dry and brown. Pupils dilated, not responding to light. Respiration 14, irregular and stertorious; breath cold. Pulse 96, and hardly perceptible; temperature 95°. Muscular tremors marked in the arms and hands. Catheter was introduced into the bladder, and about an ounce of urine drawn off, dark colored and smoky, highly albuminous, no casts. Lungs resonant and respiration feeble. Heart enlarged and sounds feeble. Abdomen tympanitic. Injected ten minims of Mag. sol. morphine hypodermically, and wrapped the patient in blankets. In one hour the surface became warm, the patient began to perspire freely, cyanosis disappeared, breathing became more regular and less stertorous. Pulse 100, and stronger; is sleeping quietly; swallows water when placed in his mouth. Ordered an enema, and left him for the night.

The next morning, at 9 o'clock, found him much improved. He slept all night and perspired freely. Pulse 80; temperature 97°; respiration 21; expiration somewhat stertorious. Has voided about four ounces of highly albuminous urine, specific gravity 1016. No casts. Ordered ½ oz. of infus. digitalis, with 20 grains of bi. tart. pot. every two hours. The next morning, April 24th, condition still improved, is easily aroused, and answers questions. Pulse 84, and stronger; respiration 18, and quiet; temperature 97½°. Has voided 3 pints of urine within past twelve hours, containing a trace of albumen, large granular and hyaline casts, and renal epithelium filled with fatty matter. From this time patient daily improved, and was discharged from hospital May 14th, 1871.

In this case the morphine was administered while the patient was in a state of complete coma. Instead of deepening the coma, in one hour after its administration diaphoresis was established and the uræmic symtoms began to abate; within twelve hours the urinary secretion was fully re-established and convalescence had fully commenced.

Case IV.—C. M., a barber, 21 years of age, was admitted to Bellevue Hospital at 4 P.M., April 24th, 1871.

He was brought to the hospital by his uncle, from whom I obtained his antecedent history. The uncle stated that the patient's father and mother had died of Bright's disease; that he had been given to excesses of various kinds, but especially to the use of intoxicating drinks, but had enjoyed good health until about two months previous to his admission into the hospital, when he began to grow pale and feeble, lost all desire for food, suffered from dyspnœa on active exercise, and complained continually of frontal headache and severe lumbar pains. On rising in the morning he experienced mild attacks of vertigo, dimness of vision, nausea and vomiting, often rejecting his morning meal. His bowels had been obstinately constipated, several days often elapsing without any evacuation. One month previous, he first noticed swelling of his face, especially about the eyes, which he said was most marked in the morning after rising. He had spoken to his uncle of the diminished quantity of urine passed, which fact seemed to cause him anxiety and alarm. The day previous he had several convulsions, which he came out of slowly, and remained in a semi-comatose state until about two hours before his admission into the hospital, when the convulsions again recurred. He had passed no urine for twenty-four hours.

Condition on admission.—Patient is of medium stature, and somewhat emaciated, surface pale, hot and dry. Countenance markedly cachectic. Face swollen and œdematous, the œdema also invading the thoracic and abdominal walls and slightly marked over the surface of both tibias. He moves restlessly in bed, rolls the head from side to side on the pillow and throws his arms wildly about. Any effort made to restrain him aggravates his nervous state, when he gives some evidence of returning consciousness. Both pupils are dilated, responding slowly to light. Conjunctivæ pale and anæmic. Pulse 100 and irregular; temperature 100¼°. He cannot be aroused so as to answer questions.

Physical examination of chest and abdomen.—Percussion negative. Auscultation furnishes a few sonorous râles over both lungs posteriorly. Heart's action tumultuous with loss of rhythm. Apex beat felt in sixth intercostal space, and to the left of the nipple. No murmur could be heard. Abdomen depressed and moderately tympanitic. Liver and spleen of normal size. An elastic catheter was then passed and one ounce of high-colored urine drawn off; when examined it was found to be gelatinous with albumen (specific gravity not taken), but furnished no tube-casts or renal débris under the microscope. His restlessness still continuing, I injected ten minims of Mag. sol. of morphia into his right arm, and had him wrapped up warmly. I remained with him one hour, when he passed into a quiet sleep, and I left him. At 6 P.M., two hours later, I again visited him, and found that his jactitation and nervousness had entirely disappeared and that he was sleeping soundly. He could be easily aroused, and when interrogated as to how he felt, said he was nauseated and had pain in his head. Skin still hot, but perspires freely. He has voided no urine and his bowels are still confined. Pulse 120, and more regular; temperature 99°. Heart's rhythm restored, so that a mitral regurgitant and aortic obstructive murmur could be heard. Injected six minims more of Mag. sol. of morphia under the skin, and ordered ½ oz. of infus. digitalis to be given every two hours,—his bowels to be moved by an enema, and warm blankets to be wrapped around him.

9 P.M. Three hours from last visit I again saw him. He was sleeping soundly, easily aroused, but soon lapsed into sleep. Breathing sonorous. Surface cover-

ed with profuse perspiration. Pulse 120°; temperature 101°. No urine yet voided. Enema failed to act. Ordered the digitalis to be given every hour and warm flannels to be applied to the abdomen. The next morning at 10 o'clock his condition much improved. Pulse 120; temperature 101°. Respiration normal. Voided two pints of cloudy urine, with a spec. gravity 1010,—considerable albumen, acid, granular casts, and fatty epithelium.

April 26th, 9 A.M. Bowels had moved freely. Œdema very much diminished. Continued to improve until May 11th, when he was discharged. Have since heard that he had another attack of convulsions and died.

This patient was brought to the hospital in a semi-comatose state, with almost complete suppression of urine, after successive convulsions occurring at intervals for 24 hours. He began to manifest the characteristic symptoms of Bright's disease about two months before the occurrence of the convulsions, and at the time of their occurrence was undoubtedly already in the second stage of parenchymatous nephritis.

The first hypodermic injection of morphine arrested the convulsive movements, and was followed in two hours by profuse diaphoresis. Two hours after a second hypodermic injection was administered, and the internal use of digitalis was commenced, but there was no evidence of a return of the urinary secretion until twelve hours after the second hypodermic injection was administered; still, during this period of urinary suppression, there was no return of the convulsions.

After the re-establishment of the urinary secretion, his convalescence was rapid, at least up to the time of his leaving the hospital. His subsequent death in a convulsion is evidence of the progressive character of his renal disease.

The abstract of the following case is taken from the note-book of Dr. Katzenbach, House-Physician to Bellevue Hospital during the service of Dr. Flint:—

CASE V.—E. G., a seaman, 23 years of age, was admitted into Bellevue Hospital on the 28th of June, 1872, with congestive remittent fever, which he contracted in Savannah. Under large doses of quinine his febrile symptoms disappeared in about ten days; his convalescence was slow and he remained in the hospital. About the middle of July, his face, feet, and legs became œdematous and his urine scanty. The œdema gradually increased, and on the 24th the urine was found of low specific gravity, albuminous, and contained granular casts.

He went on with all the ordinary symptoms of chronic Bright's disease. His anasarca gradually increases, his urine varying in quantity from 12 to 30 ounces in the twenty-four hours. Specific gravity varying from 1008 to 1020. He was treated with frequent cuppings over the lumbar region and hydragogue cathartics.

On the 13th of August, about 1 P.M., he was seized with a convulsion. Dr. Katzenbach (House-Physician) was called, and found him in a semi-comatose state. The convulsive movements continuing, he immediately administered ten minims of Mag. sol. morphia hypodermically, and soon the patient passed into a quiet state. At 7 A.M., six hours after, the patient was in a comatose condition, and ¼ of a grain of elaterium was ordered every hour. During the day he had several convulsions, and in the evening the elaterium had not acted upon the bowels, although 1½ grs. had been administered.

On the next day the patient was conscious; had no return of convulsions; bowels moved once. He was then put on ½ an ounce of infus. digitalis twice a day, with frequent application of dry cups to lumbar region. He steadily improved, and on the 22d of August was able to go about the ward, although his anasarca diminished but little.

On the 26th of August, his urine becoming scanty, he was ordered hot-air baths daily, ol. of juniper by inhalation, and ten grains of Dover's powder each night for three days.

Gradually he again improved, so that on the 9th of September he was so much relieved that he asked for his discharge from the hospital, which was not granted. On the morning of the 14th of September he was seized with another convulsion, during which 10 drops of Mag. sol. morphia were administered hypodermically. In half an hour the convulsion recurred, and continued to recur every two hours till midnight, when, his breathing becoming difficult, another hypodermic of 10 minims Mag. sol. morph. was administered. Soon after which he fell asleep, and his skin became covered with a profuse perspiration. Pulse during and after the convulsion was 150 and feeble; his urine was passed involuntarily.

At 11 o'clock the next morning, two more convulsions occurred, and another hypodermic of 10 minims Mag. sol. morphia was administered, after which he slept quietly, perspiring moderately until 3 o'clock in the afternoon, when another convulsion occurred, and a hot-air bath was given, which was immediately followed by two convulsions. After the second convulsion, another hypodermic of 10 minims of Mag. sol. morphia was administered. At 10 o'clock the same evening his pulse fell to 66; he was sleeping and perspiring freely; no symptoms of convulsions.

The next morning he was much improved. Pulse 64, sleeping quietly, breathing natural; has passed 48 ounces urine during the last twenty-four hours. Specific gravity 1012, alkaline and albuminous.

From this time he continued to improve, and left the hospital the latter part of September, improved.

This is a well-marked case of chronic parenchymatous nephritis, which was treated with cups over the lumbar region and hydragogue cathartics for a month before the occurrence of the first convulsion; 10 minims of Mag. sol. morphia were administered hypodermically immediately after the first convulsion, while the patient was comatose, which seemed to have little or no effect, for the convulsions continued at intervals for 24 hours, and, although 1½ grs. of elaterium were administered during this time, there was no cathartic action from the bowels until some time after the convulsion ceased. He was put on diaphoretics, diuretics, and cathartics. One month later another series of convulsions and coma occurred, lasting 48 hours, during which time 40 minims of Mag. sol. morphia were administered hypodermically—10 minims after each of the first four convulsions—which had the effect of temporarily arresting the convulsions and causing profuse diaphoresis.

After the last hypodermic injection, he fell into a natural sleep, and the fall of the pulse and of the temperature with profuse diaphoresis marked the commencement of his recovery.

Morphine was not fully tested in this case, for it was not given immediately preceding the convulsions, and other remedial agents were employed in connection with it; it was given, however, in large quantities and did not produce narcotism.

The histories of the two following cases of uræmic convulsions have been kindly furnished me by my friend Dr. B. W. Dudley. I present them in full as I have received them from him.

288 Fifth Avenue,
New York, Feb. 20, 1873.

Dr. A. L. Loomis:

My Dear Doctor,—Please find enclosed a history of Mr. Flannagan's case, which you saw with me in 1871, and which in compliance with your request I now detail to you.

Trusting that the history I give of the case may be sufficiently full for your purposes,

I am, sir, very respectfully,
B. W. Dudley.

Case VI.—Mr. F. called on me about 9 A.M., in the winter of 1871. As he entered my office, I observed that his face was swollen, and that he was suffering with considerable dyspnœa; said "something was the matter with his lungs, wanted me to find out what it was, and relieve him as soon as possible."

I found œdema at lower portion of each lung and bronchitis. The abdomen seemed to be enlarged, and felt puffy; looked as though it contained fluid, but I was unable to determine that point positively. The liver felt hard, and was certainly, though not much, diminished in size. Legs and feet swollen, some pain over the region of the kidneys. He had passed but little urine since the day previous—probably for about twenty hours; had been passing less than normal for several days.

I asked him to make an effort to urinate, and obtained about six ounces of cloudy urine, sp. gr. 1009, slightly acid, loaded with albumen.

I poured it into a glass, to settle for microscopical examination; directed him to go home, send for a cupper, and have dry cups placed all over the back and lower portion of the chest, and promised to see him soon. An hour later I obtained enough yellowish-white sediment to examine under the microscope, and found it contained pus, epithelial and blood casts in abundance. Dr. Polk examined it a few hours later with same result.

I saw him about 11 A.M.; found he had been freely cupped, and was breathing somewhat easier, but had considerable pain in the head. P. 115, feeble; t. 103; skin dry. I concluded I had to deal with a case of acute nephritis, and knowing but little of previous history, and that not very satisfactory—"was a drinking man; did not know whether he ever had kidney disease or not," was about all. So I determined to do battle with the trouble that was threatening the most immediate and serious consequences; and having but a few days previous heard Dr. Loomis express his views on the use of digitalis in such cases, I immediately sent for the following mixture:

℞. Infus. digitalis..... ℥iv.
Pot. acetat..... ʒiv. M.

Learning it would take nearly three hours to prepare the infusion, I went to a hotel near by, telling them to send word when the medicine arrived. I had been gone but a short time when I was called, and found the attendant much alarmed; said "the patient was in convulsions for several minutes." As soon as Mr. F. recognized my voice, he said he was suffering agonizing pain in his head, and insisted on my doing something to relieve him. P. 122; t. 102⅘; skin dry. I gave a hypodermic of ℥xv. of Magendie's sol. morphia, with gr. ¼ atropiæ sulph., which relieved him in a few minutes, and he went to sleep. The digitalis mixture came about 3 P.M., when I gave him a tablespoonful; and as he felt easy I left, stating that I would return in two hours.

Called again at 5 P.M., found him suffering a good deal with pain in the head again. P. 126; t. 103; skin dry; twitching of muscles of face; gave hypodermic ℥xv. Magendie's sol.; he became quiet and went to sleep.

5.30 P.M. I awakened him to give another dose of digitalis mixture, same quantity as before, and gave directions to repeat the mixture, at 7.30 and 9.30, if I did not return, and again left him.

I returned at 9 P.M. Patient had been perfectly quiet and comfortable. P. 105; t. 101; skin moist. He expressed a desire to pass water, and did pass fully a pint.

9.30 P.M. Gave ʒ ij. digitalis mixture, and directed it to be repeated at 1.30 A.M. and 4.30 A.M., and advised consultation; was given permission to bring any one I wished.

Dr. A. L. Loomis called with me the following morning, and after a careful examination was of the opinion that there was no danger of a return of the convulsions at present; advised digitalis to be continued with mur. tinct. ferri. He improved rapidly.

About two months later, Mr. F., feeling perfectly relieved and unusually well, again exposed himself during cold, chilly weather, which brought on another attack of acute congestion of the kidney, which was rapidly followed by convulsions, coma, and death. I saw him in this attack only a few hours before death, and did not prescribe for him at all.

This patient, when first seen by Dr. Dudley, was probably in the acute stage of the inflammatory form of Bright's disease—there was almost complete arrest of the excretory function of the kidneys, and the premonitory symptoms of acute uræmia were well marked.

The first convulsion was a severe one, and, in accordance with the usual history of such cases, was sure to be followed by a second. The first large hypodermic injection of morphine seemed to arrest the impending convulsion for about three hours, when the administration of a second controlled all muscular twitchings, established a profuse diaphoresis, and so far overcame the toxical effects of the urea that under the free administration of digitalis for four hours the urinary secretion was re-established.

This case also shows the effects in acute uræmia of morphine hypodermically and digitalis internally, uninfluenced by any other remedial measures.

New York City, Feb. 8th, 1873.
288 Fifth Avenue.

Dr. A. L. Loomis:

Dear Doctor,—In accordance with your request you will please find enclosed the history of Mr. D.'s case, including the results of Dr. H. D. Noyes's ophthalmoscopic examination. The case being one of considerable interest, I give a brief sketch of history from the beginning of his troubles.

I am, sir, very respectfully yours,
B. W. Dudley.

Case VII.—Mr. D. first came under my observation in October, 1871. He had contracted specific disease about eighteen years previous, and had been excessively mercurialized; was much exposed early in the late Southern war, and obliged to leave the service; went to a tropical climate in 1862, where he contracted malarial fever, which was followed in March, 1863, by an uncontrollable diarrhœa. In June, 1863, hemorrhages from the bowels occurred with the diarrhœa, and he returned to his home in New York, in March, 1864, thinking he had but a few days to live. His legs, feet, hands, and face were swollen, and his complexion was almost copper-colored. In this condition he went under the care of a homœopathist, and was treated for "disease of the liver." Growing worse under

this treatment he left him after several months, and was in the hands of several physicians, one after another, until October, 1871, when he consulted me.

He was broken in general health, anæmic, and had a puffed appearance, complexion about lemon-colored; was in the habit of taking from 3 to 4 grains of morphine in 24 hours, to relieve his suffering. With the above symptoms, and after careful and repeated physical examinations, and also examinations of the urine, I diagnosed "waxy degeneration of the *liver, spleen,* and *kidneys,* and hypertrophy of the left heart with mitral stenosis."

Considering his condition a critical one, I advised him to see Dr. Metcalfe or Dr. Loomis, and get an opinion from either of them before proceeding. He saw Dr. Loomis, who confirmed my opinion, and in addition pronounced the bowels to be in a state of "waxy degeneration" also, and advising him to leave New York for the winter, recommended him to go to Arkansas Springs.

Not wishing to go to Arkansas, I advised him to go to Florida, which he did; and under tonic stimulants and good nourishment, he returned to New York in March, 1872, much improved, and continued well, or rather *greatly improved,* until about January 1st, 1873, when the kidneys began to give him trouble: urine sp. grav. 1012, acid, and contained albumen, blood, and epithelial casts; quantity about as usual. After a few days' treatment, the kidneys being relieved, he again looked like a healthy man, and said he felt "very well."

The hemorrhages from the bowels still continued, but did not appear to compromise his strength much, so that I simply paid attention to his general condition. Everything progressed favorably until

Jan. 26.—11 A.M. I was called, and found him complaining of sore throat and some difficulty in swallowing; mucous congestion of pharynx, and a few small follicular ulcerations; prescribed for them without noticing anything further of interest.

Jan. 27.—5 P.M. Was called again. On arriving I found the patient comfortable, but he had been suffering with severe headache, nausea, and complained of dimness of vision, symptoms under the circumstances very suspicious; but as he had been relieved and easy for an hour or more, only complaining of being unable to see distinctly, and had passed water during the day, my apprehension was relieved; so I ordered gum camphor with comp. spts. ether if the sickness should return, and requested to be sent for if it became severe.

8 P.M. Headache returned with great severity. Nausea and vomiting and amaurosis, could distinguish nothing in a well-lighted room, and at

8.45 P.M. went into a severe convulsion, which lasted about 15 minutes.

As I could not be found, Dr. Pinckney was called, and at about

10 P.M., the patient passing into another convulsion, Dr. P. applied dry cups to the lumbar region, cold to the head, hot bottles, etc., to the lower extremities, and gave gr. xx. bromide of potassium.

11.15 P.M. Another convulsion about as before; same treatment continued.

12.20 A.M. Convulsion; above treatment continued.

I reached the patient at

1.45 A.M. Dr. P. having left about 1 o'clock, I took charge. Patient was drowsy or semi-conscious, would answer questions when aroused; p. 108, weak and intermittent. Axilla temp. 102°, resp. 10, skin dry; entire loss of vision; complained of great pain in head and *eyes;* had passed no urine since the morning before, being about 18 hours. His mother says he fell into a sleep after each convulsion; seems to be sleeping now. While again taking temperature—which went to 103—I was obliged to remove the thermometer, as he threw up his arms, groaning and complaining of pain in the head and eyes, and almost immediately went into a convulsion, which lasted fifteen minutes. Knowing that he had been exposed to cold a few days previous, I concluded that the case was one of uræmic poisoning caused by an *intercurrent* acute *nephritis,* occasioned probably by exposure to cold, and as the paroxysm was passing off, I administered ℥xx. Magendie sol. morphine hypodermically; he soon passed into what appeared to be a quiet sleep; p. 110, t. 102, resp. 10, skin dry.

3.45 A.M. Roused up, complaining of pain in the head, and threw his arms up as before, and had some twitching of the muscles of the face. I immediately gave ℥xv. Mag. sol. hypodermically. After a few slight convulsive movements, he became quiet, breathing easily and sleeping. Having sent for a soft catheter, I attempted to draw off his urine or to ascertain if secretion was going on, but before I had drawn a teaspoonful he knocked my hand with the catheter from him, and said he wanted to urinate, and did pass about four ounces—which, with what he afterward passed, was thrown out by mistake—and again went to sleep. He was quiet until

4.40 A.M. Woke and asked for water. P. 130, t. 106, resp. 15, skin hot and dry; again becoming restless, and exclaimed, "For God's sake, relieve this pain in my head," throwing his arms up to his head, muscles of face and hands twitching: gave ℥xv. Mag. sol. hypod.; convulsive movements occasionally for ten minutes, when he went into a terrific convulsion which lasted *twenty-seven* minutes, from which he passed into profound coma. The bronchial tubes seemed almost filled with mucus, breathing was very superficial, blue around the eyes and mouth; in fact, the whole face and neck became cyanotic. Fearing his death was near at hand I called the family, and as he seemed sinking rapidly, I left the room. His breathing could be heard on the floor below with the doors closed. I was soon recalled with announcement that the "patient was dead," and when I saw him supposed he was. Could feel no pulse at wrist, was not breathing, could hear no sounds over the heart, but while I was examining, he gasped a few times and again began his short, labored breathing; pulse scarcely perceptible. Chloroform, which had been tried without benefit before, was again administered, but when, or as soon as it was given, his breathing ceased, and again I supposed he was dead, and directed the chloroform to be removed. After pressure upon the abdomen had been exerted a few minutes, he again began his short, harsh breathing, and was quiet. P. 130, t. 105, skin hot and dry. He remained in this until

7.30 A.M., when his face and hands began to twitch, and he tried to put his hands to his face. Fearing another convulsion I again resorted to the morphine, and gave a hypod. of ℥xv. Mag. sol. with gr. $\frac{1}{4}$s. sulph. atropia, which quieted him in a few minutes; breathing became easy, and he slept quietly.

8.30 A.M. Woke, asked for water; skin slightly moist; p. 108, t. 103; passed six ounces cloudy urine, and went to sleep again.

10 A.M. Still sleeping; p. 105, t. 98, resp. 12, skin moist; complained of thirst; gave him ice and ordered ℥ss. brandy in milk every hour.

Having a professional appointment of importance at 10.30, Dr. A. A. Smith kindly consented to remain with the patient during my absence. I returned at

12 M. Patient had been sleeping nearly the whole time I was gone; skin quite moist; p. 90, t. 96; *perfectly rational*; has no knowledge of what passed during the night; drank water freely and slept most of the time until

3 P.M. Woke with great pain in his *eyes*; could see nothing, could distinguish no one, either near or at a distance. Some muscular contractions of face; p. 86, t. 97, skin moist; gave hypode. ℳx. Mag. sol. with $\frac{1}{10}$ gr. atropia; he soon went to sleep.

I sent for tr. digitalis, intending to administer that hypode. also, fearing his stomach would reject it. While waiting for the digitalis, advised the family to call consultation. They consenting, Dr. Loomis was sent for.

4.20 P.M. Patient again woke with same symptoms; complained particularly of pain in *eyes*, and could not see. Knew my voice; pain growing worse; gave hypode. ℳxv. Mag. sol.; he went off to sleep, and breathed naturally.

5 P.M. Dr. Loomis arrived. After hearing a history of the case, and examining the patient—patient recognized Dr. Loomis—he coincided with my views and approved of the treatment, and thought his stomach would bear digitalis if given in infusion.

I immediately sent for the infusion, which required about two and a half hours to prepare. Dr. Loomis advised, while waiting for it, to try the tr.

5.30 P.M. P. 86, t. 98¾, pupils dilating, skin moist; I gave ʒ ss. tr. digitalis, which sickened but did not vomit him. Slept some; when awake was perfectly conscious; not so much pain in head and eyes.

7.30 P.M. P. 80, t. 98¾, breathes easily, skin moist; gave ʒ ss. tr. digitalis, which he immediately rejected, and I gave a hypode. ℳx. tr. digitalis.

8 P.M. P. 78, t. 99. Is asleep and sweating profusely.

9.30 P.M. Can see much better; no pain in head and but little in the eyes. P. 84, t. 99½; asleep, sweating profusely. I now began with infusion digitalis; giving ʒ ss. with ʒ ss. acet. potash.

11.30. P.M. P. 76, t. 99½, skin very moist; gave infusion digitalis ʒ ss. acet. potash ʒ ss.

12.30 A.M. P. 66, t. 100. Feels comfortable; asked him to try to pass water, which he did, and passed 22 *ounces*; continued brandy and milk at longer intervals. Went to sleep.

5 A.M. Condition about the same as when last recorded. Gave infus. digitalis, ʒ ij., acet. pot., gr. xv.

6 A.M. Condition about same. Brandy, ss., milk, Oss.

9 A.M. Continues about same. Infus. digitalis, ʒ ij., acet. pot., gr. xij.

10 A.M. P. 74, t. 98¾. Can see perfectly well; no pain in head or eyes, skin moist, breathes naturally; passed a pint and a half of urine.

Milk and brandy.

Patient continued to improve, takes only nourishment, and Thursday, Jan. 30, began taking quinine, gr. v. every 4 hours.

Feb. 12.—Continues to improve; says he "feels perfectly well." Sits up most of the day. Temperature of the room kept constantly at 70°.

RESULTS OF OPHTHALMOSCOPIC EXAMINATION BY DR. H. D. NOYES.

"Examination on the fourth day after the attack of convulsions began, and twenty-four hours he was fully relieved. Vision not yet perfectly clear; sees imaginary figures on the wall of men and things; pupils act promptly to light; irides light blue.

"During the winter he began to use concave glasses —16.—because he thought he was becoming short-sighted; objects across the street were not distinct.

"By ophthalmoscope: find media clear, the refraction so nearly normal as to allow of a myopia not greater than one-thirty-sixth. By upright image a distinct view of fundus gotten. In it no hæmorrhage or pronounced change: the 'macula lutea' seen tolerably well; but while the retinal vessels were distinct, the retinal tissue was not well perceived; it looked foggy and soaked, as if there had been recently an œdema. The optic nerves show plainly, and the edges have a little haziness, not so as to cause any difficulty in defining the border, but it is rather less sharp than natural; a slight amount of swelling in the nerve. The nerve-substance not perfectly transparent; has a dull, sodden, and greasy or waxy look. No capillary hyperæmia. The arteries *remarkably small*, the veins a little larger, but both attenuated to a degree seen in some cases of atrophy. In the right eye the veins a little tortuous; not so in the left.

"The impression made by the examination is, that there has been a decided œdema of the retina and optic nerve, and the effusion has been great enough in quantity to distend the globe and give rise both to the pain in the eyes and the loss of sight. This transudation, of course, penetrated the vitreous humor, and when the kidneys resumed function, the eyes were relieved. A further inference is that a similar transudation has existed in the brain and cranial cavity; that this is the mechanism of the headache, convulsions and stupor; that very little *vascular* congestion was present or possible, as it is certain there could have been none or little in the eyes.

"*Query.*—Are not uræmic coma and convulsions simply the expression of a water-logged brain, as amaurosis and pain arise from infiltrated nerves, retina, and globes?"

This is an exceedingly interesting and remarkable case, not only on account of the large amount of morphine administered during 12 hours, but the fact of recovery after so many and so severe convulsions. The patient had for years suffered moderately from uræmic poisoning. But sudden renal congestion from exposure to cold caused a complete arrest of the functions of the already damaged kidneys, which was almost immediately followed by the symptoms of acute uræmia.

During the first 8 hours of his convulsions, he was faithfully plied with diaphoretics and cathartics without obtaining the action of either, during which time his convulsions increased in severity, and his case seemed hopeless. (The exceedingly large doses of morphine borne by this patient may have been due somewhat to the fact that some years before he became accustomed to its effects.) The first large hypodermic of morphine seemed for a time to arrest the progress of the disease, but the exciting cause of the convulsive seizure was so potent that the struggle between it and the arresting agent became a desperate one, and not until the system was overwhelmed with the morphine did its controlling action show itself.

During the active period of the convulsion, the temperature and pulse were both high. The fall in temperature and pulse marked the subsidence of the convulsive paroxysm.

From this case as well as others that have come directly under my own observation, I am of the opinion that the rule which is to govern us in the hypodermic administration of morphine in uræmic convulsions is to give it in quantities sufficiently large, and frequently repeated, to control the convulsions. Especially will this hold true in uræmic eclampsia. Dr. Dudley bold-

ly pushed the remedy which he believed was the only one that gave his patient any chance of recovery, and his boldness apparently saved the life of his patient. As regards the efficacy of hypodermics of morphine in the treatment of uræmic eclampsia, my own experience has been limited to a single case, the main points of which are as follows:—

Case VIII.—Early in April, 1870, Mrs. W., a young woman, 22 years of age, in the eighth month of her first pregnancy, consulted me in regard to a severe pain in her head, from which she said she had suffered for two or three weeks. On examination, I found her feet and legs œdematous, her urine highly albuminous, containing granular, epithelial and fatty casts.

I warned her family of her danger, and prescribed for her the daily use of mur. tinct. ferri and digitalis, with the frequent application of dry cups over the lumbar regions. Her headache was somewhat relieved, and she passed on to the commencement of her labor without any other unpleasant symptoms. The albuminous urine and œdema continued.

I was called to see her about six hours after the commencement of her labor. Everything seemed to be progressing favorably. The os uteri was dilated to the size of a half-dollar, but was rigid.

After watching the case for an hour or more, I noticed that she was becoming restless, her pulse became slightly accelerated and irritable in character. All at once she began to complain of pain in her head, at times screaming out on account of its severity.

I introduced a catheter into the bladder, but could get only about half an ounce of urine—was told she had not passed urine for 10 or 12 hours.

Suddenly she passed into a convulsion, which lasted about 10 minutes, after which she became partially comatose. The labor continued regular, and the process of dilatation went on rapidly. In about half an hour she began to be restless. Fearing another convulsion, I administered hypodermically 15 minims of Mag. sol. morphia. Immediately her restlessness ceased, and her labor progressed more rapidly than before. Two hours after the hypodermic injection, the os being fully dilated, and the head well down in the pelvis, I applied forceps, and easily completed the delivery of a small child. She then passed into a quiet sleep, her pulse falling to 100. I remained with her an hour or more, and left her sleeping quietly.

In about two hours I returned and found her just passing into another convulsion; immediately I injected 10 minims of Mag. sol. morphia. The convulsion lasted 15 minutes, and she passed into a more profound coma than before. In one hour the muscles of her right arm began to twitch, and I injected 10 minims more of Mag. sol. morphia. Her breathing soon became stertorous, her pulse almost imperceptible, and I thought her dying.

Gradually the stertor passed away,—her breathing became like that of one in quiet sleep,—her pulse gradually diminished in frequency and improved in character,—her skin became bathed in profuse perspiration. I did not allow her to be disturbed, and after remaining four hours in this condition, she roused to consciousness and asked for a drink, which she readily swallowed.

Her urinary secretion was soon re-established; she passed on to a complete but slow convalescence, and entirely recovered.

In this case I did not use chloroform, or any of the remedies usually employed in the treatment of uræmic eclampsia, for this reason: that the only two cases of uræmic eclampsia that had occurred in my practice had terminated fatally after the usual remedial agents had been resorted to (in one, general bleeding was twice practised by advice of the late Dr. Gillman).

I am aware that a single case proves very little, in regard to a plan of treatment, but this case, it seems to me, shows the power of hypodermics of morphine to control muscular spasms, excite diaphoresis, and perhaps diuresis, in a patient in uræmic eclampsia.

In an August number of the Med. Record of 1868 I find a much stronger support of this plan of treatment in uræmic eclampsia.

In a paper on the Diagnosis of Albuminuria in Pregnancy, etc., by Dr. F. D. Lente, is a letter from Dr. White, of Fishkill, which reads as follows (*vide* page 265, Vol. III.):—

"Case IX.—Dr. White says: 'I was called to visit her (Mrs. M—) at 5½ P.M. on Friday, 22d February, 1867. I found her in a comatose and insensible condition, having had two convulsions before I arrived. She had been complaining during the day of what they call sick-headache up to the time the convulsions came on. The pulse was full, skin hot, bowels constipated; very considerable œdema (of lower extremities). The time of her expected confinement had arrived, but no evidence of labor. I bled her sixteen ounces from the arm, applied ice to head and mustard to the neck, and gave 15 drops of Mag. sol. morphia. Within half an hour she had another convulsion, when I sent for you (Dr. Lente); and about the time you arrived she had another, when you injected the arm (with morphine ½ grain), and had her bowels moved by an enema, and the bladder evacuated by the catheter; by which operation we obtained but a small quantity of urine, there evidently being but little secretion. After this she had no more convulsions. Whenever she became uneasy, and gave evidence of their return, she had an injection per *anum* of one grain of morphine; this was repeated every six or eight hours, three times, when all unpleasant symptoms disappeared.

"'The kidneys became active soon after she was fully under the influence of the morphine. During the day and night of Saturday, she voided seven and a half pints of urine of a natural color. After this I made no note of the quantity, but remained with her until 3 o'clock Sunday afternoon. The following morning, at 8 o'clock, I was called to her, and found her in labor; and at 11 o'clock A.M. she was delivered of a full-sized child, with no unpleasant symptoms during or after the labor. She recovered rapidly, and has enjoyed uninterrupted good health since. I saw her this week, and found her in perfect health, and in the sixth month of pregnancy.'"

In connection with this case Dr. White makes the following remarks:—

"I made a verbal report of this and five other cases of puerperal convulsions (that I have had within the last two years, all treated with morphine and all terminated favorably) to our County Medical Society, at the semi-annual meeting in January last, and two cases were reported by Dr. G. L. Sutton, in which I was in attendance with him, which were treated with morphine and resulted favorably. It provoked a very spirited discussion by the members of the Society, a majority of whom had treated their cases with chloroform, bleeding and veratrum. But they were free to acknowledge that the mortality was fearfully great."

In a letter from Dr. Lente, dated March 3d, 1873, in answer to inquiries made by me in regard to his treatment of uræmic eclampsia, he makes the following statement:—"I remember one very bad case of convulsions in a primipara, some 9 or 10 years ago; they

commenced before any signs of labor appeared, and continued for several days before the pains set in, and also for a couple of days after labor, if I remember rightly. I was called in consultation. Chloroform was administered at first, and continued until it seemed as if the patient would die each time, while under the combined influence of the convulsion and the remedy. I had not then the experience with morphine in these convulsions which I have had since, and hesitated to advise it; but being driven to it, I gave hypodermic injections, with the effect of promptly relieving the paroxysm, and relieving the patient for several hours. These were continued for several days. The patient recovered well and has been well since, having borne other children, with no recurrence of albuminuria."

These histories and their accompanying statements go far, it seems to me, to place hypodermics of morphine among our most reliable agents in controlling this terrible form of acute uræmia; and it would appear, that if a large hypodermic of morphine be administered at the onset of uræmic eclampsia, and repeated whenever the premonitions of a convulsion are present, we offer these distressing cases the best chance of recovery.

I have no experience in the treatment of acute uræmia following surgical operations on the urethra.

The only patient I ever saw with uræmia under such circumstances was in a moribund condition when I was first called to him. From his history I should infer, if morphine is ever to be resorted to in this class of cases, it should be given as soon as the premonitory symptoms appear, not for its power of preventing or controlling muscular spasms, but as an eliminator.

I am not aware that any case of this class has been treated with hypodermics of morphine.

In the histories of the ten cases given I think we find answers to the two questions asked at the commencement of this discussion:

First.—That morphine can be administered hypodermically to some if not to all patients with acute uræmia, without endangering life.

Second.—That the almost uniform effect of morphine so administered is—1st, to arrest muscular spasms by counteracting the effect of the uræmic poison on the nerve-centres; 2d, to establish profuse diaphoresis; 3d, to facilitate the action of cathartics and diuretics, especially the diuretic action of digitalis.

Thus morphine, administered hypodermically, becomes a powerful eliminating agent.

The rules which are to govern its administration are as yet not well defined. My own experience would teach me to give small doses at first,—not to exceed ten minims. If convulsions threaten, and a small dose does not arrest the muscular spasms, it may be increased to twenty minims, and the hypodermics may be repeated as often as every two hours. It must be given in sufficient quantities to control convulsions; neither the contraction of the pupils nor the number of the respirations is a reliable guide in its administration.

It has not been my purpose, Mr. President, in this paper, to discard all, perhaps none, of those means which have been relied on for the relief of patients in acute uræmia, but to bring to the notice of the profession the fact, that in a certain proportion of cases (if not in all) of acute uræmia, hypodermics of morphine will not only control muscular spasms, but aid in establishing the eliminating processes, and thus become another means of saving life in these too often fatal cases.

Progress of Medical Science.

Treatment of Malignant Pustule in Portugal.—Dr. Belles, practising in the districts of Béja and Faro, where malignant pustule is very frequent, in consequence of the number of cattle raised there, says he has treated hundreds of cases of this affection without having noted a single death, no matter how advanced the case was at the time of operating. The treatment employed by Dr. Belles consists in crucial incision of the boil throughout its whole extent, in depth as well as breadth, and cauterization with chloride of antimony, repeated until bleeding ceases. The gangrenous tissue is completely insensible to both cutting and cauterization.

When the operative measures have been postponed until extensive disorganization of the tissues has occurred, the separation of the eschar is retarded by a local atony, which the author counteracts by means of poultices of meal and tapioca cooked in wine.—*Gaz. Méd. de Paris.*

Accidental Septicæmia.—Experimental septicæmia, the study of which is being pursued with such activity, and regarding which communications have been addressed to most of the European academies and societies, is, unfortunately, not always a question purely scientific and pertaining to the laboratory. In Bordeaux a young surgeon of great promise, Monsieur Marc Girard, a short time since was completing the disarticulation of the humerus of a man who had been severely injured, and presented symptoms of putrid infection, and, while uniting the flaps with sutures, pricked the index finger of his left hand with the needle. A slight inflammation of the finger and inflammation of the lymphatics of the hand followed directly. At the end of several days he had quite recovered and resumed his work, but the symptoms of septicæmia did not fail to declare themselves, and he died fully conscious of the nature of the disease, and, to quote the writer in *Le Bordeaux Médical*, "with the gloomy resignation of the man who knows that all hope is lost."

Preservation of Organic Substances by Means of Fuchsine.—Gelatine putrefies with the greatest facility at a temperature of 25°, forty-eight hours only being required for it to become covered with mould, to liquefy, and undergo complete decomposition. If to a solution of gelatine is added a fifth part of fuchsine, it can be preserved in the open air during an indefinite period. A piece of beef, weighing fifty *grammes*, has been enveloped in blotting-paper moistened with a solution of an hundredth part of fuchsine. This piece of meat has been exposed to the air for several months, and has as yet undergone no alteration.

Urine, to which one-forty-thousandth part of analine violet had been added, was placed in a test-tube in contact with the air, and at the end of six months had undergone no putrefaction.—Lanjerois, *Revue de Therap.*, No. 9.

Enlargement of the Tonsils as a Cause of Nightmare.—In the *Br. Med. Jour.* of June 7, Dr. J. W. Howard relates the case of a girl of thirteen years in whom attacks of nightmare were cured by the removal of enlarged tonsils. The attacks came on generally about an hour after going to bed.

Dr. M. H. Henry, of this city, has been appointed Surgeon-in-Chief of the State Emigrant's Hospital, Ward's Island, N. Y., vice Dr. Carnochan deposed.

New York, August 1, 1873.

MEDICAL MEN AS PUBLIC ADVISERS.

As one of the signs of the times, we call the attention of our readers to the meetings of the Albany County Medical Society, which were recently held for the purpose of discussing the propriety of supplying the capital of the State with drinking-water from the Hudson River. It is not our intention to give the reasons *pro* and *con* which were offered by the different medical gentlemen who spoke on the occasions, as the facts which were brought out are well enough understood, and are in keeping with the views of authorities on sanitary matters. The meeting in question was a peculiar one, in that it was held at the instance of the Common Council of the city, for the very purpose of obtaining the views of the medical community upon a subject of the greatest possible moment to the citizens at large. This action on the part of the aldermen not only gives evidence of their wisdom in seeking advice from those best able to give it, but proves as much as any one action can, that the profession of a city can be made useful in times of emergency—in times when every other consideration must give way to the general good.

We are gratified to know that the first meeting was held immediately after the call, was largely attended, and that the subject was very satisfactorily and very thoroughly discussed. We are prepared to believe that the remarks made at those meetings will have their due weight, not only with the board of aldermen, but with the citizens generally, and will relieve those directly charged with acting in the matter from all responsibility.

We can see no good reason why this same course cannot be taken by other municipal authorities in matters of equal importance to the health and welfare of the public. If this were the case, the profession as a body, represented as it is in our medical societies, would feel a responsibility towards the community which they do not now feel when they leave all matters entirely to a Board of Health.

The truth is, however, that two things are wanting to meet reasonable expectations: first, that the profession be asked for an opinion; and second, that they should feel a sufficient amount of responsibility to accede to a request when such a request should be made. The first obstacle is certainly at first sight a very serious one, but if we look at it in the right spirit we shall easily see that it can be surmounted. We need never expect, so long as we, as a profession, hold ourselves in the background, so long as we throw ourselves upon so-called professional dignity, so long as we refrain from making our power and our influence felt, that our advice will be courted or our opinions respected. If our opinions are not asked, we have, after all, no one but ourselves to blame. There is, perhaps, no profession numbering so many capable, educated, nay scholarly men, who have so little influence as a body with the community at large. The legal profession, with no more aggregate talent, take the lead in the discussion of all general and political questions; the clerical profession not only indoctrinate their hearers with their peculiar views, but preach to the unseen audiences whose only teachers are the daily papers. Each of these professions has its respective share in creating public opinion on subjects upon which they are supposed to be well informed. With our own profession, however, by a mistaken interpretation of our Code of Ethics, we are unwilling to do not only what we have a right to do, but what the community have long expected of us. The public are willing to listen to us on medical topics, if we choose to speak, and, having spoken, we can really create public opinion—the power behind the throne.

As a matter of right, no question of great medical importance should be considered settled by any health authority until the profession, as a body, had passed judgment thereon. If such questions are not referred to them by courtesy, as was done in Albany, we should have enough of power and influence in ourselves to compel such a reference. We believe, however, that the profession are waking up to their true responsibilities, not only as teachers and advisers on all matters connected with sanitary affairs, but as leaders in medical opinion for the public. It will, doubtless, take a long while before all the barriers of old prejudices are sufficiently broken down to enable us to realize our hopes, but we are sanguine enough to believe that the time is not far distant when our own profession will have as much to say upon State medicine as the lawyer upon general politics or the clergyman upon public morals.

BELLEVUE HOSPITAL, NEW YORK.

We are pleased to learn that, notwithstanding the threats by certain parties, Bellevue Hospital is to remain in its present site. The committee of the medical staff, to whose favorable report we have before called attention, prepared the way for the definite action of the committee from the Board of Aldermen, who believe, as does every unprejudiced medical man, that the interests of the community, of science and clinical teaching, demand that no change of location be made. Now let the Commissioners of Charities bestir themselves, and make such improvements in the present buildings as shall make the great charity a model of its sort. Science is and has been doing everything possible for the patients; now let art add its benefits.

Reviews and Notices of Books.

DISEASES OF THE RECTUM; THEIR DIAGNOSIS AND TREATMENT. By WILLIAM ALLINGHAM. Second edition, revised and enlarged.

The second edition of the above work forms a compact volume of about 250 pages, containing many valuable suggestions to the specialist as well as to the general practitioner. Among the various works on diseases of the rectum which have appeared during the last decennium, the above deserves special commendation on account of its eminently practical character; and we must congratulate its author on the perseverance which has enabled him to acquire so extensive an experience in this branch of surgery. Although the book is not a complete treatise, it shows manifold evidences of the thorough acquaintance of its author with his subject and of his diagnostic skill and surgical talent, as it embodies a review of four thousand cases of rectal disease which have been observed and treated among the out-patients of St. Mark's Hospital. In seventeen chapters the principal diseases have been discussed, to which have been added a chapter on rodent or "lupoid ulcer," remarks on neuralgia of the rectum and removal of the coccyx, and reports of two cases of villous tumor, and three cases each of gonorrhœa of the rectum and vicarious menstruation from the rectum. The book is burdened with but few reports of cases, the author having summarized his experience in a clear and concise manner.

Throughout the work great stress is laid on the importance of recognition of concomitant disease in contiguous parts, as the bladder and uterus, of derangements in the abdominal and thoracic viscera, and on the influence of hereditary disposition. In the chapter on fistula, the obstacles which are so apt to embarrass the surgeon in accomplishing a cure are very fully discussed, particularly the treatment to be adopted in the case of coexistence of several sinuses, overlapping of the edges, etc. Mr. A. dwells upon the necessity of incising *every* sinus, instead of relying upon the incision of only the principal one. The method of operation is identical with that of Esmarch: a director is introduced into the sinus and brought out at the anus; the tissues are then divided. In those cases where the rectal sinus runs high up, and this method cannot be followed, Mr. A. employs an instrument combining in itself "a spring-scissors and special director." The screw-tourniquet and ligature have also been employed successfully in these cases. Concerning injections, the author has had thirteen successful cases and nearly twice that number in which "I have failed to effect a cure after a prolonged attempt, so that I cannot say that the prospect is very encouraging." In regard to the much-disputed question of the propriety of operating for fistula in phthisical patients, he finds "that we have few clinical facts tending to show that the operation renders the lung-affection worse, or makes it more rapidly progressive," provided the operation be undertaken at an early stage, and during the mild season of the year. Several cases, some of them very unfavorable, are adduced to prove that no aggravation of the pulmonary affection followed operative interference. The surgeon is, however, cautioned to interfere as little as possible with the sphincter-muscles, to guard against the probability of subsequent incontinence.

Internal hæmorrhoids are divided into three varieties: 1st, *the capillary;* 2d, *the arterial-internal;* and 3d, *the venous-internal hæmorrhoid.* It is the first variety only which is "benefited by the application of caustics, though not always cured," and the author restricts cauterization to this form. Besides nitric acid, strong carbolic acid and persulphate of iron have been found very advantageous. In *all* cases of the other two varieties, the author invariably proposes operation, the methods for which are very fully described in a separate chapter. Decided preference is given to the ligature, the use of the "clamp and cautery" being confined to slight cases not complicated by superabundant tissue or external hæmorrhoids. Separate chapters treat of the complications and of hæmorrhage after operation, with description of a very practical method for plugging the rectum by means of a bell-shaped sponge and cotton.

In regard to the treatment of fissure of the rectum, the author, after "having given *forcible dilatation* a fair trial," arrives at the conclusion that incision is the treatment to be preferred, in which opinion he is sustained by the majority of the continental surgeons. The too indiscriminate practice hitherto followed, of dilatation, with the introduction of the whole hand for the purpose of exploration, has frequently been followed by permanent paresis of the sphincter. In connection with the difficulty of diagnosis, in some cases of stricture and malignant disease high up, Mr. A. states that he has, in a few cases, introduced the whole hand—a means which has more recently been advocated and practised by Simon, of Heidelberg. For visual examination, the author prefers, for general use, the ordinary fenestrated metal or the long glass tubular speculum to any other modification, no mention being made of the practicability of Sims's speculum.

In regard to ulceration and stricture of the rectum, the author believes that those cases attributable to constitutional syphilis are very amenable to treatment. When stricture and ulceration are complicated by fistula or sloughing of the tissues, the operation of colotomy is strongly recommended to be performed at an early period, inasmuch as, except in case of malignant disease, it is "not merely palliative but curative," the rectum returning to a healthy condition.

In the treatment of procidentia recti, the author highly extols cauterization with the acid nitrate of mercury and carbolic acid, also the plastic operation of bringing together the mucous membrane after the excision of triangular or elliptical folds with sutures of horse-hair or carbolized catgut. In regard to cancer, the early performance of colotomy is recommended as greatly ameliorating the patient's suffering, if not retarding the progress of the disease. The author has performed

the operation sixteen times, and gives a very full description of his method of operating.

An excellent description is given of rodent or "lupoid" ulcer of the rectum, of which the author has had six cases, in the treatment of which early excision or cauterization is recommended.

OPHTHALMIC CONTRIBUTIONS. I. DERMOID TUMOR OF THE CORNEA. II. AN ADDITIONAL METHOD FOR THE DETERMINATION OF ASTIGMATISM. III. CYST OF THE IRIS, REMOVED BY OPERATION. By GEORGE STRAWBRIDGE, M.D., Lecturer on Diseases of the Eye and Ear in the University of Pennsylvania; Ophthalmic Surgeon to the Presbyterian Hospital in Philadelphia; Attending Surgeon to the Eye and Ear Infirmary of the Philadelphia Dispensary. Lindsay & Blakiston. 1873. 8vo, 26 pp.

THE above articles, having originally appeared in several journals and transactions of Societies, are now combined and reprinted in a form which renders them more convenient for reference. The résumé of the pathology and literature of the two cases reported is very complete. The cyst of the iris makes the thirty-third case thus far recorded. Dr. Strawbridge's method for the determination of astigmatism is an adaptation of an optometric process proposed by Helmholtz, and is useful, not only for that purpose, but also for controlling the results obtained by other methods.

FIRST ANNUAL REPORT OF THE SUPERVISING SURGEON OF THE MARINE HOSPITAL SERVICE OF THE UNITED STATES for the year 1872. Washington: Government Printing-Office. 1872.

THIS book of about one hundred pages, the work of Surgeon John M. Woodworth, comprises a historical sketch of the service from its organization in 1798 to the present time, condensed histories of surgical cases reported in detail to the Department to the number of upwards of four hundred, by surgeons in charge of hospitals devoted, wholly or in part, to the care of seamen, and the tables of receipts, expenditures, etc., appropriate to such reports. The present number of any particular class of cases being too small to warrant classification, Dr. Woodworth does a good work in publishing them in this manner, and making them thus a permanent nucleus for further facts from the same sources. The influence of the Army Medical Museum and the reports from the Surgeon-General's office, is, we think, traceable in this, and we are somewhat surprised that the Bureau of Medicine and Surgery, with its skilled observers and numerous and well-kept medical descriptive lists, has not responded in some such way as this to the same influence.

According to the lists, ten hospitals were in operation at the date of the report, all, excepting the ones at Portland, Boston, Mobile, and Key West, being upon inland waters. The total number of seamen treated during the year was 13,156, at a daily average cost of $0.97.6, or a total cost of $396,263.11 (exclusive of building and repairs). 854 of the cases were not treated in hospital, and the total number of days of relief furnished the remainder was 405,814; with an average mortality of 3.94. The amount of hospital money collected from sailors was $323,700.4.

MEDICAL ESSAYS; compiled from Reports to the Bureau of Medicine and Surgery, by MEDICAL OFFICERS IN THE U. S. NAVY. Washington: Government Printing-Office. 1872.

WE are glad that our professional brethren of the Navy have undertaken a work which will not only to them individually credit, but will be one of the most powerful means for advancing the relative position of their corps in the service. Arguments and statements calculated to show the dignity, responsibility, and self-devotion of medical men as a class are too trite to have much weight with legislators or the public, who have little trouble in recalling instances of dignity unappreciated, trust neglected, and eager strife for personal advancement at any cost, and are quite ready to make the whole profession responsible for them.

The production by officers of the medical corps as a class of such series of essays as this book is mainly composed of, will do more, we are sure, to elevate the whole body of naval surgeons in the estimation of "The Line," and secure them immunity from the petty tyrannies of naval routine than any acts which Congress will ever be likely to pass. The papers on Naval Hygiene, by Medical Inspector A. L. Gibson and Surgeon Payne, are by no means limited in application to the naval service, but may be read with quite as much profit by officers of the army and mercantile marine.

The reports by Inspector Shippen on Certain English Hospitals, and of Inspector Browne on the Charitable Institutions and Peculiar Diseases of Peru, are exceedingly interesting; and the articles by Surgeon Bloodgood and Passed Assistant-Surgeon Pilcher on Outbreaks of Yellow Fever, of which they had experience, are of scientific merit.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 28th, 1873.

DR. ERSKINE MASON, President, in the Chair.

THE POST-MORTEM EFFECTS OF THE ASPIRATOR UPON THE BLADDER.

DR. LOOMIS exhibited the genito-urinary apparatus of an Englishman, æt. 71. The patient had been admitted into Bellevue Hospital, May 20th. He stated at the time of his admission that he had always been a perfectly healthy man up to five years ago, when, after an exposure to wet and cold, he was seized with an attack of retention of urine, which was finally relieved by a warm bath. Up to a short time before his admission, he had been in the habit of relieving himself with a catheter, when seized with retention. Seven days before his admission (May 12th), after a hard day's work on Long Island, he was seized with a chill followed by fever and pain in the side. The fever and pain in the side were soon followed by cough, and he gave a straightforward history of pneumonia. The second day of his illness, he was unable to pass his water, and the physician in attendance was compelled to resort to the catheter. At the time of admission, on the 20th, the patient had not passed urine for twenty-four hours. He was then in a typhoid condition, tongue dry and brown, temperature 99¾° F., pulse 120, skin deeply jaundiced, respiration thirty-six, and muttering delirium. Physical examination revealed pneumonia in third stage over the whole of right lung, also the lower lobe of the opposite lung.

On examining the abdomen, there was a swelling extending from the pubes as high as the umbilicus. An attempt was made to pass the catheter, but failed, and the bladder was aspirated, twenty-two ounces of normal urine being evacuated. The patient felt much

relieved, and seemed to be improved in his condition. The next morning he was much better, the pulse had fallen some, the temperature was 98° F., respiration less frequent, and he coughed and expectorated freely. On the next morning the aspirator was used, and twenty-two ounces of urine withdrawn; on the following evening twenty ounces were evacuated. On the next morning it was used again, and two pints of urine withdrawn, in the evening about twelve ounces; and so the aspirator was used morning and evening up to the day of his death. On the morning of the day of his death, two attempts were made with the aspirator, but no urine followed the introduction of the needle. He was in a state of coma at the time and was evidently dying, and all further attempts were given up.

He died of exhaustion on the third day after his admission into the hospital.

On making the autopsy the interesting point to observe was the effect of the aspirator upon the bladder and peritonæum. The bladder contained about a pint of normal-looking urine. On laying it open opposite a spot of extravasation that was noticed upon the surface of the bladder—partly above and partly below the peritoneal attachment—could be seen points where the needle entered the bladder. There were mere red dots, further than which there was no disturbance of the mucous membrane. The points on the surface of the bladder and peritonæum corresponded to the punctures upon the abdominal walls, and there was a slight sub peritoneal extravasation, but there were no evidences of peritoneal inflammation. Some of the punctures were made above and some below the peritoneal attachment. The middle lobe and left lobes of the prostate were very much enlarged. Just at the junction of the membranous and spongy portions of the urethra were two false passages. Dr. Gouley stated at the autopsy that this was the first case in which the aspirator had been used for enlarged prostate.

The condition of the thoracic viscera was of less interest. The right lung was found in the third stage of pneumonia, as was also the lower lobe of the left lung. There was slight pericardial exudation, which had probably taken place during the last twenty-four or forty-eight hours before death. The heart was slightly enlarged, and the aorta was extensively atheromatous. The liver was slightly increased in size, and a gall-stone was found obstructing more or less completely the gall-duct.

CHOROIDAL SARCOMA.

Dr. Knapp presented a specimen of choroidal sarcoma, sent him by Dr. Williams, of Cincinnati, Ohio. The specimen was removed from a girl twenty-two years of age who, two and a half years previous to the operation, accidentally discovered that she could not see with her right eye. She had no symptoms from the blind eye for two and a half years until, three weeks previous to the operation of enucleation, the organ was attacked with glaucomatous inflammation. The operation was performed by Dr. Williams.

On bisecting the specimen, the growth was seen at the back portion of the globe, close to the entrance of the optic disc, pushing aside and doubling up the retina, and overlapping the nerve. A portion of the retina covered the tumor, and on its attached surface there was an uneven surface where portions of the tumor united with the retina. The tumor itself was the size of a big cherry-stone, and around its base was a little border going over into the adjacent choroid.

The specimen did not present anything extraordinary in its structure. It was nothing more than an ordinary spindle-cell sarcoma. The question of importance was in relation to the mode of propagation of the growth. Dr. Ayers, Dr. Williams's partner, states that the first section of the optic nerve presented a diseased surface, necessitating a section further back to find healthy tissue. On examination by Dr. Knapp, the retina had an infiltration of sarcomatous elements in the shape of round small cells, with large nuclei and distinct nucleoli, while spindle-shaped cells were seen in the outer layers of the retina; while still again some portions of the retina were thickened by an increase of connective tissue in the inner layers of it. The same kind of sarcoma-cells existed in the nerves. It was interesting to know that the sarcoma could go both ways, not only through the optic nerve, but through the retina.

THROMBOSIS OF RIGHT VENTRICLE AND EMBOLISM, WITH THROMBOSIS OF BOTH PULMONARY ARTERIES —SUDDEN DEATH.

Dr. Janeway presented a specimen, of which (being removed from a coroner's case) the history was somewhat imperfect. The patient was a female who had been confined six weeks before in Bellevue, as the result of which she became much exhausted. A week before her death, she being still much exhausted, complaining of stitches in her side, dyspnœa, and having a frequent pulse, she insisted upon being discharged. Her request was granted, much against the wish of the house-physician. The next day, while walking through 26th street, she suddenly fell and expired.

The autopsy was performed at the request of the coroner. Nothing abnormal was found about the uterus or the peritonæum. In the right ventricle, near the apex, were found, embedded in the columnæ carnæ, several recent thrombi. Lying loose in the pulmonary artery was another clot, also both the vessels leading to the right and left lung were completely plugged. Besides that were found numerous recent and some yellow infarctions, and over these a recent pleuritic exudation showing all the stages of slight embolism of the smaller branches of the pulmonary arteries to complete thrombosis of the right ventricle.

BUNION AND VALGUS OF THE GREAT TOE—RESECTION.

Dr. F. H. Hamilton presented to the Society a laboring man, æt. 24, upon whom he had recently operated for valgus of the great toe, and bunion, the deformity having been caused by wearing short and narrow shoes when quite young. He had finally become so completely disabled in both feet that he applied to St. Francis' Hospital for relief. It was the usual deformity, only that the displacement was excessive; the great toes completely underlying the second toes and the great-toe joints, and were covered by large and tender bunions, projecting in such a manner as to prevent his wearing shoes and attending to his ordinary business. The bunion had never suppurated, nor was there any disease of the joints. It was apparent that no adequate and permanent relief could be furnished except by resection—an operation which, so far as Dr. Hamilton knew, had not hitherto been made upon these joints in these cases, except when the joints had become carious or necrosed, or were otherwise diseased. Nevertheless the degree of maiming caused by the deformity in this case seemed to justify surgical interference.

Operation, April 7, 1873.—The right foot, being in the worst condition, was chosen for the first operation. An incision was made upon the inside of the joint so as to avoid the flexors and extensors, and resection of about three-quarters of an inch of the distal end of the metatarsal bone was made with the bone-cutter—the

instrument used for this purpose being the large bone-cutter invented by Dr. Hamilton, and described in his "Treatise upon Surgery." No vessels required the ligature. The wound was left open, and the foot was submerged in a bath of tepid water, where it was retained most of the time for two weeks. Whenever it was removed from the bath, cloths saturated with water were applied as a dressing. No attempt was made to bring the toe into position, but as the wound healed it gradually fell into line with the metatarsal bone, and now, the wound being entirely closed, there remains no deformity, except that the toe is shortened about half an inch. Flexion and extension are perfect, and he walks with ease and comfort. The left foot not having been operated upon, the members of the Society were able to compare the two and to note the great improvement resulting from the operation. Dr. Hamilton proposes to operate upon the left foot in a few days.

Dr. H. called attention to the manner of displacement of the great toe in this case, and which he supposes to be typical of what occurs in all similar cases. The great toe was not simply tilted outwards, "opening the joint," as Mr. Bigg says it is in valgus of the great toe, but the proximal end of the first phalanx was slid around upon the distal end of the metatarsal bone, constituting a partial outward luxation, the phalanx articulating only with the outer margin of the metatarsal bone.

Dr. Hamilton desired to call attention, also, to the bath used in the treatment of the wound made by the operation, and which is used in nearly all the cases of recent injuries at St. Francis' Hospital. When Dr. H. took the place of consulting surgeon to this hospital he found Dr. Rose, the very intelligent visiting surgeon in charge, using these baths, and they have continued to be used with the happiest results. When employed a certain degree of œdema generally ensues, but this quickly subsides when the limb is removed and simple dressings substituted. Under their use pyæmia, erysipelas and gangrene are exceedingly rare, indeed almost unknown.

RESECTION AT HIP-JOINT.

Dr. Hamilton also presented the head, neck, and trochanter major of a femur resected at Bellevue Hospital before the class, April 12, 1873. The patient was a boy, æt. seven, who had morbus coxæ in its third stage. He was now progressing favorably toward recovery. The only point of special interest in the case was the fact that, while employing a slight amount of leverage to disarticulate the bone, the femur broke near its middle. He was surprised how little force was requisite to break the femur under these circumstances; and as he had not seen any allusion to this danger in the surgical treatises, he thought it important that he should call the attention of surgeons to the matter. The fracture was transverse, and under the support of pasteboard splints it united speedily and without deformity.

Dr. Sayre said this accident had happened in two cases while he was operating, and he called the attention of the President, Dr. Mason, to one case in which he was present and assisting when it occurred.

MORBUS COXARIUS.

Dr. Sayre exhibited several specimens. The first was the head, neck, and trochanter major of the femur exsected Jan. 26th, 1873. The patient was a boy who was injured in the summer of 1872, and as the result suffered from what was thought to be knee-joint disease. He was confined in the horizontal position, with Buck's extension for several months. Finally an abscess appeared on the upper portion of the thigh, discharged copiously, when it was discovered that there was a disease of the hip-joint. Dr. Sayre saw him in Jan., but in consequence of his exhausted condition did not deem it advisable to perform exsection, especially as he was supposed to have amyloid degeneration of the kidney. Improving somewhat in his general condition, but suffering greatly from pain, it was determined to give him a chance, slim as it might be, of relief. At the operation it was found impossible to luxate the head of the femur in the usual way, in consequence of the immense increase of the size of the diseased parts. It was necessary to saw off the bone below the trochanter major before it could be removed from the acetabulum. The circumference of the diseased parts was an inch and a half larger than normal. The acetabulum was found perforated. Before completing the operation it was necessary to push up the lower portion of the femur, which was found uncovered with periosteum, and saw it off. The lad was then placed in wire breeches. Everything progressed favorably, the wound healing by first intention, except at the lower portion kept open for the discharges, until a fortnight afterwards, when the knee of the affected limb became swollen, giving exit to an enormous amount of pus. Passing the finger into the abscess, the lower portion of the femur was found naked and carious. The patient died at the end of three weeks with amyloid degeneration, and on examination of the femur after death, only its lower portion was the seat of necrosis, although the whole bone was the seat of hypertrophy. In Dr. Sayre's opinion, this was another case in which the disease originated in a laceration of the periosteum covering the linea aspera of the femur, and that the disease extended from that point to the hip, ending in the condition already described.

A second specimen by Dr. Sayre was one removed by operation from a medical gentleman aged 42, who had had disease of the hip-joint when three years old, the result of a fall. Prolonged suppuration ensued, with an occasional discharge of a piece of dead bone until he was nineteen years of age, when he recovered with a limb anchylosed, abducted, and flexed against and over the opposite thigh, so that the foot was eight and a half inches from the ground. It was thought that the limb was fixed by bony anchylosis. This gentleman studied medicine and became one of the principal surgeons in Michigan. In March last he had a little accident in his wagon, whereby a fresh inflammation was started in the affected hip, and he grew worse all summer. Dr. James R. Wood saw the case and opened a large abscess. Dr. Sayre was called in consultation and advised an exploratory operation. The operation was performed. The trochanter major was healthy, except the posterior surface, which had a deep abscess ploughing through it. The head was naked, rough, and carious, and pressed against a hole in the acetabulum. The patient recovered entirely from the operation, is able to walk exceedingly well on crutches, with only three and a quarter inches shortening.

Dr. Sayre exhibited a third specimen, removed also by operation. The patient was a boy four years of age, who contracted disease of the hip when twenty-three months old by a fall from a wagon. He was treated with a plaster of Paris apparatus for two years and nine months, the limb being kept in a straight position. The joint was kept perfectly quiet, but numerous abscesses formed, attended with excessive suppuration. Dr. Sayre was called in consultation by the

Drs. Sabine, and detected disease of the hip-joint still existing. In this case the head and neck of the femur were entirely destroyed, and the shaft perforated the acetabulum and projected above the pubes. Dr. Sayre was of the opinion that this condition of things was the result of the limb being kept in the straight position without an opportunity for extension and counter-extension, the muscles being left free to exert their powerful contractile force in the direction of the long axis of the limb. The diseased end of the bone was removed, as well as fragments of diseased acetabulum.

A fourth specimen was one removed that day from a child aged four years, who also contracted hip disease as the result of a fall. The disease passed rapidly to the third stage, and two years ago Dr. S. opened a large abscess in the neighborhood of the hip. At the operation the head and neck of the bone were found to be destroyed, and section was made above the trochanter minor. There was but a small opening in the acetabulum. An abscess extending down the outer side of the thigh a distance of four or five inches below the hip, the incision was prolonged to that extent. Dr. Sayre stated that this made his forty-seventh case of exsection of the hip.

The Society then went into executive session.

Stated Meeting, June 11, 1873.

Dr. E. Mason, President, in the Chair.

PERITONITIS OF LEFT SIDE FROM PERFORATION OF APPENDIX VERMIFORMIS.

Dr. Loomis, in presenting a specimen, remarked: On the twenty-seventh of last month I saw for the first time a gentleman from whom this specimen was obtained. He was of temperate habits, twenty-four years of age, of fine physique, and had always been a very active man in business. The evening before I saw him, after a pretty hard day's work, and coming home fatigued, he ate freely of lobster salad and went to bed soon after. During the night he was seized with pain in the abdomen, accompanied with diarrhœa. These symptoms kept him awake throughout the night, and in the morning he sent for me.

He stated that he had had two severe attacks of illness, one twelve years prior to the present one, and another seven years before. The first attack occurred in Naples, and was pronounced by the physicians there to be some affection of the bowels, the nature of which the patient did not understand. The symptoms were similar to the present attack. He was confined to his bed six weeks at that time, and it was nearly three months before he could resume his occupation. Seven years ago, while in Paris, he had an attack of what was termed typhoid fever, and was ill for two months.

For a month previous to his last illness he had not been as well as usual. He had diarrhœa alternating with constipation; but as he was not inconvenienced thereby he did not regard it as serious. Four days previous to his last illness, being an officer of the Seventh Regiment, N. Y., he drilled his men four hours without fatigue.

I found him with a pulse of 80, full and soft, with normal temperature, and with slightly flushed face. His abdomen was soft, but not tympanitic, and there was but one point of tenderness, on firm pressure of the abdomen, midway between the umbilicus and crest of the ilium on left side. When pressing firmly over the point the pain occasioned was not severe, but was sufficient to make him ask me to stop. He was walking about the room at the time, and I was inclined to look upon it as a simple case of indigestion, and accordingly advised him to take some castor-oil and laudanum, and if not better in the morning to send for me.

The next morning, the diarrhœa and pain continuing, I was requested to see him again. I found him dressed and lying on the lounge. His general condition had changed very little since my previous visit; his pulse was still below 80, but it had a firmness which I had not noticed at the previous visit. His abdomen was still soft, and the pain was the same as at previous visit. He had no nausea, but said that he had a constant desire to go to stool, and that he had noticed a streak of blood in his passages. His temperature was normal and his skin was moist. His tongue, however, was heavily coated, more heavily than I had noticed for a good while. I suspected peritonitis, although I threw out the possibility of its existence on account of the localized pain on the left side as its starting-point. If it had been the right side I should have thought of perforation of the appendix vermiformis as the cause. Again, I could hardly conceive of peritonitis developing without more constitutional disturbance and without more disturbance before the commencement of the illness. There was no point where I could detect dulness over the abdomen, and the seat of pain was examined with especial reference to this point. I thought it better to be on the safe side, however, and ordered him to bed, a poultice to be placed over the abdomen, and full doses of opium to be repeated as often as necessary to keep him free from pain. I saw him in the evening. The pain was relieved, and he allowed firm pressure over the abdomen. There was then no tympanitis. He felt so well that he asked me what I would allow him to eat. The thirst of the morning had disappeared, and he proposed the next day to go down to his business. I ordered him to keep quiet, but not to take the opiate unless he had pain. He slept all night without taking opium.

The following morning, when I visited him, he seemed a little more restless than the night before. His pulse was 90, and firmer in character, the tenderness was greater and more diffuse. His skin was a little dry and he complained of thirst; and there was a slight tympanitis at the lower portion of the bowels. I was pretty well satisfied from the character of the pulse, it being of that peculiar firm character of peritoneal inflammation, and the fact that abdominal respiration was altogether suspended, that he had localized peritonitis; and I immediately commenced the opium plan of treatment, ordering enough opium to keep the respiration at eighteen and insure freedom from pain; and from that time until his death he had no suffering. At no time did he have vomiting, neither did he assume the position of peritoneal patients, being able to turn from side to side with ease. He complained once or twice of difficulty in passing water, but the catheter was not used at any time. On the third day the abdomen became very tympanitic; the pulse was rapid, small, and thready; his respiration was quick and thoracic, and he died June 1, after four days' illness.

A post-mortem examination was granted to enable me to ascertain the cause of the peritonitis, and was made by Dr. Drake, thirty-six hours after death, the body being kept on ice. The abdomen alone was examined. It was not as tympanitic as at the time of death, for the reason that the undertaker had resorted to pressure to reduce the circumference of the body. On laying open the abdominal cavity the visceral portion of the peritoneum was found injected and roughened by fibrinous deposits over its whole surface. The omentum was very large, and adherent to the left iliac fossa. It was found that the edge of the omentum on

the left side had formed the portion of the wall of an abscess, and that the cæcum and portion of the ileum was carried across the abdomen to the left side, and was bound down on the left iliac fossa. In the fossa was an abscess containing about eight ounces of somewhat offensive and dark-colored pus. The walls of the abscess were formed by the omentum, cæcum, bladder, rectum, and abdominal wall. In the abscess was the vermiform appendix, which was elongated, distended, and perforated. The walls of this abscess were thick and pigmented, and the edges of the opening in the appendix were gangrenous.

In conclusion, Dr. L. referred to the interesting point in the diagnosis of the case.

Dr. O'Sullivan in this connection referred to a case of supposed perforation of the appendix, terminating in fatal peritonitis. It was to be regretted that no autopsy was allowed to verify the diagnosis.

INTRAOCULAR HEMORRHAGE.

Dr. Knapp presented a specimen of intraocular hemorrhage, removed by operation from a man aged 45, who became suddenly blind in one eye. On examination with the ophthalmoscope, Dr. Knapp diagnosticated intraocular hemorrhage. A different opinion of the case was formed, however, by Drs. Noyes and Althof, who likewise saw the patient, and so firm were these gentlemen in their belief of the existence of a melosarcoma that Dr. K. extirpated the eye. On bisecting the organ the vitreous humor was the seat of an extensive hemorrhage, and no tumor was found. The specimen was not only interesting, in a clinical point of view, in showing the importance of accurate diagnosis in such cases, but in a pathological aspect was still more interesting as proving the formation of amyloid bodies in the lesion, in such quantity as to constitute a disease by itself—a condition of things never before recorded. The source of the hemorrhage was not ascertained.

RENAL HEMORRHAGE.

Dr. Hall exhibited a specimen of renal hemorrhage, with the following history, from Dr. McBride:—

David A. W., aged 27, admitted to Charity Hospital March 19. Feb. 13, '73, was attacked with pain in lumbar region, extending to abdomen, and attended with constipation, vomiting, loss of appetite, etc. On admission patient was much emaciated, and there was a marked aggravation of the symptoms described, in addition to which was muscular pains and swelling of the wrist and ankle joints. Urine contained a large amount of albumen with granular casts. Death occurred April 21.

Autopsy, 24 hours after death. There was catarrhal pneumonia of first stage, upper lobe left lung, and considerable fluid in pleural cavity of that side. The heart was normal; liver slightly decreased in size; spleen small and firm. Follicles of intestine enlarged, but no ulcerations were found.

On removing the viscera the left side of the abdominal cavity was occupied by a large dark tumor behind the peritoneum and extending from the diaphragm above to within a few inches of Poupart's ligament below. It presented the appearance as if an abdominal aneurism had burst, and in consequence of a suspicion in that direction the aorta was opened. It was found healthy. The venæ cavæ, vena porta were also examined and found normal. On removing the mass, which proved to be an immense clot, the kidney was found in its centre. The source of the hemorrhage seemed to be on the parenchyma of the organ, in which was a blood-cyst, which had ruptured. The kidney itself was in an advanced stage of fatty degeneration. The clot was quite soft, presented no appearance of lamination, and was effused in different places between the capsule and cortex of the organ. No secondary deposits were found in any other part of the body.

The Society went into executive session.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from July 4, 1873, to July 18, 1873.

Peters, D. C., Surgeon.—Granted leave of absence for 30 days, with permission to apply at Headquarters Division of the South for an extension of 30 days. S. O. 106, Department of the Gulf, July 1, 1873.—Retransferred from Department of the Gulf to that of the South, and on expiration of his present leave to report in person for orders to Headquarters Department of the South. S. O. 36, Division of the South, July 4, 1873.

Greenleaf, Chas. R., Assistant Surgeon.—Granted leave of absence for 3 months. S. O. 137, A. G. O., July 9, 1873.

Woodhull, Alfred A., Assistant Surgeon.—To report in person to the Commanding General, Department of the South, for assignment to duty. S. O. 143, A. G. O., July 15, 1873.

Brooke, Jno., Assistant Surgeon.—To repair temporarily to Portland, Oreg., and report to the Attending Surgeon for medical treatment. S. O. 78, Department of the Columbia, June 24, 1873.

Smart, Chas., Assistant Surgeon.—When relieved by Assistant Surgeon Meacham to report in person to the Commanding General, Department of the Platte, for assignment to duty. S. O. 143, c. s., A. G. O.

Phillips, H. J., Assistant Surgeon.—Assigned to duty with troops about to march to the Columbia River. S. O. 76, Department of the Columbia, June 20, 1873.

Miller, Geo. McC., Assistant Surgeon.—Assigned to duty at Camp Grant, Arizona Territory. S. O. 51, Department of Arizona, June 20, 1873.

Lippincott, H., Assistant Surgeon.—When relieved by Assistant Surgeon King, to comply with orders received from War Department. S. O. 125, Department of the South, July 12, 1873.

Koerper, E. A., Assistant Surgeon.—To report to Commanding General, Department of the Lakes, for assignment to duty. S. O. 137, c. s., A. G. O.

Meacham, Frank, Assistant Surgeon.—Assigned to duty at Fort Monroe, Virginia. S. O. 143, c. s., A. G. O.

King, Wm. H., Assistant Surgeon.—Assigned to duty at Atlanta, Ga. S. O. 125, c. s., Department of the South.

Medical Items and News.

University of Michigan and Homœopathy.—To answer numerous inquiries, the following preamble and resolutions, passed by the Board of Regents at a late meeting, are published:—

Whereas, The Legislature of the State of Michigan at its last session re-enacted the law of 1855, requiring the appointment of Homœopathic Professors in the Medical Department of the University; and, whereas, it has always been claimed by the Board of Regents that the law was an infringement upon the rights and prerogatives of the Board; and, whereas, the Supreme Court of the State has refused to grant a mandamus requiring the Regents to comply with the law, thereby substantially confirming their action, therefore,

Resolved, That we maintain the position heretofore taken, and decline to make the appointments required by the law.

Resolved further, That we do this in no spirit of factious opposition to the apparent will of the Legislature, but because we believe the true and best interests of the University demand it.

Resolved, That we re-affirm the former action of the Board expressing a willingness to take official charge of an independent school of Homœopathy, and connect it with the university, whenever the means shall be provided for the payment of its professors.

Resurrectionists.—Henry Day, Esq., a prominent member of the New York Bar, writing from Edinburgh, Scotland, to the *New York Observer*, remarks as follows: Many of the plots in the old burying-yards of Edinburgh are covered with a strong iron grating, fastened at the corners into hinges set in masonry, and these gratings are locked with heavy padlocks. Fifty or more years ago, the practice of robbing the graves by the so-called resurrectionists, for the dissecting-room, was carried to such an extent that this device was adopted to protect the graves. Guard-houses were also erected.

Anecdote of Dr. Louis.—The late Professor Louis, of Paris, was, at one time, president of the *Société médicale d'observation*, the members of which were to take complete daily observations of the cases which they were called upon to treat. Their mode of questioning their patients was so strict that M. Ricord was led to make sport of them, and M. Louis especially, by representing the following dialogue to have taken place.

Presupposing that Dr. Louis has been called to attend a stoker on a locomotive, who has been run over by his engine, he commences by asking him,—

Well, my friend, do you have much pain?

Can you cough?

Is this the first time such an accident has happened to you?

Has anything of the kind ever before occurred in your family, etc., etc.

State Medical Society of Virginia.—The officers elected for the ensuing year were: *President*, Dr. Harvey Black; *Vice-Presidents*, Drs. A. S. Payne, H. Latham, R. K. Burgess, J. H. Claiborne, S. Kennerly, and O. Fairfax. The next meeting is to be held on the second Tuesday in November, 1873, at Norfolk.

Hartford Medical Library and Journal Association.—The following is a list of the officers of the Hartford Medical Library and Journal Association: President, Dr. W. A. M. Wainwright; Vice-President, Dr. C. A. Dennison; Corresponding Secretary, Dr. C. A. Hart; Recording Secretary, Dr. J. Campbell; Treasurer, Dr. C. W. Chamberlain; Librarian, Dr. H. P. Atherton; Directors—Executive Committee, Dr. G. B. Hawley, Dr. C. W. Chamberlain, Dr. G. W. Russell, Dr. G. P. Davis, Dr. E. R. Hunt, and Dr. J. Campbell.

A Valuable Prize.—The *Nation* says the Royal Institute of Science, Literature and Arts, in Venice, offers a medal of the value of 3,000 francs, to be awarded in 1874 to the best essay on the following subject: "The advantages derived by the medical sciences, especially physiology and pathology, from modern discoveries in physics and chemistry; with a retrospective view of the systems which prevailed in medicine in past times." The medal is open to foreigners, and the essays may be written in French.

Tea.—Garway, the founder of Garraway's, claimed the merit of being the first to offer tea in leaf and drink for public sale in 1657, earning the patronage of many physicians, noblemen, merchants, etc., by retailing it at from sixteen to fifty shillings a pound, whereas, before he embarked in the trade, it was difficult to get it at the rate of six to ten pounds.

Jeddo School of Medicine, Japan.—Dr. Hilgendorf, Senior Professor of the Polytechnic Institute in Dresden, has accepted the chair of Natural Science in the School of Medicine at Jeddo, Japan. Dr. Cochins, late of the Victoria College in Berlin, has been elected Professor of Physics and Chemistry in the same college.

The Philadelphia Medical Register and Directory.—The publication of this Register, for 1873, is under the supervision of Dr. John H. Packard. It contains 308 pages, and much that is interesting to medical men in that section.

College of Physicians of Philadelphia.—The following officers were elected: for *President*, Dr. George B. Wood; *Vice-President*, Dr. Geo. W. Norris; *Secretary*, Dr. John H. Packard; *Treasurer*, Dr. J. Rodman Paul; *Recorder*, Dr. J. Ewing Mears; *Librarian*, Dr. Robert Bridges; *Censors*, Drs. Isaac Hays, Joseph Carson, Lewis Rodman, Edward Hartshorne; *Councillors* (for three years), Drs. W. S. W. Ruschenberger and James H. Hutchinson.

Braun.—Dr. Carl Rudolph Braun, the renowned Professor of Obstetrics and Gynæcology at the University of Vienna, has been raised to Knighthood, with the title of "Fernwald."

Philadelphia County Medical Society.—The following officers were elected for the ensuing year: *President*, Dr. Wm. B. Atkinson; *Vice-Presidents*, Drs. Henry H. Smith and H. St. Clair Ash; *Recording Secretary*, Dr. Henry Leaman; *Asst. Recording Secretary*, Dr. Lemuel J. Deal; *Corresponding Secretary*, Dr. Wm. Goodell; *Treasurer*, Dr. Wm. M. Welch; *Censor*, Dr. N. L. Hatfield.

Rush Medical College, Chicago.—Dr. Walter Hay, of Chicago, Ill., has been appointed Adjunct Professor of Principles and Practice of Medicine in the Western Medical Institution.

Homœopathic Journalism.—The editor of *The American Observer* (Homœopathic) states that of the fifty homœopathic periodicals that have been issued by the American press, only nine are now in existence; and of these, only one has remained under the same general editorial management for the space of nine years. The failures and wrecks are credited to "in-

efficient commanders, poor vessels (springing many a leak), bad canvas, and the loss of charts and compass."

Almost Instantaneous Death of a Physician from Carbolic Acid.—S. D. V. Hill, M.D., of Macon, Miss. (*Rich. and Louisville Med. Journ.*), writes that Dr. R. S. C. Foster, one of the oldest practitioners of his county, left town at nightfall with a friend, having a flask of whiskey in one pocket and a bottle of Calvert's liquid carbolic acid No. 5 in the other. After riding two miles, and being cold, he proposed to take a drink of the whiskey, and took out of his pocket the carbolic acid, withdrew the stopper with his knife, and after offering his friend some, who refused, took about half an ounce before discovering his mistake. He died in ten or fifteen minutes after entering the cabin of a negro. A quantity of mustard and lobelia were given him, but of course it produced no emesis. The poison seemed to produce sudden and fatal sedation of the nerve-centres; he states that he must have died without much suffering. Dr. Hill testifies that Dr. Foster was perfectly sober at the time, and was a man much above mediocrity in intellectual ability. The mistake was made by the two bottles being about the same size and shaped alike.

The Medical Register and Directory of the United States.—Dr. S. W. Butler, of Philadelphia, desires us to say that work on this important publication is resumed with energy, and it will be issued as soon as the vast amount of material can be collected and arranged. The coöperation of medical men in every section of the country is earnestly solicited in replying to circulars, which will be sent out, and in giving brief outlines of the history of medical institutions, hospitals, colleges, etc.

Antimony.—A new source of antimony of excellent quality has been discovered in the Italian Alps, by W. P. Jervis, the director of the Industrial Museum of Turin. This observer has in press a large volume on the "Practical Mineralogy of Italy," containing accurate analyses of the more important minerals.

Peruvian Skulls.—The Anthropological Institute of Great Britain has received a present of 150 specimens of Peruvian skulls from Consul Hutchinson, of Callao, which were dug out of the old aboriginal burying grounds of Pasamaye and of Ancon.

Embryology.—Professor Hyatt, of Cambridge, Mass., by means of sections of the central spirals of Ammonites and Goniatites, has been able to obtain some valuable results on the subject of the Embryology of Fossil Cephalopods.

A Proposed Museum of Distorted Pelves.—The Philadelphia Obstetrical Society, William Goodell, M.D., President, makes an appeal for aid in the formation of a Museum of Distorted Pelves, Obstetrical and Gynæcological Instruments, and earnestly solicits such specimens of contracted Pelves as may be in the possession of members of the medical profession, who may be willing to assist in forming a collection which will allow a wider and more comprehensive survey of this subject. If the original specimen cannot be sent, casts or photographs are solicited. Specimens of Instruments, Pessaries, and special mechanical contrivances are also desired. All objects for the museum may be sent to the secretary of the society, Dr. J. V. Ingham, No. 1342 Spruce street, Philadelphia, who will at once acknowledge their receipt.

Society of the New York Hospital.—The annual report of this society, for 1872, shows that the total receipts were $611,801.12, and the expenditures $596,884.65. The annual expenses of the hospital for ten years prior to its close averaged over $20,000, more than its receipts, as State aid had been discontinued.

Gordenio.—Wm. Gordenio was the first person upon whom the degree of Doctor of Medicine was bestowed. He received it from the college at Osti in 1320.

Tyndall's Receipts in America.—It is said that Professor Tyndall received 23,100 dollars for the course of thirty-five lectures delivered in the United States. After deducting expenses, he handed over 13,000 dollars to a committee, with instructions to spend the money in encouraging and aiding students of science who devote themselves to original investigation.—*Students' Journal and Hosp. Gaz.*

American Medical Association.—The following resolutions, introduced by Dr. Franklin Staples, of Winona, were passed almost unanimously by the Minnesota State Medical Society at its semi-annual meeting held at Mankato, Minn., June 10th.

Resolved, That as physicians we appreciate and acknowledge the importance and value of the *American Medical Association*; that such an organization is indispensable, not only to the government of the profession in the ethical relations of its members, but as an aid to the highest advancement of the science and art of medicine in this country; that it tends to promote these ends by the establishment and maintenance of a national code of ethics, and by furnishing a standard for, being the head and centre of, and giving an impetus to, all our local medical societies.

Resolved, That the history of the American Medical Association for the past few years has developed the fact that important changes in its organization and government are required to secure its perpetuity and highest usefulness.

Resolved, That the following are among the more important reformatory measures needed, viz.: 1st, such a change in the By-Laws of the Association as will keep all ethical questions as far as possible out of the public meetings of the Association, and that, in our opinion, the plan proposed at the last meeting by *Dr. N. S. Davis*, of Chicago, to refer all questions of a personal and ethical character directly to a judicial council for decision, would best accomplish this object; and 2d, a restriction of the membership, so that only permanently organized State and recognized county or district medical societies, and the medical departments of the army and navy, shall be permitted to send delegates to the National Association.

Resolved, That while we admit existing imperfections and are willing to aid in effecting improvements in the organization and working of the American Medical Association, we heartily disapprove any and all manifestations of a spirit of fault-finding among the profession, or in the medical journals of the country, that has not at least a practical suggestion to offer in the way of reform.

Resolved, That we have heard with pleasure the report of our delegation in attendance upon the late meeting of the National Association as presented to us by Dr. A. B. Stuart; that we are gratified with the harmony and good feeling prevalent in that meeting; that, in various actions of the Association, among which was that to reorganize the sections, the vesting of discretionary power in the Committee of Publication in regard to papers which shall appear in the *Transactions*, and the provision for complete stenographic reports of the proceedings of the various sections, we can see evidence of efficient work in the right direction.

Resolved, That the *Minnesota State Medical Society*

hereby pledges itself to labor for the advancement, the improvement, and the perpetuity of the American Medical Association rather than for its destruction.

NEW YORK FREE DISPENSARY FOR SICK CHILDREN.—The Second Annual Report for the year ending March 31, 1873, shows that 4,661 children, chiefly infants, received medical and surgical relief during the two years it has been established; 2,672 were treated in the past year. The beginning of the second year found but $815.61 of funds in bank; its close exhibits $5,397.15, with which to enter upon the third year. *Attending Physicians*, Drs. P. B. Porter, John C. Jay, Jr., H. T. Hanks, David Magie, B. F. Dawson, F. H. Rankin. *Consulting Physicians and Surgeons*, T. G. Thomas, Thos. Addis Emmet, Fordyce Barker, J. B. Reynolds, Willard Parker, J. Marion Sims, T. M. Markoe, J. S. Thebaud, J. Kammerer, J. J. Hull.

ALBANY MEDICAL COLLEGE.—The Circular of this College, Department of Medicine, University of Albany, for 1871–72, exhibits the names of 100 students who attended lectures in 1872, and those of 25 graduates. The college library contains about 5,000 volumes, which are accessible to students. Since its organization in 1839, diplomas have been conferred upon 1,116 graduates.

NEW YORK HOSPITAL AND BLOOMINGDALE ASYLUM.—The annual Report of the Governors of the Society of the New York Hospital for 1872 gives the following particulars: The Hospital Library contains 9,074 volumes, 408 of which have been added during the past year. Two hundred and ninety-nine insane patients were treated in the Bloomingdale Asylum for the Insane, in the same time; of these, 124 were males and 175 females. Recovered, 46; improved, 37; not improved, 25; died, 21. Remaining, Dec. 31, 1872, 170. Since 1821, 6,149 patients have been admitted to the asylum.

ENGLISH MIDWIVES.—The London correspondent of the *Philadelphia Medical Times*, in a recent issue, writes that it is calculated that there are ten thousand midwives practising in Great Britain, and that from 30 to 60 per cent. of the women in many rural places and manufacturing towns are delivered by midwives, many of whom are very ignorant. A great excess of mortality among lying-in women is the result. A deputation of the Parliamentary Committee of the British Medical Association has waited upon the President of the Local Government Board, on the subject of establishing an examining and public register of trained midwives.

CRANIOLOGICAL COLLECTION.—The 150 skulls contributed to the London Anthropological Institute by Consul Hutchinson of Peru, will be presented to the Museum of the Royal College of Surgeons.

OLIVE-OIL TRADE OF NICE.—The olive-tree is planted over an extent of 15,000 acres at Nice, and the average yearly produce is from 180,000 to 200,000 gallons. The analysis of the best oil produced in that district is as follows: carbon, 77.21; hydrogen, 13.36; oxygen, 9.43.

LUNATIC ASYLUMS.—Tennessee is to have two new insane institutions; one in the eastern and the other in the western division of the State.

Dr. Daniel H. Kitchen has been promoted to be second Assistant Physician of the New York State Asylum at Utica, *vice* Dr. Walter Kempster, appointed Superintendent of the Northern Wisconsin Hospital for the Insane. Dr. William S. Whitwell, late of Charity Hospital, has been appointed third Assistant Physician to fill the vacancy.

Dr. W. S. Chipley, formerly Superintendent of the Eastern Lunatic Asylum of Kentucky, has been reappointed to that position, in place of Dr. John Whitney, whose time of service has expired.

DEATH OF DR. TYLER SMITH, OF ENGLAND.—The death of this eminent physician took place from apoplexy, in one of the suburbs of London, on the 22d of June. He was found insensible by the roadside and expired shortly afterwards. For some time he had been suffering from Bright's disease of the kidneys and arterial degeneration, and had recently several attacks of epistaxis and subcutaneous ecchymosis. He was fifty-nine years of age at the time of his death, and for nearly half of that time had been prominently known as an obstetrician both in England and abroad.

VERMONT ASYLUM FOR THE INSANE.—Dr. Joseph Draper, formerly an assistant physician in the Vermont Asylum, and more recently in the New Jersey State Asylum, has been appointed superintendent to fill the vacancy occasioned by the resignation of Dr William H. Rockwell.

BELGIAN INSANE ASYLUMS.—The Belgian Government has recently ordered securely-locked letter-boxes to be placed in all the insane asylums of the country, public or private, in positions where they will be easily accessible to all the inmates. They are designed to allow complaints and suggestions to be made to the authorities in a way independent of any of the officers or attendants. No one connected with the institution can have access to them. They are in charge of the *Procureur du Roi* of the district, and the letters they contain are taken to him weekly for examination. The complaints are then investigated, and if any one claims to be sane, the case is ordered to be examined by medical experts. Abuses are corrected. The system, it is said, exerts a wholesome influence, and tends to secure proper management in all its details.

TREATMENT OF BILIARY CALCULUS BY CHOLEATE OF SODA.—Schiff admits that these calculi are formed of cholesterin, not because this substance is formed in too great abundance, but because the bile does not contain the principles which maintain it in solution. These are the cholates and choleates of soda and potassa, more than the alkalinity of the bile which dissolves the cholesterin. Schiff therefore advises the administration of eight grains of choleate of soda, to be given twice daily, and increased until "saturation" is indicated by irregularity of the pulse, which becomes slow during repose and accelerated by the least effort. The dose may then be diminished, but not entirely suspended—a considerable time, a week at least, being required for the remedy to produce amelioration of the symptoms.—*Imparziale & Gaz. Heb.*

Original Lectures.

MICROSCOPIC FUNGI.

LECTURE DELIVERED AT THE COLLEGE OF PHYSICIANS AND SURGEONS.

By JOHN C. DALTON, M.D.,

PROFESSOR OF PHYSIOLOGY.

[Phonographically reported for the MEDICAL RECORD.]

GENTLEMEN:—I do not expect to be able in this evening's lecture to give you a complete account of all the microscopic fungi, and shall only direct your attention to individual examples of those which are perhaps the most important, or will be of most assistance to you in a physiological point of view. I wish simply to present to you an idea of what fungi are, in what way they grow, and in what way they are related to each other; so that you may better understand the books devoted especially to this subject. Microscopic fungi of all kinds belong to or represent a similar class of vegetation. An ordinary flowering plant presents to the eye externally certain very well-marked parts. Besides a very complicated microscopical structure, it has a root, a stem, branches, twigs, blossoms, and fruit.

In the interior it is composed not only of vegetable cells, but also of cells which have taken on a different formation and become fibres or ducts, marked by a peculiar outline, and tubes occupied by the life-element of all vegetable growths. The internal structure of the flowering plant, accordingly, is an exceedingly complex one, while that of the fungi, the microscopical as of all the flowerless plants, is comparatively simple. If you will notice one of the larger fungi, as the mushroom, for example, you will see that it consists, so far as regards its external configuration, of what may be called a stem, irregular in form, and loosely set upon the ground, and covered with an umbrella-like cap, upon the under surface of which there are radiating laminæ, or folds of soft substance, diverging from the upper part of the stem to the edges of the cap. These folds are the parts of the fungus where the so-called fruit is produced. The mushroom has no root, properly speaking, and its stem is the only part which shows much resemblance to that of a flowering plant. Its umbrella-shaped cap represents the branches, foliage, and fruit all combined.

If you now take a small piece from any part of the mushroom, tear it up with needles, and place it under the microscope, you will find in it nothing but cells. No matter how large the plant may grow, no ducts will be found in it, no tubes, no fibres, no glands,—nothing but cells. Its soft, spongy, semi-solid material is made up of cells alone. Sometimes the cells are seen to have an elongated or cylindrical form, but that is all. There is nothing in them like the compound structure of the higher forms of vegetation. These are the characteristics which are common to all fungi.

It is, however, the microscopic fungi in which we are now particularly interested at present; and by this, of course, we mean those which require the use of the microscope in order to recognize their distinctive characteristics.

Perhaps the most familiar examples of this class are those of the common moulds. All the varieties of moulds, mildew, and smut belong to the same group, and they all go to make up the great division of microscopic fungi. It is these lower forms of vegetation which come into contact with our medical studies, and sometimes rise into considerable pathological importance.

It is a fact which doubtless you all have noticed, that when leather, or anything which is made of leather, is left for some time in a damp and dark place, after a while it will become covered with layers of whitish material like spots or stains, or as if it had been dusted with some white powder. If, however, the material be examined, it will be found to consist of a microscopic fungus. On a close examination, it is seen to be composed of two parts; namely, a vegetative part and a reproductive part; and in this respect this white mould of leather will answer as an example for all the microscopic fungi. The greater part of the white leather-mould is composed of a network of minute interlacing filaments, having the form of tubes; but they are in fact cells, lying in contact for a certain distance and then most frequently bending or curving in various directions, and sometimes branching, each filament frequently sending out a lateral prolongation, which itself divides and thus gives origin to another secondary division. If several of these branching filaments are followed in the field of the microscope, they are seen to produce a network such as is represented here upon the blackboard. These filaments are more or less divided by transverse partitions, and are thus formed of elongated cells, placed end to end. Their substance is very slightly granular, almost always absolutely colorless, and sufficiently transparent to permit us to see distinctly their outlines, even when closely entangled with each other. This network of filaments is what is called the *mycelium* of the fungus, or its vegetative portion. There is no fructification here; nothing but a repetition of elongated cells and filaments. The mycelium will continue to spread almost indefinitely, extending outward from the centre by the continuous growth of branching diverticula, which in their turn produce other elongated cells and filaments. This vegetative part of the fungus, or its mycelium, is not, in general, sufficiently characteristic to indicate any particular species, but is very similar in its appearance in all of the microscopic fungi. Besides its mycelium, however, the fungus has also a *reproductive* part, in which is produced a kind of fruit somewhat analogous to the seed of the higher plants.

In this very mould which appears upon the surface of leather, you will see some of the fibres which are rather larger than the rest, and stand up in a vertical position. They grow in this direction until, after a time, they become expanded at the top into a globular-shaped extremity, and about this are placed radiating, club-shaped cells which adhere to the sides of the globular head. On the extremity of each of these club-shaped cells there grows a very highly refractive body of an ovoid or spherical form; so that we have the whole head covered with a crown or globular mass of club-shaped cells and refractive spherical bodies. These little refractive spherical bodies are the spores of the fungus.

What we mean by a "spore" is this: The flowering plants produce a seed, which is itself formed from the fertilized germ. What we call a seed is therefore really an embryo; and the germ of the flowering plant requires to be fertilized by the pollen before it can become a seed capable of reproduction. Hence we have, in these cases, both a male and a female element; and the germ of the plant needs to be impregnated in order to reproduce its kind, as much as the

ovum of an animal. But it is not so in the case of the fungus; or at least if such be the case, we do not at present know how the process is accomplished.

The fungus, in fact, produces a globular body which, without any special impregnation so far as we know, has the power of reproducing a like fungus, as the fertilized seed of the flowering plant may do; and to this reproductive body the name of spore is given. In this case the spores are produced on the outside of the globular head which crowns the stalk. Great care, however, is necessary in order to show them completely in microscopic examination. The fungus growing in this way upon leather is known by the name of *Aspergillus*, from the appearance of its reproductive part, because it looks something like the nozzle of a watering-pot (aspergillum). The whole group or genus of microscopic fungi which present this peculiar and characteristic form of reproduction all go by the name of aspergillus. This particular species growing upon leather is called the *Aspergillus candidus*, because its reproductive part is colorless, and appears white by reflected light.

There is also a greenish-blue and a black aspergillus, all resembling each other in every particular, excepting the color of the spore-heads. We now see the distinction between the mycelium and the reproductive portions of a fungus.

In the examination of microscopical fungi it is well to recollect that you can hardly ever distinguish them with certainty by their mycelium alone; for the reason that this is often very similar in different species and genera. You will always see in it tubular filaments, more or less divided by transverse partitions, more or less curved and ramifying, more or less transparent and colorless, and more or less granular. The mycelium of the same species, also, will sometimes grow differently according to the variation in surrounding circumstances, such as the degree of light, moisture, temperature, etc., etc.

It is the reproductive part, on the other hand, that marks distinctly the genus and species. When, therefore, you see the reproductive filaments standing upright, each crowned with a globular head surrounded by club-shaped cells bearing spherical spores, you know that the fungus in question belongs to the genus aspergillus, and if the spore-heads are white, it is the "aspergillus candidus."

The spore, when ripe, is discharged from the head of the reproductive filament, and if transported to a favorable locality, immediately begins to germinate, sending out a little tube-like prolongation, which increases in length, divides and ramifies, until after a while there is produced another mycelium, at a distance from the first, by the growth from the germinating spore.

This description will answer for a general sketch of the main features of microscopic fungi.

I next propose to speak of two fungi which are particularly interesting as being connected with the process of decay, or rot in fruits. These two fungi exist and grow as parasites in the decaying fruit. It may perhaps occur to you that fruit is not a living thing, and therefore that it is hardly proper to speak of its fungus as a parasite; but a moment's consideration will convince you that fruit is really alive, since it contains the seed which has the power of germination and growth; so that really the fungus is just as much a parasite, whether living in the fruit, the leaves, or the stem of a plant, or in the tissues of a living animal.

First, then, with regard to the nature of the process of decay, as we commonly see it in fruit. The true nature of this process has not been understood until within a recent period.

It was formerly supposed to be a kind of continuation or exaggeration of the ripening process; that it was simply a series of chemical changes going on in the interior of the fruit, a sort of addendum to those which had already taken place and by which the fruit had become ripe. This, however, is not true, for in the first place if the ripe fruit be kept with certain precautions, it may never rot at all. It may wither and dry up, but that is a very different thing. And, on the other hand, a fruit may sometimes decay when it has never become ripe.

We know very well what are the ordinary appearances presented by decaying fruit. The decayed part is readily recognized by its change in color, a softening in consistency, an altered unwholesome taste and a disagreeable odor. These changes present an appearance which is easily recognized.

There is one feature of this process which is of peculiar interest, and which has been known, I think, from time immemorial. That is, that there is an element of contagion about it which is very well marked and easily observed. The rot is communicated by contact. It is as if you were to take venom from a diseased tissue and place it in contact with sound tissues. In that case the sound tissues will become infected. In the same way the sound tissues of the fruit are infected by the contagion of rot, just as a man will take small-pox from a patient already suffering with that disease. Perhaps it is hardly necessary to call attention to this, but where you see decay occurring in fruit from this cause, it always appears upon the surface at exactly the point of contact; and it is contagious precisely in the same sense and to a similar degree as any communicable disease with which we are familiar. Now decay, as I have said, is always accompanied by the appearance of a fungus. This fungus grows in the cellular substance of the fruit. Its filaments penetrate and ramify between the cells of which the pulp of the fruit is composed. These filaments are small, and send their branches among and around the fruit-cells and envelope them everywhere in a network of mycelium. The filaments of this mycelium for their growth require nourishment, and they take it from the substance and juices of the fruit. It is this process of absorption and chemical transformation by the growth of the fungus that produces the alterations in the fruit which we know as decay.

There are two kinds of microscopic fungi which are the most common in decaying fruit. The first and most frequent is that known as *Penicillium glaucum*. This fungus, like the others, has its mycelium and its reproductive part. The latter consists of filaments bearing a tuft of from four to eight little branches, which in turn produce upon their extremities a chain or chaplet of small, highly refractive oval spores. It is called Penicillium on account of the brush, or pencil-like tuft of its spore-bearing filaments, and "glaucum," for the reason that its tint, when in fructification, is that of a bluish green.

[Some oranges were shown which were covered in places with this growth.]

The fungus grows most readily in a damp atmosphere, and it will cease to grow if the air be entirely deprived of moisture. As you see here, the white mycelium generally occupies the external portion of a decayed spot, while the bluish-green fructification occupies the centre.

The other form of fungus which grows in decaying fruit is the *Mucor mucedo*.

This species exhibits a very similar form of mycelium to the last, but its mode of fructification is different. The reproductive filament bears a globular swelling upon its superior extremity, but the spores, instead of growing upon the outside, as in aspergillus spores, are produced in the interior of the globular sack.

We have thus three different genera of microscopic fungi which we have now noticed; namely, Aspergillus, Penicillium, and Mucor.

In all three the mycelium is very similar, while the reproductive part, on the contrary, is different in each; and it is the form of this reproductive part from which the genus derives its name. The two latter are both apt to appear in decaying fruit. Their physiological properties vary mostly in the rapidity and extent of the changes which they induce. The Penicillium grows rather slowly, and produces comparatively less alteration in the physical properties of the fruit than the Mucor.

The latter causes a great amount of softening and discoloration, and is accompanied by the evolution of a considerable quantity of carbonic acid, in consequence of which the decaying fruit is apt to appear tumefied from the accumulation of the gas in its tissues. Otherwise the changes produced by the two fungi are nearly identical.

When a fruit is invaded by either one of these, the mycelium filaments penetrate everywhere through the cellular substance, spreading continuously in every direction from the point where it was introduced. But the fructification of the fungus does not take place except when it comes in contact with the atmosphere.

Take, for instance, a fruit like the apple or pear, in which the epidermis is smooth, dense, and resisting. In such a case the interior of the fruit continues to be invaded by the mycelium, yet fructification does not take place, because the air is not present to assist the process, and the fungus may not appear externally perhaps for a long time. In fruits with a delicate epidermis, on the other hand, such as the strawberry or the orange, the fungus readily penetrates from below through the epidermis and covers the fruit with an abundant fructification, sometimes in a remarkably rapid manner.

Now you see why it is that decay is contagious. It is because it is produced by the communication of a fungus from one fruit to another. It is the presence and growth of a fungus that causes the decay. This can be very easily demonstrated by placing sound oranges, for example, in contact with a decayed one; and in the specimens which you see here, this appearance is prevented, because the mycelium has spread from one point to another, the contagion being accounted for by the presence and continuous growth of the fungi.

There is another condition, however, which is necessary before such contagion can be effectual; and that is, a wound or rupture of the epidermis. The epidermis of most fruits is too firm for the penetration of the delicate fungus-filaments through its surface. There are, it is true, some fungi which have the power of penetrating the leaves and tissues of growing plants from the exterior, but these two are not among them; therefore, in order that a fruit should decay, the epidermis must be broken and give access to the fungous growth. All these points have been most satisfactorily examined by Davaine, in France. He showed that some injury of the integument was necessary for the contagion of decay to be communicated. He took some apples, and placing them in contact with decaying ones, found that if the epidermis were uninjured, they did not decay; but if the integuments of the sound apples were first wounded, the decay was soon communicated to them. If the apples are perfectly uninjured, they may remain for several weeks even enclosed in the interior of a rotten one, without suffering any alteration. There is still another point which is of importance in this connection. I have thus far spoken of the decay as produced by the presence of the fungi. But the question will at once occur to you, whether this is really the fact. Supposing that we have these two phenomena in company with each other, namely, the decay of the fruit and the growth of the fungus, we might explain it in either of two different ways. We might, on the one hand, regard the growth of the fungus as the cause of the decay; or on the other, the decay as the cause of the fungus. For the fungi are plants; and all plants require a particular kind of soil to sustain them, and will not grow in any other. The water-plant, for example, must grow in the water, and the land-plant must grow on the land.

We might suppose, therefore, that the Penicillium was merely a fungus adapted for growing in the substance of decaying fruits, and therefore always found associated with it. M. Davaine, however, showed not only that the fungus was accompanied by decay, but that it was its cause. This was demonstrated by the results of inoculation. By inoculating sound fruit with the spores of Penicillium, it was proved that decay originates and spreads from the points of inoculation. The evidence is the same in character as when a patient is inoculated with vaccine virus, and the pustule follows as a consequence.

This makes it altogether probable that the decay is a direct consequence of the fungous growth. There is only one point which still remains open to question. In order to inoculate the fruit with the fungus, its epidermis, of course, must first be wounded. Under these circumstances is it not doubtful whether the decay may not be due to the chemical influence of the atmosphere, thus admitted to the interior of the fruit and coming in contact with its cellular substances? Experiment shows, however, that the chemical action of the air alone will not cause decay. For if two apples be wounded on the surface in the same way, and one of them inoculated, in addition, with Penicillium, the inoculated apple will rot, while the other will remain sound.

[Examples of apples treated in this way were then shown.]

There is no question, therefore, that the decay of fruit is really due to the growth of the fungus. Microscopic fungi will not only grow upon fruit, but also upon living plants, and sometimes will attack and destroy very valuable crops.

One of the most remarkable of these parasitic fungi is that which appears upon wheat. It not only is interesting in itself, but it also brings to our notice two very extraordinary features, sometimes connected with the growth of microscopical fungi, and especially those which appear upon the cereal plants.

These two peculiarities are, first, that of the alternation of generations, and second, migration of the fungi from one plant to another.

In the first place, what do we mean by the term "alternation of generations"?

Perhaps it may be best understood by remembering that in all ordinary cases with which we are familiar, the successive generations do *not* alternate; but the same one constantly repeats itself, without deviation, in a regular and continuous series. For example, if we sow wheat, we always get wheat as a crop; if we plant potatoes, we get potatoes, etc. etc.

Suppose, however, that turtle-eggs, instead of hatching into turtles, should produce a brood of oysters, and these in turn should give rise to star-fish, and from these again turtles should be produced. This would be an example of the alternation of generations, and something almost as remarkable happens in the parasitic fungus which grows upon wheat. Properly speaking, however, the term alternation of generations is not exactly a correct one.

There is no instance in which really different species of animals or plants follow each other in this manner, nor are they ever related to each other in the way of progeny. On the contrary, the generations which follow each other all really belong to the same species.

It is true that they sometimes *look* very differently from each other; so differently that they have been occasionally regarded as different species. But time has always shown that in point of fact they are actually members of the same species, however different they may be in appearance. Still, the process is a very remarkable one. Perhaps it may be better illustrated by a supposition with regard to the butterfly or the moth and its caterpillar and chrysalis. The moth lays an abundance of eggs which hatch into caterpillars. The caterpillar feeds upon vegetable matters; growing very rapidly, until after undergoing certain changes and moults, it becomes a chrysalis; a creature without legs or organs of vision, without any motion, and hardly looking like a living thing. After a time the chrysalis again moults its integument, and comes out a perfect moth. These three creatures, therefore, are entirely different in appearance, so much so that we should hardly suppose them to belong to the same species unless we knew that they successively changed into each other. Suppose now that each caterpillar, instead of giving rise to a single chrysalis, should produce a hundred of them; and that each chrysalis should hatch into a hundred moths. That would be analogous to what we call the alternation of generations. Nothing of this kind takes place, in point of fact, in the case of moths and butterflies; but it will, perhaps, illustrate the points better than it could be done in any other way.

Now with regard to the microscopic fungi which really present the phenomena of alternation of generations. In the month of June, the young leaves of the wheat sometimes have upon them little narrow streaks of yellow or reddish color. If you will cut them open, they will be found to be little furrows or pustules in the substance of the wheat-leaf, which are filled with microscopic spores. These spores are the products of a mycelium growing in the substance of the leaf beneath. The spore-bearing filaments of this mycelium burst through the epidermis of the leaf, so that the spores are then brought into view. These are yellow in color, globular, or nearly so, in form, and about $\frac{1}{1000}$ of an inch in diameter.

Each spore has upon it a minute filament by which it was attached to the spore-bearing filament. The yellow spots upon the wheat-leaf are called by the farmers *rust;* because their color looks as if rust-powder had fallen upon the plant. The botanical name of the fungus is *Trichobasis*, from the hair-like filament attached to the base of the spore; and this particular species is called the "Trichobasis rubigo-vera," or the true rust-producing Trichobasis. It has long borne this designation, as a peculiar and independent kind of wheat-fungus.

If, however, you examine the same wheat a little later in the season, in the latter part of July or first of August, you will see that these yellow spots are then mingled with brown ones; and the later in the season the wheat is examined, the more numerous will be the brown spots in comparison with the yellow. These brown spots are also formed by a fungus, which has both spores and a mycelium. These spores are longer and thicker than those of Trichobasis, and are of a deep brown color instead of yellow. They are also double-celled, being divided internally by a transverse partition. The brown spots thus produced are the *smut* of wheat, as the farmers call it. The scientific name of the fungus is "Puccinia graminis."

The distinctive mark of this genus is the division of the spore into two cells. There are other allied genera in which the spores are made up of three, four, or five cells; but it is the two-celled arrangement which marks distinctively the genus Puccinia.

Towards the end of the season, we find nothing of these parasitic growths but the black or brown spots. Now, although these two fungi are so different in their external appearance, although the fructifying part is so different in each that they have for twenty years been enumerated as two different species, nevertheless the Trichobasis rubigo-vera and the Puccinia graminis are in reality the same thing.

Their vegetable part is identical; and it produces the two different kinds of spores at different periods of the season. The earliest spores, or those known as Trichobasis, are capable of germinating immediately, whenever transported by the wind or otherwise to a new lodging-place. During the early part of the summer, accordingly, the wheat-rust is undoubtedly disseminated in this way. The brown spores of Puccinia, on the other hand, are the spores of autumn. They do not reproduce their mycelium during the same year, but are intended to last over winter until the opening of the following spring. We have therefore really two generations growing upon the same stalk, two different reproductive organs produced by the same plant, having different structures and intended for different purposes.

The microscopic fungi are disseminated in two different modes: first, by immediate contact, as where the mycelium of the decay-fungus passes directly from one fruit to another; and secondly, by dispersion of the spores, which may be wafted in every direction by the atmosphere.

Perhaps the communication by spores is the most important of the two. For the very diminutive size of the spores and their extreme lightness render them liable to be caught up and disseminated by every breath of wind; and when they reach a favorable locality they at once begin to germinate and produce a new growth. The atmosphere, accordingly, is the great vehicle for the transportation of these spores, all of them being capable of reproducing their parent mycelium, and many of them giving origin to diseases of parasitic nature. There is no better example furnished us of the extreme delicacy and lightness of these spores than that shown by the common puff-ball.

This well-known fungous growth has an external envelope of a papery consistence, and is filled internally with a quantity of smoke-like dust, which is composed of nothing but spores. These spores, as you see, can be dispersed from the fungus like so much smoke; and each little puff which is discharged from its surface, carries with it literally millions of microscopic spores, which float in the atmosphere and are carried in every direction by the moving currents of the air.

Bowdoin College.—This college has sent out 1,765 graduates, and 1,093 of them have become physicians.

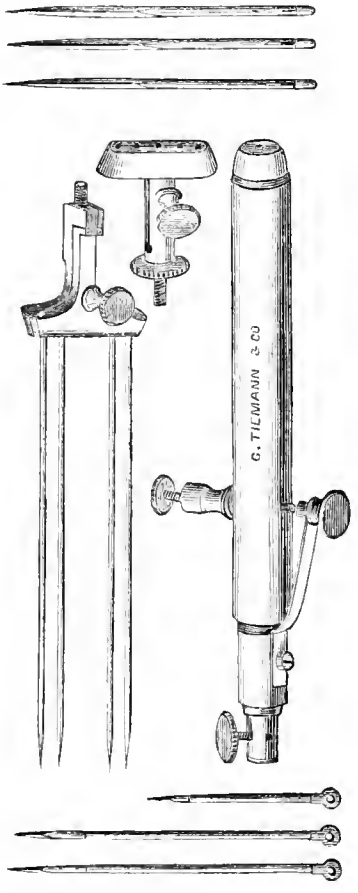
CLINICAL RESEARCHES IN ELECTRO-SURGERY.

By GEORGE M. BEARD, M.D., and A. D. ROCKWELL, M.D.

III.

CERTAIN DISEASES OF THE SKIN.

The accompanying cuts represent the needles—insulated and non-insulated—and needle-holders that we have been accustomed to employ in the operations recorded in this series of papers. The large spear-shaped needles, with sharp edges, we devised for the method of working up the base.

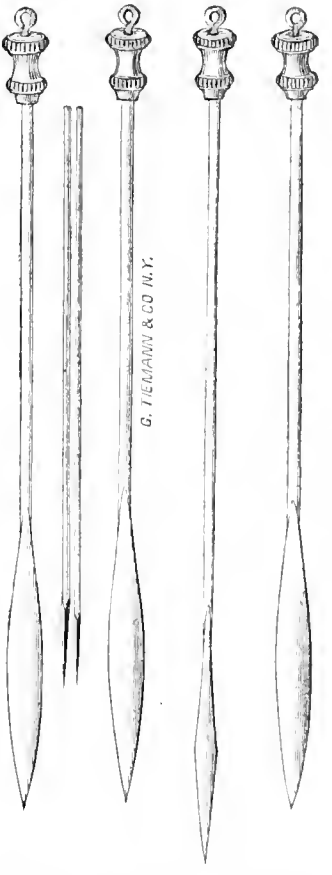


The theoretical arguments in favor of using electricity in diseases of the skin, and the methods to be employed, with the general results, we have elsewhere considered.* Our present purpose is to illustrate by cases what we have previously stated in an abstract form. We present the cases just as they appear in our note-book—the successful, the unsuccessful, and the doubtful.

We may, perhaps, so far repeat what we have previously written on the subject, as to state that in the electrical treatment of diseases of the skin both currents are required in the various forms of electrization, with wet sponges and cloths, with dry metals and the metallic brush. The best results are obtained by the *galvanic* current, and for reasons that will be clear, without argument, to those who are familiar with the differential action of the two currents.

During the past two years we have treated a number of cases of eczema, prurigo, and acne by *central galvanization* alone, *without* making *any application to the diseased surface whatever*; and under this method of treatment, the results have in some instances been more satisfactory than under any other method of using electricity in these affections.

*In central galvanization the negative pole is applied to the epigastrium (the patient holding it by an insulated electrode), while the positive is applied at the top of the head, over the region of the pneumogastric and the cervical sympathetic, in the neck, and down the entire length of the spine, in such a way as to bring the brain, the pneumogastric, the spinal cord, and all the prominent ganglia and plexuses of the sympathetic—indeed the whole central nervous system,—under the influence of the current.**



Not only after medication has failed, but after ordinary *localized electrization* has accomplished but little, central galvanization is sometimes rapidly and quite permanently efficacious. We should judge from our observations up to the present time that under this treatment the more *peripheral* patches of cutaneous disease yielded earlier than those on the trunk, and

* *American Journal of Syphilography and Dermatology*, January, 1872; also *Medical and Surgical Electricity*, pp. 600, 601.

* This method is described in full detail in the *New York Medical Journal*, October, 1872.

near the centre; for example, eczematous spots on the hands and feet would sooner show signs of improvement than spots of the same disease on the upper arm, leg, and back. The dependence of certain diseases of the skin—as eczema, acne, prurigo—on the nervous system is by the remarkable results of this method of treatment demonstrated in a most interesting and suggestive manner.

We first used central galvanization in hysteria, hypochondriasis, insanity, and other allied nervous affections, and the excellent results accomplished by it suggested its use in cutaneous affections.

ECZEMA.

It is an interesting comment on the value of theory in medicine that in eczema, which has not been supposed to be a nervous disease, the effects of central galvanization, according to our present experience, are as decided as in prurigo, and the results here recorded are more satisfactory than in almost any other form of cutaneous disorder.

At first we used localized galvanization in eczema, with sponges, cloths, and the metallic brush, and obtained thereby great relief of the itching, and in time cure; but during the past year we have used central galvanization for this disease, making no application whatever to the diseased surface, and have obtained far more rapid and we believe more permanent results. The following case illustrates the power of central galvanization in a most striking manner:—

SEVERE AND OBSTINATE CHRONIC ECZEMA OF LEG, EIGHT YEARS' STANDING—INTOLERABLE ITCHING—FAILURE OF VARIOUS REMEDIES—RAPID RELIEF AND PERMANENT CURE UNDER CENTRAL GALVANIZATION.

CASE I.—Mrs. S. M., an Irish servant-girl, aged 51, was admitted to the Long Island College Hospital, February 14, 1872, with chronic eczema of the left leg about the ankle, and extending one-third of the distance to the knee. The itching and pain were intolerable, and there was much soreness. The patient was in other respects strong and well, but had suffered from this affection by intervals for eight years. Four years before she had been under treatment at the City Hospital, and had been discharged apparently cured, but relapsed.

The case was treated by iodoform, arsenic, bicarbonate of soda, rhubarb, carbolate of zinc, glycerine, cod-liver oil, iodide of potassium, dulcamara, acetate of lead, wine of colchicum, and acetate of potash. These remedies were variously used, in various modifications externally and internally. From some of these agents the patient derived temporary relief of the itching and soreness; but the average and ultimate effect was that, on April 1st, the following record of the case was made in the hospital book: "Very painful, red and angry, rapidly extending, and now covering nearly the whole leg below the knee, and most of the dorsal aspect of the foot."

Arsenic and tincture of cinchon. comp. were now ordered, but April 15th, the record was: "very much the same." At this time, Dr. Davis suggested *localized faradization*. This suggestion was acted on with gratifying result; the intense distress was at once in a measure relieved.

April 16th, the patient was more comfortable than for a long time previous.

April 23d, very much improved and comparatively comfortable.

At this time Prof. A. B. Crosby, the surgeon in charge of the ward, requested us to see the patient, stating that she had been very obstinate under the various remedies that he had tried. The patient was suffering greatly from the severe itching and burning, and the soreness was so great that only with difficulty could she hobble about the ward. The appearance of the diseased part was red and angry, and some portions were more or less covered by scales.

We decided to try on the patient the effect of *central galvanization, making no application whatever to the diseased part*. We were induced to make this trial on the strength of successes in other and milder cases of cutaneous diseases. Our chief hope was, perhaps, to relieve the itching and pain; a permanent cure we had no reason to anticipate. As the patient was a good and willing subject on which to demonstrate electrical applications, she was taken before the class of the Long Island College Hospital, and treated by central galvanization, the statement being made, that we did not hope thereby to cure, but simply to illustrate the method of using electricity.

The details of the applications were entrusted entirely to Dr. Edwin E. Smith, house-surgeon, who carried out the treatment with great faithfulness, and to whom we are indebted for the full history of the case as here presented.

The relief of the itching and pain was very rapid, although on the 25th Dr. Smith made the following record: "A little more irritable." This result was probably due to over-treatment, too strong currents, or too prolonged applications.

April 30th.—Patient "much better."

May 10th.—"Still steadily improving." The appearance of the leg was now much changed for the better. The most obstinate portion was the region about the ankle. The applications were made four and five times a week with a 12-cell zinc-carbon battery of Kidder for about ten minutes at a séance.

May 25th.—A lotion of acetate of lead wash was ordered by Dr. Crosby, to contract the enlarged capillaries.

June 5th.—"Patient is walking about out-doors with comparative ease, and is nearly well."

At this we again presented the case before the class of the College, demonstrated on her our method of central galvanization, and pointed out the extraordinary and unlooked-for improvement. The skin of the whole leg, except around the ankle, was well, and the patient for a long time had been entirely free from itching and pain.

June 15th.—The patient was "discharged cured."

Jan. 13th, 1873.—Dr. Smith informs us that there has been "no recurrence of the difficulty."

The above case, taking all the facts into consideration—its long standing, its inveteracy under manifold treatment, and the immediate and rapid relief and cure under central galvanization, is certainly most extraordinary, and it will not subtract from the instructiveness and brilliancy of the result, if in future years a fresh attack of the disease should occur. Although the case was not, so far as we know, studied by any recognized specialist in dermatology, yet among the very many surgeons and physicians who watched its progress before and during the electrical treatment, there was, we believe, no difference of opinion in regard to the diagnosis, and there was no question that the cure was wrought entirely by *central galvanization, acting upon the central nervous system*, and thus improving the *peripheral* nutrition.

ECZEMA OF HEAD AND FACE AND LOWER LIMBS IN A CHILD; RAPID IMPROVEMENT, WITH DISAPPEARANCE OF THE ERUPTION UNDER CENTRAL GALVANIZATION.

CASE II.—John B., aged 3 months, was admitted to

the Electro-Therapeutical Department of Demilt Dispensary, March 8, 1872. The child was affected with eczema of the scalp and face, which was most marked between the eyes, and extended down the back, and on the legs from the knees to the feet.

The eruption was very moist, and the diseased part was covered with thick yellow scabs. The child was very restless at night; was very constipated, and could scarcely open its eyes. The case had been treated by various poultices and ointments. At that time we were experimenting with central galvanization in diseases of the skin, and we resolved to test the method in this case. After the third application the bowels became more free, the child slept well, and the eruption had dried up, and the scabs peeled off. At the end of two weeks the fourth and last application was given; the disease had then nearly disappeared from the back and legs. Since that time we have seen nothing of the patient.

It is proper to remark of the last case that, because of the situation of the disease, it was impossible to use central galvanization without directly acting on some portion of the diseased surface. It is possible, therefore, that the benefit was due in part to the local action of the current, and yet we were not able to trace any more rapid improvement in those portions thus slightly acted on than in the portions not touched by the electrodes.

The effect of merely localized applications is illustrated by the following case:—

CHRONIC ECZEMA OF THE LEGS AND FEET, ONE YEAR'S STANDING—RELIEF OF PAIN AND ITCHING UNDER LOCALIZED FARADIZATION AND GALVANIZATION.

CASE III.—Michael P., aged 64, had suffered for twelve months from chronic eczema of the legs and feet, accompanied with terrible itching and burning sensations. The affected parts were but little sensitive to the electric current, either galvanic or faradic. Localized galvanization and faradization were employed, and some of the time the electric brush with a strong current was not only well borne, but was most grateful to the patient. The applications were made from five to twenty minutes. *In all cases there was relief of the distressing pain.* Symptoms of relief began to appear soon after the beginning of the séance, and at the close was sometimes absolute. This relief lasted at first from two to twelve hours.

The patient continued treatment for three weeks—in all six applications were made. The intervals of relief were sensibly lengthened, and the patient abandoned treatment. With the relief in the itching and pain there was corresponding relief in the appearance of the diseased parts.

ECZEMA OF ARM AND HANDS; RELIEF OF PAIN AND ITCHING UNDER LOCALIZED GALVANIZATION.

CASE IV.—Mary C., aged 46, had been afflicted for some time with eczema of the forearm and hands. In the palm and back of the hand there was considerable disease, and the pain was very intense. She complained of severe itching and scalding. The general condition of the patient was very good. The hands were considerably swollen, and patches of various sizes appeared on the fingers.

Localized galvanization was used, with good results. There was relief of the pain; corresponding with the relief of the pain there was improvement in the appearance of the disease.

The patient abandoned treatment before an exhaustive trial had been made.

The advantage of central galvanization over merely localized applications was shown in the following:—

CHRONIC ECZEMA OF TWENTY YEARS' STANDING—LOCALIZED GALVANIZATION AND IMPROVEMENT—SUBSEQUENT RELAPSE, AND MORE RAPID AND SATISFACTORY IMPROVEMENT UNDER CENTRAL GALVANIZATION.

CASE V.—John P., aged 52, had for twenty years suffered from chronic eczema, that attacked by turns different parts of the body. For four years he had by intervals been attending the Skin Department of the Demilt Dispensary, under the treatment of Dr. Woodruff, who had given him various remedies, relying chiefly on arsenic. Under the arsenic treatment the improvement was quite decided, but beyond a certain point he could not be carried.

When brought into the Electro-Therapeutical Department of the Dispensary, there was a small patch of eczema on the back of the left hand, and a little of the disease on the right foot. The history of the disease had been, that it spread over the hand from this one centre.

Treatment by localized galvanization was used for a month, with positive evidences of benefit.

The disease subsequently recurred, and the patient again desired treatment. At that time we were using central galvanization, and we resolved to test it in his case, making no electrical or other applications to the diseased surface. Under this method of electrization the relief was apparently more satisfactory than under merely localized applications. It is more than probable that the patient will again suffer relapse; but, up to the date of writing, we have heard no more of him.

CHRONIC ECZEMA OF THE RIGHT FOOT OF TEN YEARS' STANDING—RAPID AND COMPLETE RELIEF FROM LOCALIZED GALVANIZATION.

CASE VI.—Thomas D——, aged 28, came into the Electro-Therapeutical Department of the Dispensary, Sept. 19, 1871. For ten years chronic eczema of the right foot and ankle had afflicted him, and for two weeks the distress had been so great that he had been obliged to give up his occupation, which was that of waiter. The relief from pain, on galvanization with wet sponges, was immediate, and continued for some time after the séance was concluded. Some of the time, dry metallic electrodes were used, and *always with rapid relief to the distressing sensation of heat, by which the disease was marked.* The electric brush was used at times, and even with a strong current was grateful to the patient. The patient apparently recovered in the course of a month's treatment, and we then lost sight of him.

In the above, as in some other cases of painful diseases of the skin, strong currents were not only well borne on the diseased surface, but were exceedingly grateful.

ACNE.

Our first experiments in the electrical treatment of acne were failures. These failures were due partly to the neglect of the patients to persevere, and partly to our not using *central* treatment. Under the combined influence of central and peripheral treatment, or under central alone, or peripheral alone, something may be accomplished in this affection, although great perseverance is necessary, and it is not impossible that cases which are relieved, or apparently cured, may relapse.

Our observations in this department are as follows:—

ACNE ROSACEA OF LONG STANDING—IMMEDIATE IMPROVEMENT UNDER LOCALIZED GALVANIZATION.

CASE VII.—A medical gentleman, aged about 60, in

April, 1872, requested us to treat him for acne rosacea that had for some time caused him annoyance. The blood-vessels were considerably enlarged on both sides of the nose, the color was a decided red, and there was the usual thickening. The health of the patient was in other respects pretty good, excepting attacks of indigestion with acidity.

We began treatment with localized galvanization—with wet cloths and sponge, sometimes using pure metal with a sharp edge. When the metal was used, the dilated capillaries were electrolyzed under the negative pole, and gases escaped with a sound that could be easily heard. There was a tendency to reappearance of the dilated vessels, but after a few weeks' treatment they were entirely destroyed, leaving no scar or trace, and the color of the nose on both sides had disappeared. There appeared to be also a diminution of the hypertrophied tissues.

There has been, since that time, some return of the affection, but he is very much better than formerly. The habits of the patient were never intemperate, but he had always been accustomed to use more or less alcoholic liquors.

A French physician has reported excellent results in the treatment of acne rosacea by electricity.

The following is one of the earliest cases of disease of the skin that ever came under our observation :—

Case VIII.—Mrs. —— was referred to us in 1867, for treatment for acne of very long standing. The limbs and face were affected by the disease. An immense variety of treatment had been employed, and the patient had consulted very many American and European authorities—among others, Hebra, of Vienna—and she was nothing better.

At that time we had not used central galvanization, and had had no experience in the treatment of diseases of the skin by any method of electrization.

As a matter of experiment, we used general faradization, but the patient did not continue the treatment long enough to determine just how much benefit was obtained thereby.

It is by no means impossible that general faradization, by improving the digestion and relieving the constipation, might be of great service in acne, either alone or in connection with central galvanization.

In the above case all the symptoms were aggravated at the monthly period ; it is not unlikely that general faradization or localized faradization of the patient, internal or external, might have been of service in relieving the dysmenorrhœa as well as the digestive disturbance, and this might have relieved the acne.

ACNE OF SEVERAL YEARS' STANDING TREATED BY CENTRAL GALVANIZATION AND DRY FARADIZATION.

Case IX.—In May, 1872, a young man of 26 was brought to us by Dr. Carpenter, complaining of acne of the back especially, that for several years had been his companion. The back was well covered with the eruption. The digestion was not right, and the bowels were constipated.

Central galvanization was at once used three times a week, which a part of the time was varied by *dry* faradization with the hand and metallic electrodes—a method Dr. Piffard had suggested to us as efficacious in acne. There was very soon improvement : the large spots began to dry up, but the patient went away after eight applications.

During the present summer (1873) we have been treating a case of acne indurata of the face—a patient of Dr. Thayer—with the negative pole of the galvanic current connected with metallic disks and points, and electrodes armed with many sharp points, alternating with central galvanization. This case has improved slowly but decidedly, and is still under treatment.

Our assistant, Dr. J. H. Sterling, informs us that one year ago a case of hereditary acne indurata of the face and back under his care was treated by eighteen applications of central galvanization without any other treatment, and the disease disappeared. The constipation and headache, which had been very distressing, were also relieved. Up to date (July 1873) the patient was well.

PRURIGO.

In prurigo it would be consistent to expect benefit from electrical treatment. Experience shows that this expectation is well grounded. All methods of using electricity seem to do good in prurigo. Relief of the itching is obtained by dry faradization and galvanization with wet sponges and cloths, but the most permanent results seem to come from central galvanization.

GENERAL PRURIGO, SIX YEARS' STANDING—INTENSE ITCHING—APPROXIMATE CURE AFTER FIFTEEN SEANCES OF CENTRAL GALVANIZATION.

Case XI.—W. R., 9 years of age, came into the Electro-Therapeutical Department of Demilt Dispensary, April 11, 1872. The history was: At the age of three had scarlet fever; this was followed by general prurigo that had never been relieved. The disease covered the back, abdomen, and legs. The itching was most severe. Sleep at night had for years been interrupted by this distress, and marks of scratching were everywhere seen. The disease was at its worst on the back.

Acting on the theory that the disease was of a nervous character, Dr. Woodruff referred the case to the Electro-Therapeutical Department, when treatment by central galvanization was begun and continued for two months. Towards the close of the treatment, June 1, little remains of the eruption were seen excepting on the back, and there was very little itching.

June 15.—The patient abandoned treatment; the recovery appeared to be satisfactory. We have no further intelligence of the case.

Dr. Sterling gives us the following case, the diagnosis of which was not fully clear to him :—

LICHEN ÆGRIUS OF LONG STANDING—SOME IMPROVEMENT UNDER LOCALIZED GALVANIZATION, AND GALVANIZATION OF THE CERVICAL SYMPATHETIC—MUCH GREATER IMPROVEMENT UNDER CENTRAL GALVANIZATION.

Case X.—Mr G——, at the age of twelve, was attacked with an eruption all over the body, after seabathing. Treatment cured the eruption, but a burning, smarting sensation was left in the fore-eye, that always was increased on any excitement. Drinking a cup of tea or coffee, or entering a heated room would bring on burning and smarting in the face, with very decided puffiness. Arsenic and various other remedies had been used faithfully.

May 1, 1871.—Treatment by galvanization of the sympathetic and localized galvanization was begun, and the result was satisfactory; but relapse occurred, and some months subsequently he was treated by central galvanization alone with very great improvement. He still suffers from slight relapses that are always benefited by electrical treatment.

PSORIASIS AND PITYRIASIS.

These diseases have not, in our hands, yielded to electrical treatment with great rapidity. They improve slowly, however, up to a certain point, and in some cases an apparent cure, or something approxi-

ate to a cure, may be obtained by a long course of treatment. Our first experiments in the treatment of psoriasis by electricity were made with Dr. H. G. Pifford at the Dispensary for Diseases of the Skin.

GENERAL PITYRIASIS OF FOUR YEARS' STANDING—SLOW BUT DECIDED IMPROVEMENT UNDER GALVANIZATION, LOCALIZED AND CENTRAL—RELAPSE.

CASE XII.—Miss O——, aged 19, had for four years been a victim of pityriasis, that attacked first the scalp, causing profuse "dandruff," and extending to the trunk. Treatment of various kinds, external applications and internal medication had been used by good surgeons, and with great perseverance, for many months. The benefit had been slight and transitory. A short interval of disappearance of the patches of the disease would be followed by a rapid reappearance, and at no period had she been ever approximately free from the disease.

The patient was brought to us November, 1871, by Dr. Freeman, who, at that time, had the patient under observation. The scalp was then pretty well covered with the disease, and behind the ears were large patches. Dandruff was very abundant. The health of the patient was excellent. Patches of the disease were also on the back, sides, breast, and abdomen.

Treatment by localized galvanization was commenced and continued for three months by intervals. The improvement was quite slow, but after about a month, some of the spots on the breast had entirely disappeared. The patches on the back and sides were most obstinate, and although they changed in their character, had not entirely disappeared when the patient left the city.

The first evidence that the treatment was taking hold was observed on the head; for several weeks before the close of treatment, the amount of "dandruff" had been reduced to a minimum. The patches of disease behind the ears yielded with great slowness. The patient relapsed the next season, and was as bad as ever.

PITYRIASIS CAPITIS OF MANY YEARS' STANDING TREATED BY GALVANIZATION WITHOUT IMMEDIATE EFFECT, BUT SUBSEQUENT IMPROVEMENT.

CASE XIII.—A physician had for many years been annoyed by "dandruff," that was constant and very profuse. By our request he took a course of galvanization. The hair was thoroughly moistened, and the applications were made over the head, as well as over the neck and spine; combining localized with central galvanization.

During the course of treatment, which lasted for several weeks, there was no apparent improvement; but since the abandonment of the experiment the disease has diminished. It is not improbable that here, as in other diseases, the *after* effects may be observed even when the effects during treatment are negative.

PSORIASIS OF THE ARMS AND LEGS OF THIRTY YEARS' STANDING—SOME IMPROVEMENT UNDER LOCALIZED FARADIZATION.

CASE XIV.—Mary P——, aged 63, had suffered for thirty years from psoriasis that attacked the arms and legs. She was sent into the Electro-Therapeutical Department of Demilt Dispensary, April 14th, 1871. Treatment was commenced that day by localized galvanization, by means of adjustable* electrodes, covered with flannel. Both poles were employed.

This treatment was combined with central galvanization. The patient discontinued treatment before a fair trial had been given; but some improvement was observed, even during the short time that she was under observation.

HERPES.

More than a century ago herpes zoster was treated by Franklinic electricity, and, it is claimed, with success. A spot of *herpes circinatus* disappeared under galvanization, and up to date has not returned.

In a case of herpes zoster associated with neuralgia, that we treated during the past year, the neuralgia was rapidly and permanently cured by faradization; the herpitic eruption had nearly disappeared before electric treatment was begun.

In another very ugly and obstinate case of herpes zoster of four weeks' standing there was a decided improvement in the condition as soon as the galvanic current was applied. The most remarkable results of the electrical treatment of herpes have been obtained in the variety known as *herpes frontalis seu ophthalmicus*. This disease, besides being very painful, sometimes excites inflammation of the cornea, and destroys the eye. In two cases that were treated at the Brooklyn Eye and Ear Hospital by localized galvanization, the relief of pain was immediate, and the cure was rapid and permanent. Both of these cases we saw, and one we treated. In both cases the eye was saved.

ELEPHANTIASIS OF THE LEGS, OVER TWO YEARS' STANDING, ATTENDED WITH ULCERATION AND GREAT PAIN—RELIEF OF PAIN—REMOVAL OF THE ELEPHANTINE SKIN AND VERY REMARKABLE REDUCTION IN THE SIZE OF ONE LEG UNDER LOCALIZED GALVANIZATION.

CASE XV.—Mr. P., an Englishman of middle life, a man strong and vigorous beyond the average, a distiller of oils by occupation, returning from his daily duties on the evening of February 22d, 1870, observed, on removing his socks, a small blister on the inner side of the left ankle. The next day he called on his physician, Dr. Rotton, under whose care he remained for one year and more.

The disease spread over the *left* foot and ankle, and in about two months the right foot was similarly attacked. The blisters as they ruptured left inflamed and angry surfaces in their track. The disease involved the surface of the feet, and both legs up to the knees. The treatment carried out by Dr. R. was mainly of a tonic and alterative character, with local applications of glycerine, carbolic acid, and lead wash. At one time Dr. Johnson saw the case, confirmed the diagnosis of elephantiasis, and rendered a diagnosis positively unfavorable.

We first saw the case by request of Dr. R. in May, 1872. At that time the right leg below the knee measured *twenty-five inches* in circumference, and it was covered all over with elephantine skin, excepting an ulcerating surface below the ankle. This ulcer was treated with charcoal poultice and discharged freely. The *left* leg was not greatly enlarged, but was red, angry, and inflamed, and kept up an incessant discharge from the surface.

The patient *suffered horrible agonies*, so that at night the neighbors were disturbed by his howling. He was unable to move from the sofa on which he sat, and where he worked at his newly-learned trade of cleaning gloves.

By our request Dr. E. Mann, one of our assistants,

* Adjustable electrodes is a term that we have applied to flat metallic electrodes of different sizes and shapes; these are provided with flannel or chamois covers. These covers are provided with elastic borders, and may be put on and off at pleasure, and may be washed like towels.

undertook the experimental treatment of the case by electricity. We had never known of elephantiasis being treated electrically, and gave an unfavorable prognosis, and were indeed inclined not to attempt it; only by the earnest request of the patient and his physician we decided to try and see whether we might give him some relief. Localized *faradization* at first tried by Dr. Mann accomplished nothing, and, so great was the anæsthesia, was not felt by the patient.

Localized *galvanization* by means of wet sponges and both poles with zinc-carbon battery of 16 cells was appreciably felt, and very soon began to relieve the pain.

The applications, from 10 to 30 minutes in length, were made at first by Dr. Mann, and subsequently by the daughter of the patient under our supervision.

After two months' treatment the elephantine skin on the left leg was removed, the pain had ceased, and the leg was reduced in circumference from *twenty-five* to *seventeen inches*. The ulcerated portion below the ankle was also nearly well.

The electrical treatment was then discontinued for several months. During the latter part of this time there were evidences of relapse and reappearance of ulcers and pain. The case has been seen by a large number of the profession.

The features in the cases here recorded most worthy of note are the following:—

1. The rapid relief of the itching and pain of eczema, prurigo, and herpes by local applications.

2. The relieving and curative effects of *central galvanization* not only in prurigo, but also and especially in eczema, which has not generally been supposed to be so closely dependent on the nervous system.

3. The fact that herpes, prurigo, and eczema yield in some instances very rapidly, while psoriasis and pityriasis are quite slow and obstinate.

4. The tendency of some cases to relapse even after they have been greatly benefited, while in other cases —notably in eczema and herpes—the cure is more or less permanent.

FREQUENTLY RECURRING SPASM OF THE GLOTTIS

DEPENDENT UPON CHRONIC HYPERÆMIA OF THE LARYNX.

By ANDREW H. SMITH, M.D.,

NEW YORK.

Prof. J. C. L., a distinguished member of the medical profession, from the South, was referred to me by Dr. Agnew in November last. A laryngoscopic examination showed a general relaxation of the mucous membrane of the larynx, accompanied by slight hyperæmia. The history of the case is contained in the following memorandum, furnished by the patient himself, under date of June 16th, 1873:—

"The patient is 59 years of age. Though commonly enjoying good health and supposed even by his neighbors and friends to have rather robust health, he has actually been more or less delicate all his life, and has had several attacks of severe illness, as continued fever in childhood, pneumonia in early manhood, jaundice, probably from catarrh of the bile ducts, and occasionally dyspepsia, which sometimes has continued for a year or longer.

"More than thirty years ago, when in his best health, he was suddenly seized, without assignable cause, with a very intense and distressing laryngeal irritation, causing apparently a spasm of the glottis, which was very much aggravated by swallowing a mouthful of wine, and then almost instantly and completely relieved by a lump of white sugar dissolved in the mouth before it was swallowed. He has often experienced similar attacks, first at wide intervals, but latterly much more frequently. When unaccompanied by catarrhal inflammation they are always promptly and entirely relieved by a concentrated solution of white sugar and less completely by gum-drops or jujube paste.

"If the sugar be exhibited in the form of flavored candy the flavoring essence seems in a measure to neutralize the effect of the sugar. Horehound candy, however, is as effectual as the simple sugar. When the laryngeal irritation is accompanied by catarrhal inflammation the relief procured by sugar is less complete and durable, but is still very appreciable. This was the condition of the parts when I sought your advice last November, there being a constant sense of irritation and daily attacks, generally at night, of spasmodic exacerbations. There was an immediate change for the better after the commencement of your treatment. The applications were made Nov. 16th, 18th, 19th, and 20th, and no attack or spasm occurred until I contracted an epidemic catarrh, some time in December or early part of January. After the cure of the influenza the laryngeal symptoms wholly disappeared and did not recur until about two weeks ago, when I took cold from a trivial change of dress, or concurrently therewith, when they returned with some degree of severity for a few days. They are now subsiding with the spontaneous subsidence of the catarrh which was contracted at the same time."

Finding nothing else to account for the constantly recurring spasm of the laryngeal muscles I considered it to be due primarily to irritability of the larynx caused by the chronic congestion present. This I aimed to correct by the application of an astringent, and I selected for this purpose the perchloride of iron dissolved in glycerine in the proportion of sixty grains to the ounce. This was carefully applied with a brush to the whole interior of the larynx, the hand being guided by the laryngeal mirror. The stay of the patient in town being limited, but four applications were made, but the success of the treatment seems to have been very complete.

ON THE TREATMENT OF

COMPOUND DEPRESSED FRACTURES OF THE SKULL, WITHOUT IMMEDIATE BRAIN SYMPTOMS.

WITH THREE CASES.

By ALFRED NORTH, M.D.,

WATERBURY, CONN.

Case 1.—Thomas Alman, aged 26, born in Ireland, of robust constitution, was first seen

Dec. 6, 1872, at about 4 o'clock P.M. Half an hour previously, while engaged in an altercation in a saloon, he was struck on the forehead with a Scotch ale-bottle. On examination I found a wound upon the forehead which communicated with a comminuted and depressed fracture of the frontal bone between the frontal eminences. A fragment of bone of a semicircular shape and an inch and three-quarters in length was depressed, and its straight edge driven under the overhanging adjacent edge of sound bone,

the depression lessening as it approaches the arc of the semicircle. A fracture or crack also extends from the depression down the side of the head towards the temporal bone. Patient's mind was not affected, nor did unconsciousness follow the accident; in fact, he regarded himself as only slightly injured. Pulse 90, temperature of body natural. As it was uncertain what disposition was to be made of patient, simply brought the edges of the wound together with sutures, and ordered him to be kept quiet and rubber bags of ice to be applied to his head. Twenty-four hours afterward I again saw him at his home, and found indications threatening brain trouble. I immediately proposed the operation of trephining, and performed it with the assistance of Dr. McDonald in the following manner: After etherization, which was promptly accomplished and maintained with a very small expenditure of ether, I exposed the depressed bone. The overhanging edge of sound bone was then gnawed away with Louis' rongeur forceps sufficient to allow the edges of the depressed fragment to be seized and the entire fragment to be brought away. It was now ascertained that the inner table was comminuted and depressed from the outer table. Several bony spiculæ had penetrated the dura mater, and two clots of considerable size were found. Considerable hemorrhage took place and required the persistent application of ice to arrest it.

The edges were brought together and cold applications continued. He was ordered bromide of potash in 20 gr. doses every four hours.

Dec. 8.—Patient passed a very quiet night, sleeping most of the time. Redness of the eyeballs, and the threatening brain symptoms are subsiding. Pulse 80; respiration 20; temperature of body natural, and takes a good amount of nourishment.

Dec. 11.—Wound has healed by first intention except where the syringe is introduced to wash out the part with a weak solution of carbolic acid (grs. 10 to a pint). Pulse 90; at times considerable heat about the head; mind undisturbed; ordered half a dozen leeches to the temples; bowels to be freely moved.

Dec. 13.—Last night, for the first time, patient was delirious and required restraint to be kept in bed. Head very hot; eyes suffused; pupils contracted. He continued to fail rapidly until 6 P.M., when he died. No post-mortem could be obtained.

Case II.—James Hearney, aged 34, while returning home late in the evening of June 4, 1870, was struck on the head with a slungshot in the hands of an unknown assailant coming up stealthily from behind. The blow felled him to the ground. He remained insensible until early morning when he recovered consciousness and walked about forty rods to his home. Not supposing that he was seriously injured, he walked half a mile further to my office to have his wound dressed. Recognizing the serious nature of the accident, I sent him home in my carriage. On arriving, he lightly put his foot upon the wheel and jumped to the ground as if nothing was the matter. On examination I found on the top of the skull, at the junction of the sagittal and coronal sutures a depressed portion of bone of a quadrilateral shape and about the size of the face of an ordinary hammer. This was comminuted and driven down upon the brain a quarter of an inch in every part. An operation being urged as of immediate necessity to save life, he consented. After etherization the rongeur forceps was employed to gnaw away the edges of the opening sufficiently to get at the depressed bone, which was removed piece by piece. After the removal of all the loose fragments an opening in the skull about an inch square remained. The dura mater was uninjured; hemorrhage was slight. The edges of the scalp were brought together and sutures applied.

June 5.—Patient passed a very restless night; mind wandering; head hot; eyeballs congested; pulse 120; bowels confined. Ordered pill cathartic; continued constant application of bags of ice to head.

June 8.—Patient passed a very restless night; delirium increased, and in spite of his attendant he jumped from the bed and had the window raised to get out before he was restrained. His head was hot; the wound commencing to discharge freely; union not having taken place by the first intention. Injection of carbolic acid was used (10 grs. to the oz.).

June 11.—General condition much improved; mind undisturbed; heat about the head subsiding. Wound granulating and discharging freely.

June 26.—Patient up and about the house; discharge from wound diminishing.

August 1.—To-day for the first time patient went to the factory. All unpleasant sensations about his head have disappeared except a slight dizziness, which frequently troubled him previous to the accident.

Feb. 1, 1873.—Present condition as good as before the accident.

Case III.—Mrs. W. Upson, aged 30, an American, on the 10th of February, 1872, while coming out of a store was struck on the head with a soldering-iron, let fall from the roof, a height of twenty-five feet. It penetrated the scalp over the left parietal bone. Aside from being dizzy for a moment she experienced no inconvenience from the blow. As she complained of no unfavorable symptoms, and as the man throwing the iron was positive that the point of the instrument did not strike the head, nothing was done but to relieve the bowels and make cold applications.

Feb. 13.—Patient's condition very favorable, aside from a slight headache; no unfavorable indications were recognized.

Feb. 14.—Patient passed a very restless night; had a severe chill; head was hot and very painful; eyes suffused; pulse 120 and irregular; complains this afternoon of numbness of little and ring fingers of right hand; at times has the same feeling along the forearm. Ordered half a dozen leeches to temple, and bowels to be freely moved.

Feb. 15.—Had no sleep last night; congestion about the head increasing; right arm and leg paralyzed; pupils unequally dilated. As patient was evidently suffering from irritation or compression of the brain, I advised an immediate operation of an explorative nature, which was accordingly done.

Patient being etherized, the scalp was dissected back, which showed a small puncture in the bone about the size of a buck-shot. A circular piece of sound bone surrounding the opening being removed, a cone-shaped piece of skull, having a base of about half an inch in diameter, was found embedded in the brain substance; the dura mater having yielded to the pressure, had given way, and inflammation had followed. The bone and matter were removed, and the soft parts were approximated.

Feb. 16.—Passed a more quiet night, sleeping most of the time; paralysis of arm and leg gone; congestion about the head subsiding; pupils natural; discharge from wound free and mixed with brain matter; mind clear.

Feb. 17.—This P.M. patient had a miscarriage, which produced great prostration, from the effects of which, in her then condition, she died.

Remarks.—From observations made during our late war and my experience at the N. Y. Hospital, as well

as in my practice here. I have been led to believe that a compound depressed fracture, without immediate symptoms, requires a resort to operative treatment. In this class of fractures the injury to the brain is of a more local nature; hence, general symptoms are absent. If now the offending cause is removed before inflammatory action has taken place, we may expect a favorable result by averting inflammation. It cannot be a matter of indifference whether the sharp and partially detached pieces of the inner table are left pressing upon or perforating the sensitive membrane of the brain. If we listen to those who counsel delay, and our patient should survive the immediate injury, it may be only to save him for a lingering and slow death of years, from epilepsy or some kindred disease. Gross says of compound depressed fractures, "that practitioners have long been agreed that the proper plan of treatment is trephining, performed at the earliest possible moment and without the slightest regard to the character of the head symptoms." Then he goes on to state that the case being compound cannot be aggravated by an operation. All loose pieces and those partially detached should be removed. Hamilton advises an immediate operation as involving no additional risk, and removing what we must consider as continued danger to the patient's life. Sir Astley Cooper, Sir Benjamin Brodie, Erichsen, Holmes, Hewit and Druitt make it an imperative rule of surgery, that when the fracture is compound and considerably depressed, to operate immediately, whether there be symptoms or not.

John Asshurst, of Philadelphia, who of all modern authorities restricts the trephine to the remotest limit, says that in depressed fractures although impacted, if thereby the air be not excluded, they should be operated upon at once, whether there be symptoms of compression or not. The question of impaction to the exclusion of air in compound comminuted fractures I should regard as a fanciful nicety; at least no such cases have come under my observation.

The time of operation being settled, the question is, How shall it be done? If the depressed bone can be elevated without leaving fragments of the inner table still pressing on or perforating the dura mater, then this should be done; if not, then remove the bone with the least possible loss of sound material, which, as in cases I. and II., can generally be better accomplished with the rongeur forceps than the trephine or any other instrument.

Results.—The records of N. Y. Hospital gave one recovery to every four deaths; University College, London, one to every three; while in Paris, according to Nélaton's own statement, the operation has been almost uniformly fatal. In the late war 107 operations gave 47 recoveries and 60 deaths, while to set off against this we have reports of 483 cases not operated upon, giving only 99 recoveries to 384 deaths.

REMARKS UPON THE MECHANICAL TREATMENT OF UTERINE DISPLACEMENTS.*

By W. M. CHAMBERLAIN, M.D.,

PHYSICIAN TO CHARITY HOSPITAL AND THE DEPARTMENT OF DISEASES OF WOMEN IN THE BELLEVUE DISPENSARY.

The use of pessaries in the treatment of uterine displacements is an admitted necessity. Debate on this matter, which has been long and sometimes warm, is almost at an end. All the leading gynæcologists, both here and abroad, some *ab initio* and others after a slow conversion of opinion, have recorded their unequivocal judgment in favor of the use of mechanical means as an adjunct to the medical and surgical treatment. Grailey Hewitt and others teach that they are often alone sufficient to cure all the consequences of displacements in removing the cause.

Since the instrument-shops offer us the choice among some hundreds of varieties, it is important to consider the principles which should guide in the selection.

We are thus brought directly to the question, What are the natural forces which retain the womb in its place? This question has been argued ingeniously and at length but to very various conclusions. Charles Bell and Matthew Duncan assign the principal rôle to the tonicity of the vagina as a supporting column; Hodge to the broad-round and utero-sacral ligaments; Priestly and Wright to the pelvic connective tissue. Admitting that all these influences may be combined in the result, it may be said that we have no necroscopic evidence that uterine displacements are dependent upon morbid conditions either of the ligaments or connective tissue: in life these structures are not fairly within reach of our methods of clinical investigation, and we have no means of effecting any direct alteration in their condition, even if we were satisfied as to the occasion for so doing. On the other hand, whatever relates to morbid conditions of the vagina may be fully known, and all the methods of medical art are applicable here.

The lower two inches of the vagina is much more complex in structure and endowment than the upper. Its orifice is closed by a proper sphincter—cylindrical rather than annular—inasmuch as it extends a little distance up the canal. This is re-enforced by the sphincter and levator ani—the transversalis perinei—by a layer of erectile and elastic tissue, and by rugæ of mucous membrane rich in glandular follicles, and in vascular and nervous trunks.

The upper portion of the vagina, on the other hand, is thin, membranous, almost devoid of muscle of its own, and furnishing small attachment to other muscles. It permits of great distention and furnishes comparatively little secretion. Nature thus indicates an active contractility of the lower portion as necessary to the normal condition of the adjacent organs.

It has been very frequently observed that when the vagina is torn or permanently relaxed the transversalis perinei pull the labia apart, and to supplement the vacuity thus occasioned the folds of the vagina are everted, bringing with them both the bladder and rectum. The vagina is thus shortened at *its external* end, and the uterus drawn down. In its natural site the fundus is nearly on a level with the second division of the sacrum, and is prevented from antero-posterior displacement by the mass of small intestines in front and the sharp forward curve of the sacrum behind.

But when the elastic support of the vagina is withdrawn the uterus descends toward the outlet, and as it descends its relations to the bladder are changed. While in its natural site the distending bladder applies against its cervical zone, and thus tends to elevate and even to antevert it, but as it descends it comes to sustain a much more continuous pressure exerted upon the fundus of the organ. At the same time the posterior sustaining force is withdrawn by the rapidly receding concavity of the sacrum. Thus we see ruptured perinæum pretty constantly followed by cystocele, rectocele, prolapse, and retroversion or flexion. Just in proportion as the uterus descends its circulation is deranged; the delicate and inelastic

* Part of a paper read at a meeting of the N. Y. Academy of Medicine.

veins are lengthened and lessened in calibre, as the broad ligaments which contain them are stretched. Reflux of blood thus prevented, congestion ensues, which is greatly aggravated if flexion or version coexist.

If the female cadaver be opened so as to show the true pelvis, and the uterus be retroverted manually so as to make the fundus impinge on the concavity of the sacrum, and a lever pessary be then passed to the fornix vaginæ, the following changes of position are seen: Increase of pressure puts the utero-sacral ligaments on the stretch, and the fundus is brought to apply by its posterior surface upon the anterior curve of the sacrum. As the elevation is increased anteversion becomes inevitable, the direction being given by the promontory of the sacrum—far above the bar of the pessary.

To make the axis of the uterus coincide with the axis of the superior strait, it is only necessary to extend the vagina by pressure upon the fornix.

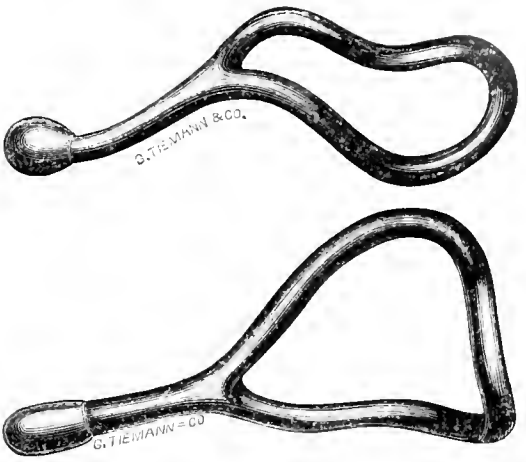
The elevation of the uterus restores the natural condition of the broad ligaments, and whatever measure of congestion may have been dependent upon mechanical causes subsides without further treatment. Commonly this is by far the larger portion.

It may also be observed that, in case of an elastic canal like the vagina, lateral extension antagonizes longitudinal extension. If through an india-rubber tube you pass a body which distends its calibre, its length will be proportionately decreased.

Instruments which distend the vagina interfere with its tonicity and contractility in various ways. Muscles splinted, restrained of their natural function, become atrophied from want of use, from diminished nutrition and from increased absorption, the result of pressure. This criticism will apply to the globes, cushions, inflated bags, and in less degree to the different forms of rings, long ellipsoids, etc. etc. Very excellent results are secured by the rings and levers as used by our most esteemed gynæcologists, but, if the foregoing considerations are true, this must be not without sacrifice.

Something may be said of the fulcra from which the extending power of pessaries is exerted. These are the posterior surface of the pubic bone, the angle formed by the converging rami of the pubes, and the fourchette. Hodge's instruments, resting upon the pubes, exert a certain and constant pressure, and are therefore preferred where the uterus is heavy or restrained by acquired adhesions. But for the same reasons they are liable to excite absorption and ulceration and to strangulate the vaginal veins, thereby increasing congestion and leucorrhœa. Albert Smith's, resting in the angle, allow a greater mobility to the uterus, inasmuch as the fulcrum will move under sufficient pressure; but they are less efficient in support, and open the vulva. Cutter's instruments distend the vagina less than either of the others, but, since the power and the weight are close together and the resistance is at the end of a disproportionately long arm, they act at a great mechanical disadvantage and involve a degree of pressure which the fourchette does not well endure. Scanzoni's instruments and the proprietary modifications of Banning, Wadsworth and Babcock have an external fulcrum in a stem attached to an abdominal belt.

It has occurred to the writer that a fulcral point may be dispensed with, in cases where the vagina is entire, and the muscular force of the canal itself be so utilized as to supply sufficient extending and lever power. With this view I have devised the instrument figured in the accompanying wood-cuts. It



may be described as a skeleton wedge mounted upon a slender stem. The upper or fenestrated portion combines the shape of a spoon with that of a wedge. The concave bowl receives the intra-vaginal portion of the uterus, and is applied in the posterior cul-de-sac in cases of retroflexion and version, and in the anterior cul-de-sac in cases of anterior version and flexion; the smaller end of the wedge descends nearly to the muscular portion of the vagina; the stem still lower, so that the terminal bulb is just covered by the labia. The approximation of the thighs in sitting, and their sliding movement upon each other in walking, are supposed to operate upon the smaller end of the wedge, and thus to exert a constant though gentle elevating force, while the slender stem, three or four lines in diameter, is embraced by the muscular portion of the vagina and gives direction and steadiness to the instrument. The bulb is perforated and moves upon the stem by a screw-motion, thus allowing the stem to be varied in length half an inch or more. The uterus should in all cases be reposited or straightened before the instrument is applied. The instrument is made of vulcanite (hard rubber), by Tiemann & Co. I am much indebted to Mr. Stohlman, of that firm, for aid in mechanical details and for the wood-cut.

I subjoin a few cases in which it has been employed.

Case I.—Mrs. A., aged thirty, mother of one child. Anteflexion had existed for an unknown period, recently aggravated to such a degree, that on account of vesical tenesmus, hypogastric pain and lameness, she was practically confined to the supine position. Applied the instrument January 18th, after repositing the womb. Increasing relief followed; in a few days she was able to walk a little, and in the middle of February to go abroad. Has made a very rapid tour of the Continent, and writes (May 5th) from Venice, "The instrument remains as you placed it. It has never given me inconvenience, and I dare not remove it lest I should be unable to go about."

II.—Mrs. B., aged 25; 3 children—aggravated anteflexion—has worn the instrument six weeks, removing and replacing it herself from time to time. The uterus has been elevated to its natural position—locomotion rendered much more comfortable.

III.—Miss C., aged 28. Uterus sharply retroflexed, congested and enlarged. Reposited, and applied the instrument; three days after, the bulb was found protruding half an inch or more, and the flexion partially returned. Removed the instrument and

applied a Hodge's closed lever, which corrected the flexion, but excited pain and tenderness. Removed Hodge's and reapplied the "wedge." After wearing it three weeks the patient reports the subjective symptoms all relieved. She can now stand and walk with ease. Physical examination shows the womb erect and in its proper place.

IV.—Mrs C., multipara, aged 35. Uterus enlarged, and retroverted by intramural fibroid in left posterior wall. Hodge's and Cutter's instruments were tried, but could not be adapted on account of tenderness. The "wedge" was worn two months, and retained the uterus nearly erect. Finally the increase of the tumor partially extended it, and no instrument could be employed.

These are all the cases in which I have found opportunity to use this instrument, and, though insufficient in number, they seem to me to invite further trials.

If, as would here appear, an anteflected womb may be thus erected, it is a valuable result; for, as is well known, anterior displacements have proved much less amenable to mechanical treatment than posterior.

Vulcanite being flexible, under the influence of heat, the angle at which the upper portion of the instrument meets the lower can be varied to suit the varying requirements of individual cases. This is necessary in *all rigid* instruments.

No. 102 W. Thirty-fourth Street.

Progress of Medical Science.

On the Diagnosis and Treatment of Lipomata.—Monsieur Montmeja publishes a new observation of symmetrical lipomas collected in the service of M. Panas, and calls the attention of surgeons to a peculiar characteristic of lipomas which admits, in many cases, the establishment of their presence when the diagnosis is attended with difficulties. This characteristic is the property possessed by fatty tumors of becoming harder by the action of cold. In the cadaver fatty tumors are very hard; a lipoma removed from a living body hardens in proportion as it cools.

It is possible to cool by ice or atomized ether a tumor of doubtful nature, and if to the touch there is manifest induration following the action of the cold, there is every reason to predicate the existence of a lipoma.

Medical treatment, however varied, is powerless to effect the removal of lipomata; but those of small size have been known to disappear under the influence of continuous electrical currents, and M. Montmeja cites one case favoring this mode of treatment.—*Rev. Medico-photo. des Hôp.*, and *Lyon Méd.*, June 22.

The Emetic Property of Apomorphine.—At the Congress of German naturalists and physicians at Leipzic, Dr. Kohler, of Halle, spoke of the emetic properties of apomorphine. This substance is diametrically the opposite of morphine, and produces vomiting when administered in doses as follows:—1. Subcutaneously; six to seven *milligrammes*. 2. By the mouth; twelve to eighteen *centigrs.* 3. By the anus; eighteen to thirty-six *centigrs.* 4. Placed upon the surface of the tongue, six to seven *centigrs.* Animals who were subjected to subcutaneous injections of one to two *décigrammes* experienced stupor, lassitude of the posterior extremities, and troubles of the motor powers. A fatal dose exceeded four *décigrammes* injected subcutaneously.

Prof. Mosler, of Greifswald, thought apomorphine needed to be used when quite fresh in order to produce emesis.

Dr. Riegel, of Würzburg, had used it in more than a hundred instances, and considered it to be the best of emetics. He said that its emetic property is preserved at the end of even six or eight weeks from its preparation, if care be taken to exclude light.—*Revue Scientifique.*

Traumatic Herpes.—M. Verneuil read a paper before the *Société de Biologie*, of Paris, on the 3d of May, saying, *in résumé*, "That herpes should be considered as a complication of traumatic lesions, and should be recognized as having three varieties, viz.: peripheric, that which is developed in the neighborhood of the lesion, and that which occurs at a distance. Herpes may be either rapid or slow in its development; it may supervene with or without general symptoms; it follows wounds of nerves or ganglia; it is owing sometimes to a neuritis, sometimes to reflex irritation, and sometimes to blood changes; it may relapse; it may accompany erysipelas, and it is desirable to distinguish between cases of erysipelas attended by the vesicles of herpes and those of phlyctenular character; lastly, herpes may give origin to a change in the granular layer resembling diphtheria."—*Le Mouvement Médicale*, May 10th.

A New Sign of Pyelitis.—When an alteration in the character of urine is recognized, it is of importance to know if the lesion which gives origin to it is located in the kidney or its pelvis. Several signs have been given by authors to aid in establishing a diagnosis of pyelitis, the most important of which is the presence in the urine of the epithelial cells which line the pelvis and calices. By means of reagents it can be determined if albumen is present or if the quantity of urea is normal. Acid reaction of the urine, according to Oppolzer, is the best symptom of pyelitis. M. Pascalluccì, impressed with the insufficiency of these means, thinks he has found in the appearance of the crystals of nitrate of urea a more reliable sign. After an examination of the epithelium, he directs that nitric acid should be added and the precipitate examined with the microscope. If catarrh is limited to the bladder the formation of these crystals is normal, that is, they are present under the form of rhomboidal hexagonal plates, joined like roof-tiles. In pyelitis, however, these plates are irregular, the angles cut, and some have the form of little pencils, brooms, and feathers. This sign, if constant, is more important than any that have heretofore been mantained.—*Le Mouvement Méd.*, May 10.

Successful Case of Gastrotomy in Extra-uterine Gestation.—At the meeting of the Royal Medical and Chirurgical Society on February 11th, Mr. Lawson Tait reported a case of a woman, aged 27, in whom a retro-uterine pregnancy was diagnosticated on the 23d of September, the child having arrived at term and died about the end of July previous. On November 2d, the operation of gastrotomy was performed as for ovariotomy. On opening the sac the feet presented, and the child was extracted without trouble, excepting in the liberation of the head from the pelvis, into which it was closely packed and to the floor of which it had contracted adhesions. The cut edge of the sac was stitched by a continued suture to the edge of the peritoneal wound, thus completely closing the peritoneal cavity. The upper half of the parietal wound (which was about seven inches altogether) was closed by deep sutures and a drainage tube inserted deep into the pelvic cavity, which was washed out once in eight hours with a solution of sulphite of soda. On the eighth day the discharge lost its fetid character and became purulent, occasionally fragments of pla-

centa coming away, together with hair. On November 29th, the great mass of the placenta was removed and the cavity thereafter closed rapidly, so that by the end of December only a small sinus remained. The chief peculiarities in this case are: the absence of any false labor previous to the death of the child; the leaving of the placenta undisturbed; and the method adopted for closing the peritoneal cavity, and leaving the parietal wound partly open. To leave a communication between the cyst and the peritoneum is to run the gauntlet of pyæmia and peritonitis. Closing the parietal wound entirely must lead to similar results.

If possible, the operation should be made near term and before the death of the child has occurred. If, however, the child is dead, the operation should not be delayed, since the adhesions which take place between the fœtus and the cyst give origin to serious complications.

In the discussion which followed, Mr. Spencer Wells declared his preference in such a case for an incision through the posterior wall of the vagina, since it would have facilitated drainage and would have more closely imitated the natural discharge of the fœtus.—*The Doctor.*

Use of Ozocerite.—Ozocerite, or vegetable wax, or combustible earth, is a paraffine or hydrocarbon, found in Moravia, in Valachia, in Caucasus, near to the Caspian Sea, and can be used for making illuminating gas. In its raw state this substance is of a dirty green, of slight density and fibrous structure. Kneaded in the hands for a few moments it assumes the appearance of ordinary wax. It can be moulded, and with a wick can easily be made into candles. For therapeutical uses either the crude ozocerite or its yellow oil is used.

This substance has upon diseases of the skin an action resembling somewhat that of pitch, without being so harsh. It can be employed mixed with glycerine or with linseed oil. Used in the form of an inunction, it is specially useful in psoriasis; also in chronic cutaneous disorders, such, for example, as eczema, tinea tonsurans, and ringworm.—*Giornal Ital. del Malat. Ven. et del Pelle*, Apr.

Oxygenating Remedies.—Under this name are embraced several remedies which, when introduced into the blood, lead by their decomposition to a liberation of oxygen. They are best known in this country, in England, and in Belgium; and in the latter Dr. Van den Corput has made a number of experiments to show their efficacy and demonstrate that the alkaline hypochlorites are to be preferred to the chlorate of potash, recommended by Dr. Smith. Lately Dr. Richardson, of London, has introduced into practical medicine the use, for this purpose, of peroxide of hydrogen, the dose of which is from half a drachm to a drachm daily. These remedies are indicated in two classes of affections, viz., those in which respiration is imperfectly carried on, and those which depend upon incomplete nutrition. They render valuable service in asthma, pneumonia, croup, certain heart affections, and are none the less valuable in stimulating the forces which govern nutrition, oxygen being one of the best of tonics.

Dr. Van den Corput has had considerable experience in the administration of a mixture of hypochlorite of soda with cod-liver oil. The latter is administered as an aliment, but when given pure is frequently attended with bad results. When there is a deficiency of oxygen in the blood, owing to pulmonary lesions, it becomes very often injurious to increase the carboniferous elements of the blood without associating with them elements capable of furnishing the oxygen for their combustion.

Dr. Foster, of Dublin, has, on his part, published two cases of occlusion of the foramen of Botal, in which he has been able to show in the most evident manner the influence of chlorate of potash and peroxide of hydrogen upon the phenomena of hematosis. In these two infants the cyanosis was accompanied with evident lowering of temperature, especially in the extremities. Chlorate of potash, in doses of fifteen to twenty centigrammes, caused a diminution in the degree of cyanosis and an elevation of 5° to 6° in the temperature of the fingers. The peroxide of hydrogen, however, produced results even more marvellous, causing the cyanosis to nearly disappear, and raising the temperature of the feet and hands to quite the normal degree. This improvement, in order to be maintained, required the continuous use of the remedy.—*Journ. de Méd. de Bruxelles* and *Lyon Méd.*

Slowing of the Pulse after Labor.—The retarded pulse which follows parturition has been remarked by McClintock, Blot and Marey, and more recently by Prof. Emilio Falaschi, of Sienna, who contributes to *Lo Sperimentale* of March the results of one hundred and eight observations in the hospital of that city, in which he has paid special attention to the age of the patient, her state—whether primiparous or multiparous, the presentation of the fœtus, duration of labor, etc.

He determines that retardation of the pulse is met with in a sensible and persistent degree in only about the fourth of those recently delivered. The number of pulsations varies in each case from 44 to 52; in one case becoming as low as 38.

This slowing, with certain exceptions, shows itself nearly always within eighteen to thirty hours after *accouchement*, and ceases ordinarily at the fifth or sixth day from the same time. The age of the woman seems to exert a certain influence, the pulse remaining quicker in the young than in those who have passed thirty-five years. Primipara manifest this symptom more frequently than multipara. Neither the season, hour of the day or night, duration of labor, nor presentation and position of the fœtus, have any influence in modifying it

Slowing of the pulse takes place not only after simple labor, but also after the birth of twins; not only after labor at term, but also—according to a few observations—after premature labor at the fourth and sixth months and abortion before the fourth month. The phenomenon followed, as well, expulsion of fœtuses which had died four or five days previous to birth; but in these cases Sig. Falaschi has never observed it to occur previous to the birth. Whenever accouchement is complicated with considerable hemorrhage the retardation of the pulse fails to take place, or lasts for so short a period as not to deserve mention.

The labor pains have no influence upon the number of pulsations, at least not when they are not very intense, and the lacteal secretion is also without effect if the slowing of the beats has preceded its establishment. If, however, it is developed before this phenomenon occurs, the latter is prevented.

Whenever it is well marked, and when it persists for several hours, it is to be taken as a very favorable sign.

Method of Treating Functional Dyspepsia, Anæmia, and Chlorosis.—Brown-Séquard has employed successfully a method, which consists in giving at one time a small quantity only of liquid or solid food, and that at regular intervals, varying from ten to twenty minutes or half an hour.

The articles which he recommends for this mode of dieting are roasted or broiled meats, eggs, well-cooked bread, milk, with butter and cheese, and a very small quantity of vegetables and fruits. This mode of alimentation should be continued for two or three weeks, after which the patient may be allowed to return gradually to the usual mode of three meals daily. Dr. Brown-Séquard has not always succeeded with this mode of treating the conditions above named, but in no case has it produced aggravation of symptoms. He recommends its trial in the vomiting of pregnancy, having had several cases in which it succeeded.—*Bulletin de Thérapeutique.*

Albuminous Expectoration following Thoracentesis.—Dr. Terrillon, writing in the *Gaz. des Hôp.*, says he has met with twenty-one cases in which this phenomenon was observed. It was very commonly accompanied with more or less dyspnœa, but was not so grave in its nature as many have supposed. The first hypothesis with regard to its causation was, that the lung had been punctured by the trocar; the second that spontaneous perforation had occurred, and third, that the fluid remaining in the pleura had traversed the lung-tissue and been rejected by the bronchia. This writer rejects these to agree with the explanation of M. Hérard, that it is due to pulmonary œdema.—*Lyon Méd.*

On the Viability of Infants Born before Term.—Dr. Lavirotte remarks (*Lyon Méd.*, Apr. 13) that the intra-uterine age of the fœtus is not the only condition of viability, and has undertaken to discover the other conditions. After the age, he says, "it is on the volume of the child, on its weight, its muscular force, the more or less advanced organization of its skin, or its nails, that one ordinarily relies for determining the degree of viability." But it will not do to rely on these external signs only. Observations of the functions of the internal organs afford much more certain signs. Respiration sufficient to vivify the blood is necessary; and so above all are those acts relating to digestion, from suckling to defecation. Two fatal cases are given—one of a child born at the eighth month, in whom the cerebral development was wanting; the other, a seven months' child, in whom digestion was not performed. No one, he says, denies the fact that the weakness of infants born before term is due, above all, to a default of development, and he wishes to emphasize the importance of estimating the development of the digestive function when one would judge of the degree of viability of a weakly infant, the appearances of the skin, nails, etc., being of secondary value.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month, by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, August 15, 1873.

OUR INFLUENCE WITH THE PUBLIC.

THE subject of our last leader, having reference to the influence which physicians, as a class, should exercise upon the community, suggests some remarks upon the best means that can be used to gain and to maintain such an influence.

We believe that it is necessary to educate the people. It is a recognized fact that one of the greatest barriers to a communication with the public is the rigid exclusiveness which hems in all our purely professional acts. There is, no doubt, much to excuse this state of things in the very nature of the science of medicine, requiring as it does the possession of a certain amount of special culture to appreciate the real force of its fundamental truths. As a science, it must be considered an exclusive and special one. Those who look at the subject only in this light, and who are intent upon the cultivation of the higher branches of our art, naturally care not to trouble themselves to teach others than those who are cultivated to the point of understanding them. To a certain extent this must always be the case, but the serious question which presents itself at this juncture is, Have we not carried this exclusiveness too far? Have we not also, in the fear of being undignified, not to say unprofessional—in the fear of transgressing our Code of Ethics—damaged our best interests as a community, and thoughtlessly allowed golden opportunities to pass by, which, if decently improved and prudently used, would have given us the very power in the body-politic which we now find we so much lack.

We cannot expect outsiders to listen to us when speaking of abstract subjects—the particular character of a microscopic cell, the peculiar significance of a given symptom, or the intricate and ingenious explanations which belong to pathological manifestations—for if there was such a desire to be informed upon such matters, no benefit could be derived therefrom. We are willing to go far enough to admit that such a knowledge would be absolutely detrimental alike to the teacher and the would-be pupil; that in many things connected with medicine, and especially medical treatment, our patients and the public had better be kept in ignorance. But beyond this we think that the requirements of the age do not demand us to go. There is a middle ground upon which the profession and community should meet for mutual benefit. There are certain truths which should be laid before the people, certain facts which they should know, and they expect to hear them from the profession. We have always believed, and still believe, that these requirements can be met without laying any of us open to the charge of advertising ourselves or of cheapening our calling. If we can succeed in finding this middle ground, and occupying it as becomes educators and advisers, we can obtain and maintain a hold upon the community which we can do in no other way. Nothing will better convince the people of our usefulness than by making ourselves useful to them; nothing will conduce more towards gaining public respect and confidence than proving to them our capabilities as instructors and counsellors.

We have no disposition to underrate our standing as a profession; there are no arguments that can be used to prove that we are not capable of sustaining the requisite dignity, that we are not able to stand as a body of scientific men upon our own merits; but, notwithstanding this, we must admit that the public do not hold us in that estimation which our attainments as scientific men entitle us; that as a body of educated men we are only occupying a third rank in the liberal professions. We cannot see how we compromise our dignity by coming in the same relations to the people as do the clerical and legal professions. We can address our audiences of outsiders in as becoming a way and as effectively as can either of the other learned professions, and by so doing we can have an equal amount of influence with them, leading popular opinion upon subjects concerning which we can speak with authority. Within the last ten years physicians have made a commendable progress in this respect, and we have no hesitation in saying that the profession of medicine has been raised thereby in public opinion. The doctors are not so much ridiculed as they were formerly, but are being more and more respected for the learning of which they prove themselves possessed. Popular lectures upon medical and scientific subjects by representative medical men are not unfrequent affairs, and such lectures are as numerously attended as any other similar entertainments. We have not heard that any harm has come of this practice; even the most fastidious caviller for medical dignity, the most literal interpreter of the Code, having failed to

find objections. On the contrary, however, we have conquered a prejudice among ourselves which now enables us to present our claims for respectability and attainments in the same direct way as has been done by the lawyer and the clergyman.

By increasing a respect for us by the community we gain proportionately in influence, and, gaining in influence, our opinions on all subjects connected with sanitary matters will have their due weight. As it now is, the profession has very little to say on these matters, and generally allows any one to represent it who may have the requisite impudence to pull the necessary wires. There is no question in our minds that if medical men chose to exert their power they could use it to the best of advantage; our health-bills would be made to please the profession, instead of being left to a few conniving medico-political hucksters, whose only concern is to have laws so framed and compromises so effected as shall secure some personal benefits in the shape of large-salaried offices. In other countries, where medical men have their proper standing with the community, their wishes in all projects connected with health and educational matters are respectfully considered by legislative bodies, their special organs are considered the legitimate and authoritative mouthpieces of a powerful class; the resolutions of their societies are always well considered, and not unfrequently medical men are honored by a request to give their opinions in the shape of addresses in the legislative halls. We are convinced that by placing ourselves in our proper relations to the community, by proving to them that we are not too exclusive to look after their interests, they will in turn repay us by respecting our advice and courting our opinions.

There is now more of a necessity than ever that physicians should serve man in something more than his individual state. Important as may be his functions in the latter, the service which he may now render to man in his social or relative state is, if possible, still more so. His relation to mankind, as a whole, is a peculiar and responsible one, especially in reference to the means that can and might be employed to prevent and arrest the spread of epidemics, and to establish sanitary regulations founded upon medical experience and observation. The progress of civilization, the increase of knowledge, etc., among the people, the means which are in daily use for their enlightenment upon matters which relate particularly to their social welfare, create a demand for the very knowledge which the physician, above all others, can impart. The daily press is beginning to appreciate this want, by leading articles on sanitary matters, and publish regularly the doings of health boards, sanitary conventions, and the like.

More than this, many of the laymen, statesmen, and thinkers, not satisfied with information they can obtain from these sources, are beginning to look to the medical journals for more advanced ideas upon the subject. The majority of the community are taking a deep interest in these matters, and the want of the right kind of knowledge concerning them is considered as important as that which relates to ordinary commercial, interpersonal, or international ills. The field is now more than ever open for the medical worker to become a public benefactor, to perform a duty which society has a right to expect of him. It will be the legitimate sphere of the medical man of the future, and if he fails to take advantage of his opportunities, there will be others more ambitious, but less capable, who will occupy the field for him. Already we see quack sanitarians springing up, ignorant pretenders who presume to educate the community on health matters, the publications of whom are beginning to replace the advertising almanacs of the nostrum-venders, all of which give indications of a growing want on the part of the public. This want must be supplied in some shape or other, and it remains to be seen whether the physician of the present and the future will be equal to the emergency.

In our efforts to present facts to the people, there is no necessity for advertising ourselves. When we address popular audiences, either from the rostrum or the magazine, the scientific journal or the daily paper, we are only expected to give opinions, to teach the people, to speak for the cause, but not for ourselves. Popular audiences are critical enough to understand motives, and if such motives be pure they are sure to be appreciated. It is not necessary, for the benefit of a principle, to uphold the expounder as a pivot upon which such a principle revolves. But it is obviously unnecessary to enlarge upon this point, as the boundary line of professional propriety and professional dignity is plainly marked out for every honorable man.

There is another aspect in which to view this subject. The physician, as an educated citizen, stands in another relation to the community. As a medical man, pure and simple, he can speak for his profession and create himself an authority on medical matters; but he has an extra privilege to enjoy, an extra obligation to discharge by virtue of his superior educational advantages and extra-mental culture. He should have the same opportunities to discuss pure political questions as any member of the other professions. We do not advise physicians to become politicians, but we see no good reason why they cannot, as scholars, aid in solving the questions of the day. There are, in fact, questions in the politics of the present and the future which can only be discussed by the educated classes, and the physician should seize the opportunities that may be offered to do his share in this great work. He can in this way not only use what influence he may gain for the benefit of the community, but he can employ it for the good of his profession. All this can be accomplished without sacrificing any dignity, without laying himself open to the charge of being an

office-seeker, or without spending time which might be devoted to professional pursuits.

There used to be a time when it was considered highly reprehensible for a physician to have any dealings, directly or indirectly, with political questions; but happily there has been a change of sentiment in this respect. It is no longer disgraceful to be identified with any political question, or even to hold political opinions. We find physicians in our legislative halls all over the country, and we have not heard that they, as a class, have proved themselves stupid in dealing with public questions, nor have shown themselves disloyal to their profession. On the contrary, we know of many instances where an educated physician in a legislature has saved the infliction upon his brethren of many an unjust enactment, the passage of which, under other circumstances, might have been inevitable.

Very few medical men can afford the time to occupy political offices, but each and every physician can do his part towards creating that sentiment of esteem for the profession which shall increase its influence and give force to its opinions. In purely political relations each one must choose his own side; there is good enough in both parties to enlist the labor of the best men, but for strictly medical influence the profession should be a unit. Whenever the public welfare is at stake, whenever discussions come up, we should throw our united influence towards the creation of sanitary reforms, and not bewilder the public with hair-splitting distinctions or trivial differences of opinions concerning pet theories. It is this disposition to differ in matters of detail which the public cannot appreciate; and for the pains we take to be precise in ventilating individual opinions, we earn for ourselves the unenviable title of quarrelsome. In fact, almost all of the discussions which have been published in the daily papers partake of that character, and help to maintain such a reputation for us. Prominent among these stand the published deliberations of the American Medical Association, the only use of which, in the eyes of the public, seems to be an opportunity for all sections of the country to represent themselves in a general family quarrel once a year.

We have tried to protect our interests by legislative enactments; but this has so signally failed that we must give up all hope in that direction. In fact, we cannot expect our legislators to respect the claims of one set of citizens at the expense of another set. Our very efforts to protect ourselves have resulted in a diametrically opposite direction. The best way to guard our interests is to make them common with the community, and prove ourselves, by our desire to benefit the people as a whole, entitled to claim their countenance and respect. We have it in our power, if we move in the right direction, of creating for ourselves an influence with the people which no law can make for us—neither any legislative body, by any of its enactments, overthrow.

Reviews and Notices of Books.

THE MICROSCOPE AND MICROSCOPICAL TECHNOLOGY. A text-book for physicians and students. By Dr. HEINRICH FREY, Professor of Medicine in Zurich, Switzerland. Translated from the German, and edited by Dr. GEORGE R. CUTTER, M.D., Clinical Assistant to the New York Eye and Ear Infirmary. Illustrated by 343 plates and containing the price-lists of the principal microscope-makers of Europe and America.

WE regret that continued illness of the reviewer has prevented this excellent book from receiving the notice it deserves. It has been so favorably known to microscopists who have been able to read it in the original that it has already, doubtless, been in the hands of most of those who have made an especial study of this branch of medicine. It therefore seems superfluous to give it an extended notice. The present volume is a translation of the fourth and last German edition, which itself had been considerably altered by the author to correspond with the advance in this science. The first 107 pages are occupied with the theory of the microscope, the different kinds in use, the apparatus for drawing and measuring, and the methods of testing and of using the instrument. Such optical principles as are indispensable for the student to know are laid down with clearness, but theories that are still unsettled receive only a passing mention. This part of the book teaches also the use of the various parts of the instrument and the implements necessary for ordinary microscopic work.

In the following 102 pages the author gives an account of the different ways of preparing microscopic objects, the reagents to employ, tells us how to stain, how to impregnate the tissues, the way to freeze, inject, and how to arrange objects. These chapters will be the delight of the practical microscopist, as they are exceedingly rich in the details essential in obtaining elegant specimens for study or permanent preservation.

The 386 pages immediately following are devoted to a brief description of the minute anatomy of the various organs and apparatuses. The author does not aim to furnish a manual on this subject, but leaves the thorough and detailed account for larger books. The text of this portion is illustrated by numerous plates, and its dryness is thereby very materially relieved. There is little allusion made to the minute changes that take place in diseases, as the limits of the book do not allow it. The American editor and translator has much increased the value of the book by adding important notes and information for students generally. The history of the successive steps by which American skill has gradually brought the American microscope to its present high standard is extremely interesting.

Valuable improvements that have been made by Americans are also noticed. Finally, he has appended to the work a list of the microscope-makers of the world, with their catalogues and price-lists, and gives directions for making purchases here and abroad. With these additions it is the most complete book of the kind we know of. Every practitioner or student who wants a practical instructor and companion for microscopical study should own this book. The fund of information that it contains is not to be found elsewhere.

In conclusion, we have little fault to find with the way in which the work has been rendered into Eng-

lish. It is in general a vast improvement on many of the translations which are current among us. In some places we could wish that the names which have already had the sanction of use had been retained. Such terms as "iodized serum," "beaker cells," "reef and ribbed cells," have been recognized in this country and in England. It would seem more sensible, too, to adopt the terminology of our own Pharmacopœia than to retain the German. In other respects there is little to complain of. There are but few typographical errors, and the whole get-up of the book is extremely good.

THE FUNCTION OF THE EUSTACHIAN TUBE, ETC. By THOS. F. RUMBOLD, M.D., Saint Louis. South-western Book and Publishing Co., St. Louis.

WE have before us a pamphlet of 40 octavo pages on the "Function of the Eustachian Tube," by Thos. F. Rumbold, M.D., St. Louis.

The author announces at the start that he will endeavor to prove the correctness of the following propositions, viz.:—

1st. That during the act of deglutition the Eustachian tube is not an open passage into the tympanum.

2d. That the walls of the Eustachian tube are constantly in slight contact.

3d. That the air continually permeates the Eustachian tube into the tympanum, thus maintaining the normal air-density in this cavity.

4th. That the air in the normal tympanic cavity is not of equal density with that of the surrounding atmosphere, the air in the tympanum being rarefied.

5th. That one of the functions of the Eustachian tube is the maintenance of this normal air-density.

6th. That the rarefied condition of the air in the tympanum is the cause of the uniform concavity of the membrana tympani, especially that portion of it from which the "light spot" is reflected.

He then proceeds to narrate the histories of seven cases from which, in a somewhat disjointed manner, he deduces the conclusions formulated above into distinct propositions.

In regard to the last of these, we would say, that the uniform concavity of the membrana tympani is not due to the rarefied condition of the air in the tympanum, but to its own peculiar anatomical construction, as described by Helmholtz (*Mechanism of the Ossicles and Membrana Tympani*). As to the other propositions we have no serious objections to raise, except that they lack the element of novelty which the author would seem to claim for them. Rüdinger has taught, since 1869, that in the normal ear there is a constant communication between the air in the pharynx and that of the tympanum. He has even gone so far as to demonstrate anatomically the existence in the uppermost portion of the Eustachian tube of a minute canal, whose function is to maintain this constant communication.

As to the question of there being a more rarefied air in the tympanum than in the external auditory canal, we have simply to say that the difference between the two must be very slight, for otherwise the tympanic mucous membrane would be in a constant condition of hyperæmia, which is not the case in the normal ear. We admit, however, that there is a constant *tendency*—if we may so term it—to rarefaction of the air within the tympanum, and that this tendency is sufficiently marked to establish a steady current of air from the naso-pharyngeal space into the tympanum. This tendency, moreover, is shown by the fact that cicatricial portions of the membrana tympani, if not too richly provided with regenerated radial or circular fibres, are usually found to be outwardly more concave than the surrounding portions. It is proper, however, to state that Rumbold denies the fact that these cicatricial portions ever contain regenerated radial or circular fibres. We also confess surprise at his statement that the circular and radial fibres are muscular in character.

The chief faults we have to find with this essay are, first, its great length. The facts could all have been stated and properly elaborated in an essay of ten instead of forty pages.

In the next place, the author is in a constant hurry to *prove* his points. The reader is thus constantly obliged to dissent from the writer in regard to the interpretation of certain phenomena observed.

Finally, we object to the tendency of the essay, which is to convey to the mind of the reader the impression that otologists are all wrong in their views about the workings of the Eustachian tube and membrana tympani, and that the author, while "dreading to contrast his experience with the learned and matured opinions of such eminent authors as Toynbee, Helmholtz, Tröltsch, and others," was, nevertheless, in duty bound to show these specialists the errors of their beliefs.

Correspondence.

"LABOR PAINS" VERSUS "RETRACTION OF THE UTERUS."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I beg leave to lay before the readers of the MEDICAL RECORD the following extracts from a paper* published in the (June) number of the *New York Medical Journal*, together with some remarks, bearing upon what I consider its most extraordinary theories and conclusions.

Page 562. "To avoid confusion, I propose using in the following discussion the term 'labor pains,' in the sense of uterine contractions, a distinction made necessary in our language by the frequency with which we hear it stated that women are having strong 'pains,' when, upon examination, we find only a feeble measure of uterine contraction—the word pains evidently here signifying nothing more than an unduly severe amount of physical suffering. . . . . However revolutionary as it may seem, there is tolerably good ground for questioning the pretty generally accepted opinion, that in the independent action of the circular, oblique and longitudinal layers of muscular fibres, which may be demonstrated in the pregnant uterus, we have furnished us the key to these forms of abnormal uterine action. The existence of such layers is not of course denied, but their importance has unquestionably been greatly exaggerated by the desire of the anatomist to answer the questions of the obstetrician. . . . . Now, it is not probable that these circular fibres possess any more functional importance in the uterus than they do in the vagina, yet I hardly think any one would invoke spasmodic stricture of the vagina proper as a cause of dystocia. . . . . There is strong *à priori* reason to doubt whether the uterus during labor ever contracts, except in its totality. . . . It is matter for consideration whether all the pretended strictures of the os, instead of being due to spasm, are

* The Etiology and Indications for Treatment of Irregular Uterine Action during Labor. By William T. Lusk, M.D., Professor of Obstetrics, etc., Bellevue Hospital Medical College.

not dependent upon insufficient uterine contraction. . . . . Persons often speak of the pains being strong, but affirm that labor does not progress on account of the resistance offered by a firm catgut-like band at the uterine orifice. I have often met with this condition, but have failed to ever find it associated with good pains *of a markedly expulsive character* (the italics are mine—P. C. B.). The patient usually gives expression to an intense degree of suffering, but intense suffering is the constant accompaniment of weak pains and prolonged labor, when the uterus presses upon, or is pressed upon by, its contents for any considerable period of time. . . . . Now, were really good pains associated with this form of rigid os, the same danger (laceration) would be incurred by pressure from above. Instead of the os arresting the expulsion of the fœtus, it would be torn through in most instances like so much paper. As a matter of fact this does not take place, because under the influence of strong pains the os rapidly loses its catgut-like feel, and softening and expansion occur simultaneously. . . . . The uterus, in addition to contractility, likewise possesses retractile properties. These are shown in a very marked way by the manner in which the uterus closes upon its contents after the rupture of the membranes; so, too, by the manner in which the uterus follows down the fœtus during the period of expulsion. . . . . To the same retractile properties of the uterus are to be ascribed the irregular pains so common in cross births and contracted pelvis. . . . . We then have what is termed stricture of the os internum. It is not due to the spasm of any special bundle of circular fibres, but the uterus, as it retracts upon its contents, becomes conformed to the irregularities of the fœtus. The small size of the child's neck permits a more complete retraction of the muscular fibres at that point. . . . . In either case,* the indication is to excite expulsive pains, and this is best fulfilled by kneading and compressing the uterus, seeking thus by a *vis a tergo* to overcome the constriction. . . . . A somewhat exaggerated form of this condition (retraction) produces the familiar hour-glass contraction. Previous to the rupture of the membranes the existence of weakness of pains can hardly be determined. Only after rupture are we in a condition to recognize the presence of primary weakness. Primary weakness becomes dangerous when the uterus, instead of exercising expulsive action, retracts upon its contents so as to closely invest the fœtus. In such a case, the child's life is compromised both by pressure and by interference with the utero-placental circulation. Secondary weakness results where an obstacle exists which the pains prove ineffectual to overcome. . . . . Uterine retractility is not precisely the same force as that which causes the expulsion of a fluid from an over-distended elastic bladder, for retractility and contractility are in the uterus rarely disassociated from one another. When the uterus ceases to contract, it forfeits, in the rule, its retractile properties likewise."

I will make but one more addition to these extracts from the article (although there are other ideas advanced which challenge examination); for I discover that I am in danger of exceeding the length that such a communication is entitled to, in the crowded columns of your journal.

"Every busy man will find in the ordinary events of his own practice the sort of evidence best qualified for verifying or disproving the opinions I shall endeavor to maintain."

Accepting the restriction, I will discuss his "opinions," mainly in the light of my own obstetric experience, extending back through thirteen "busy" years.

It is his opinion that physicians, and others, err in stating that strong "pains" exist when upon examination only feeble contractions of the uterine fibres are found to accompany the "unduly severe amount of physical suffering." Now it is often necessary, for purposes of description, to indicate whether these two symptoms are associated or not. When they are, his use of "labor pains" is brief and (when understood) explicit enough; but when they are not, while it may be elegant to say, "the patient had an unduly severe amount of physical suffering, with but feeble contractions," or, perhaps, none at all, still it takes too much time; and probably the authority of long-continued usage, as well as the force of habit, would cause most people to say that the patient had "false pains," and it is altogether probable that every medical man would know exactly what the expression implied, no matter what his idea concerning the etiology of them might be. On the other hand, "good pains" is an expression used by common consent, when gentle contractions of the body, accompanied by dilatation of the os, attend the physical suffering of the patient.

Prof. Lusk recognizes the existence of the different layers of muscular fibres, but asserts that they possess no more "functional importance in the uterus than they do in the vagina as a cause of dystocia." He doubts "whether the uterus during labor ever contracts except in its totality" on one page, and admits the condition usually described as contraction of the circular fibres of the external and internal os, and of the body of the uterus, in other places; nay, more, he makes repeated use of these phenomena to illustrate his "opinions" on retraction; and in one place uses the word *constriction* as applied to the internal os.

"Pretended strictures of the os" are "dependent on insufficient uterine contraction." As many times as he has met with this condition, he has never found it accompanied by pains of a *markedly expulsive character!* The intense suffering attending these delayed labors is dependent on the *weakness of the pains!!* These are truly unique explanations.

"Vis a tergo" is all that is necessary to overcome these "pretended strictures of the os," from contraction of the circular fibres; and it is also his opinion that if such a spasm were ever associated with really "good pains" (expulsive), the os "would be torn through, like so much paper." His prediction was antedated by fact, several years, in my experience, I having observed this very accident happen to four patients,—in one instance (a "primipara") proving fatal:—He says, "as a matter of fact, this disaster does not take place, because strong pains cause *softening* and dilatation to occur simultaneously."

I have many times, including those above mentioned, met with cases in which strong contractions in the body of the uterus were accompanied by decided contraction and temporary rigidity of a half dilated "os,"—particularly after the exhibition of ergot.* In fact, this result followed its use so constantly in my experience, not only in this stage of labor, but the second and third as well, and upon all the circular fibres of the organ, that I long since discontinued the administration of ergot entirely during labor; and

* Delay during the passage of the neck through os internum in either vertex or breech-presentation.

* See an article by the writer in *N. Y. Med. Jour.* for June, 1869, pp. 265–266. Cases V. and VI.

now, when I give it after the expulsion of the placenta, I always combine it with opium to insure a contraction of the uterus "in its totality."

Dilatation of the "os uteri" seems to me to partake of both an active and passive character, in a "normal physiological labor." The circular fibres cease to exercise their contractile powers for the time being (just as the powerful muscles of the perinæum and "sphincter ani" are often observed to do during the progress of the child in the second stage). And the connective tissue of the "os" alone resists the active, though gentle, contractions of some of the fibres of the body of the uterus. These contractions, besides exercising a direct, dilating force upon the "os" (as I believe they do, and which I shall again refer to), force the "bag of waters," first against, and subsequently through the partly dilated orifice; and thus they become a useful auxiliary in the process. But there are two conditions in which neither the "bag of waters," nor contractions of the uterus in its totality, would be competent to produce dilatation; and yet, in both instances, I have repeatedly observed a satisfactory completion of the process. I refer to a transverse position of the child, with an escape of the "waters," and to complete "placenta prævia." In this latter condition, the os is strongly reinforced by the adherent placenta; and the impulse must at least be much impaired as a dilating force.

Now, a muscle contracts, if at all, in the direction in which its fibres run. The longitudinal fibres of the body of the uterus are in part continuous through the whole length of the cervix, becoming lost in the connective tissue surrounding the os. This may be called their attachment. If these fibres contract the effect will be to shorten the uterus by causing the "fundus" and the "os" to approach each other. Owing to the "incompressibility" of the contents of the uterus, this can only be accomplished by the dilatation of the "os."

I submit that this supposed activity of one set of fibres, alone, is no more wonderful, nor incomprehensible than is the acknowledged passivity of another.

The author of the article under consideration seems to consider that the uterus possesses not only the power, but the disposition to "retract upon its contents" under various conditions. "The closure of the uterus upon its contents, after the escape of the waters," the manner in which the organ "follows down the fœtus during the period of expulsion," the "closure" of the circular fibres at the "os internum," around the neck of the child (in both head and breech presentations), and the hour-glass condition of the body of the uterus which imprisons the placenta,—all these are different manifestations of "retraction," and the latter a "somewhat exaggerated" form of it.

When in pelvic presentation, after the passage of the shoulders, the circular fibres "retract around the neck" of the child, he says the indication is to "excite expulsive pains by kneading and compressing the uterus," seeking thus to overcome the constriction by a "vis a tergo." Strange advice to give a young practitioner, to drop the body of the child, whose very existence depends upon the skill and dispatch which he brings to bear in the management of the case, that he may "knead" a nearly emptied uterus, in the expectation of exciting sufficient "vis a tergo" to expel the child alive. As soon should a helmsman leave his rudder, to trim a sail, in a storm. "Kneading" the uterus is well enough, if an assistant is at hand to do it; but (it seems to me) the "accoucheur's" first duty is to attempt to deliver the head in the usual manner; and if the first hurried effort fails, he should pass a piece of firm rubber tubing (say ⅝th-inch in diameter and a foot long) previously prepared, into the child's mouth, and give his whole attention to exciting respiratory efforts in the child. After respiration has been fully established, and the semi-asphyxiated condition of the child has been relieved, the uterus, having had time to collect its energies, may be able to complete the delivery.

A word more concerning "retraction," and I will bring my "too-extended" remarks to a close. There seems to be no particular objection to the use of the word, if applied to the "os" in the process of dilatation, though that is not at all the sense in which Dr. Lusk uses it; but I can imagine no other condition or function of the uterus, nor do I think he has used the word in connection with any, in which retraction describes the actual phenomena.

MORRISTOWN, N. J.

FOUL WELLS AS A CAUSE OF TYPHOID FEVER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Fearing that there yet may be some who doubt the drinking of impure water to be a fruitful cause for the development of typhoid fever, I deem it to be my duty to contribute to the columns of your journal some recent experience I have had, and which is, I think, sufficient proof of the fact.

I was recently summoned many miles into the country for the purpose of visiting the son of a farmer, fifteen years of age. I found him with the usual symptoms of typhoid fever.

While in attendance, and within four days, I was asked to see another son, aged ten, in an adjoining room.

He was then confined to the bed the greater part of the time, having had the symptoms attending the prodromic period for about a week. Not yet suspecting the real cause, I made no particular inquiry relative to the condition of the premises except so far as related to the cellar. I found that to be, with a slight exception, free from any poisonous matter.

Within three days I was again asked to see still another child, a little girl aged seven, who was suffering almost precisely as were the other two.

I then began an investigation relative to the house-drain, and found, so far as I then deemed it necessary to examine, nothing which I considered of sufficient cause to produce the particular illness.

But when within three or four days my attention was again called to another child, aged twelve years and four months, I concluded there must be some cause, aside from contagion, which could be discovered. I might add that the children composing the family numbered eight in all, and that upon summoning the balance, and instituting the necessary inquiries, I found that two of the remaining four were complaining of "not feeling well." "Some diarrhœa, with chilly feelings and headache."

I then desired the drain, which received the slops of the house, to be thoroughly opened. It ran in the direction of the well, the water of which was used for the family's general use, although it passed it to the right some four feet. Upon inspection, the following day, I found that there was a perfect communication between the drain and well at a point directly opposite the well, so that all matters thrown into the drain passed directly into the well. And I found all the surfaces of the drain beyond this opening perfectly dry.

I might state that this occurred at what is called "a very dry time," and the water in the well, as I was informed, was much lower than it had been in years. Its use was at once abandoned, but its effects did not cease until the two children who were then slightly ailing, and the mother, took to the bed, and all passed safely through a severe trial of the disease, save the mother, who succumbed to it in six days from the time she went to bed.

The only ones of the family who escaped the terrible scourge were the father and oldest daughter; unless the youngest child, which was still nursing when the mother was seized, was amenable to it (which I very much doubt).

I will not extend this paper by any further remarks, as it will now occupy too much of your valuable space.

D. Colvin, M.D.

Clyde, N. Y.

PERINEORRHAPY.

To the Editor of the Medical Record.

Sir—In perineorrhaphy I use, instead of metallic wire, a suture of horse-hair. Take two horse-hairs, each sixteen inches long; pass them through the eye of a large semicircular needle; bring the four ends together and tie in a single knot. Arm in this way as many needles as you intend to introduce sutures. Then proceed as in the ordinary operation, using Dr. Sims' matchless needle-holder; cut off each strand, after its introduction, close to the eye of the needle, and knot the end. Insert the sutures pretty close together, say half an inch apart. After all are in place, bring each pair of ends together and tie in a surgeon's knot, making the common interrupted suture. For superficial stitches a single horse-hair answers admirably.

Horse-hair is easier of management than silver wire; it causes no suppuration along its course; it does not chafe or excoriate the external genitals; it is not liable to catch in the patient's linen; and when its office is ended it can be withdrawn painlessly. I have never used it in the quilled-suture.

E. S. Bunker.

Brooklyn, July 14, 1873.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from July 19, 1873, to August 4, 1873.

Simons, J., Surgeon and Medical Director.—Granted leave of absence for 30 days with permission to apply for an extension of 30 days. S. O. 124, Department of the Gulf, July 28, 1873.

Frantz, J. H., Surgeon.—Leave of absence extended from July 20, 1873, seventy days, on Surgeon's Certificate of Disability. S. O. 153, A. G. O., July 29, 1873.

Webster, Warren, Surgeon.—Granted leave of absence for thirty days. S. O. 143, Department of the East, July 28, 1873.

Knickerbocker, B., Assistant Surgeon.—Leave of absence granted by S. O. 88, Department of the Columbia, July 15, 1873, extended 30 days. S. O. 135, Military Division of the Pacific, July 23, 1873.

Woodhull, Alfred A.—Assigned to duty at McPherson Barracks, Atlanta, Ga. S. O. 131, Department of the South, July 23, 1873.

Brooke, Jno.—Relieved from requirements of par. 2, S. O. 78, c. s., from these Headqurs. S. O. 87, Department of the Columbia, July 12, 1873.

Phillips, H. J.—Assigned to duty as Post Surgeon, Camp Warner, Oregon. S. O. Headqurs. Department of the Columbia, "in the field," July 8, 1873.

Lippincott, H.—Assigned to duty at Camp Lowell, A. T., S. O. 53, Department of Arizona, July 8, 1873.

De Witt, C.—Assigned to duty at the Presidio of San Francisco, Cal. S. O. 86, Department of California, July 11, 1873.

Cleary, P. J. A. Assigned to duty at Fort Griffin, Texas. S. O. 139, Department of Texas, July 25, 1873.

Munn, C.—Assigned to temporary duty at Fort Independence, Boston Harbor, and to return to his proper Station (Fort Adams, R. I.), when Surgeon Webster returns from leave. S. O. 143, c. s., Department of the East.

King, W. H.—When relieved by Assistant-Surgeon Woodhull, assigned to duty at Yorkville, S. C. S. O. 131, c. s., Department of the South.

WAR DEPARTMENT.

SURGEON-GENERAL'S OFFICE,

Washington, *July* 24, 1873.

CIRCULAR ORDERS, NO. 5.

The Surgeon-General has observed that certain medical officers neglect to furnish the quarterly reports of wounded and of surgical operations required by Circular Orders, No. 3, Surgeon-General's Office, June 20, 1866. Attention is therefore directed anew to the provisions of that order:

"Washington, D. C., *June* 20, 1866.

CIRCULAR ORDERS, NO. 3.

The directions embodied in the Circular Letter from this Office of January 20th, 1864, relating to the Register of Sick and Wounded and of Surgical Operations to be kept at General Hospitals, will, hereafter, apply to Post Hospitals of a permanent character.

The same form of registration will be employed by Medical Officers serving with detachments or temporary posts, the blank forms for the quarterly reports of wounded and of surgical operations being used for this purpose. These blanks will be issued upon requisition upon this Office.

All Medical Officers will forward to this Office, quarterly, on March 31, *June* 30, *September* 30, *and December* 31, *reports of wounded and of surgical operations in the form heretofore required of Medical Officers in charge of General Hospitals, or else a statement that no such cases have been treated by them. These reports are additional to the ordinary monthly reports of sick and wounded, which will be made as usual.*

A Medical Officer, upon being relieved of the charge of a temporary hospital or detachment, will make the reports above required without awaiting the expiration of the quarter.

By order of the Surgeon-General:

C. H. Crane,
Surgeon, U. S. Army."

Medical Directors will enforce the strictest compliance with this order, and also with General Orders, No. 355, Adjutant-General's Office, November 4, 1863,

and Circular Letter, Surgeon General's Office, March 23, 1864, relative to casualty lists and classified returns of injuries received in action. These instructions have force not only in time of war, but on the occasion of any hostile engagements, however limited.

There are other modes by which officers may aid in maintaining or elevating the character of the corps for scientific usefulness, which must, of necessity, be spontaneous or voluntary. Since the publication of the report of surgical cases observed in the army during the five years succeeding the war, the Surgeon-General has had gratifying evidence that the materials accumulating for a similar report for the next quinquennial period have been prepared with increased and laudable care.

During the past two years the contributions to the Army Medical Museum have been valuable, the number of contributions having slightly augmented in the last year. In the former year, fifty-two, and in the latter sixty-two medical officers were upon the list of contributors. The number of donations from practitioners in civil life has also steadily augmented. But the development of the Museum must always be mainly due to the zeal and industry of the individual members of the corps; who, it is hoped, will ever be keenly alive to its interests, and suffer no suitable means of aiding in its objects to pass unimproved.

Notwithstanding the multifarious correspondence on the subject, both official, and personal and informal, it is found that there are misconceptions regarding the nature and extent of the subject matter to be embraced in the professional reports, and, in a greater degree, respecting the miscellaneous data, the anatomical, pathological, ethnological material, the descriptions of specimens and of autopsies, the accounts of cases not borne on the sick reports, the minutes of analysis, and reports of original researches, in short of all the varied results of professional labor which, in addition to the strictly official returns, it is desired to collect and preserve. In regard to the official medical and surgical reports, it appears impracticable to give more specific directions than are either printed in connection with the blank forms, or in regulations or orders, unless by giving the force of an order to the recommendation in the report published by Circular 3, of 1871, viz.: that the name and military description of all cases entered under Class V., on the monthly report of sick and wounded, should be noted in the remarks, and that the patient should appear, by name, on the reports of the succeeding months until finally accounted for. Nor does it appear possible to express more clearly the wishes of the Office respecting reports of cases of citizens not borne on the official returns. Such reports, and all other information of professional interest, are acceptable, and provision is made for using them to the best advantage, by indexing and preserving them for reference and for publication. In regard to the second class of materials, it is hardly possible to dwell too strongly on the importance of the study and preservation of examples of morbid anatomy, human or comparative, resulting either from disease or from injuries. Medical officers are often deterred from forwarding specimens belonging to pathological groups in which the collections of the Museum are presumed already to abound. But there are few if any classes of subjects in which the Museum can forego the advantages of comparing analogous specimens, and duplicates can always be advantageously used in exchange. Autopsies are often omitted in cases of accidental or criminal homicide, when the proximate cause of death is apparent. But examination of such cases will often prove instructive, leading sometimes to the detection of unsuspected alterations, sometimes to the observation of curious anomalies. Frequently the preservation of normal structures and of entire organs is desirable. It has been objected that some posts are unprovided with dead-houses, or suitable facilities for *post-mortem* examinations. Zealous medical officers will readily improvise means for overcoming such obstacles, and will not fail to make autopsies whenever it is possible. It is important further to note with precision the symptoms in the cases of sudden and violent death. They are usually dismissed in general terms. Yet a comparison of averages, in such cases, may lead to important inferences. The general rule to weigh, measure, or describe in exact terms, whatever is susceptible of precise definition, would not be supposed to require iteration, were it not so often disregarded. The thermometric determination of the animal temperature after grave injuries is a promising field of investigation. The remote results of injuries are often brought to the notice of medical officers, and they will bear in mind the desire of the Bureau to accumulate information on this subject. Everything relating to recoveries after penetrating wounds of the three great cavities, or of the large joints, to examples of successful major amputations, excisions, and ligations, to symptomatic nervous disorders, to instances of the lodgment of foreign bodies, will be of interest. Accurate observations are especially needed in regard to the comparative results of formal excisions and that form of conservative treatment which is restricted to the removal of detached fragments, conjoined with free incisions, when requisite, for the elimination of foreign matter; and, secondly, regarding the ulterior conditions of consolidated shot fractures of the femur.

The Museum possesses numerous crania: but it is the opinion of anthropologists that inferences must be made very cautiously from measurements that do not represent large averages. It is desired that every opportunity be improved of adding to the collection of human skulls. Such labors as those of Surgeon Swift and of Acting-Assistant-Surgeon Comfort, in exploring the tumuli near Vicksburg and in Dakota, and adding scores of aboriginal crania and skeletons to the collection of the Museum, are deserving of commendation, and should excite emulation.

A large number of vesical calculi have been presented to the Museum, which have been classified according to their pathological relations and again according to their chemical composition. The advantages of analyzing and grouping such specimens are obvious, and several leading lithotomists and lithotrists now habitually send to the Museum all the concretions they remove, that they may be analyzed and preserved permanently, and contribute to the formation of statistical data, on a large scale, of the results of operative interference.

These few of the many means by which the Corps can aid in the advancement of knowledge are adverted to, with the hope that the standard of its efforts in this direction will not only be maintained, but continually advanced, as demanded by the requirements of scientific progress.

By order of the Surgeon-General:

C. H. Crane,
Assistant-Surgeon-General, U. S Army.

Eye Hospital at Geneva.—Baron Adolph de Rothschild has given $100,000 for the foundation and endowment of a hospital for diseases of the eye and ear.

Medical Department of Life Insurance.

THE LAWS OF TRANSMISSION OF RESEMBLANCE FROM PARENTS TO THEIR CHILDREN.

By JOHN STOCKTON-HOUGH, M.D.,

OF PHILADELPHIA.

PART I.

Infantem plus ex matre quam a patre habere.*

Mares similes matri, fœminæ similes patri generentur.†

Mas avo materno similis: Fœmella avo similis paterno ‡

THE question of resemblance of children to their parents is one in which many ancient and a few modern authors have found a field for much close observation and profound philosophy, carrying their discussions and deductions to all possible degrees of differentiation and detail. Some of their reasons and conclusions as to causes are scarcely plausible, but many of them bear evidence of close observation and careful consideration, for modern research has in several instances discovered proximate causes which fully corroborate these ancient opinions.

Aside from the physiological and philosophical, this question of resemblance has a practical bearing, and that is in regard to the estimate one may make of the prospect individuals may have of longevity, from an examination of their family history, determining from this their resemblance to their ancestors, and judging of their likelihood or predisposition to hereditary or acquired affections.§

In order to avail one's self of the advantages of a knowledge of this subject, it is necessary to be conversant with the laws which govern the transmission of resemblance, and this is the province of our paper to determine. Ludovicus Mercatus says that there are three similitudes of children to their parents: Prima quidem est in specie, secunda in sexu: tertia verò et ultima in proprietatibus individualibus. The last division comprehends all that we shall have to say on the subject. Several authors have given us works on hereditary diseases, some of which I have named below.¶ We cannot enter very far into this feature of resemblance, and have therefore cited only such cases as bear upon the practical part of the topic under discussion.

It is the object, then, of this paper to bring before the reader such facts as are at hand to determine the general laws which are brought to issue in the following questions:—

1. Do children derive their resemblance and inherit diseases more frequently or more easily from their mothers than from their fathers?

2. Are males more apt to inherit the diseases of their mothers, and females those of their fathers; or is the reverse the case?

3. What are the laws of physical and physiognomical inheritance?

4. Is there any constant relationship between the physiognomical resemblance of an individual to an ancestor, and the likelihood of this individual being afflicted or dying of the same constitutional or acquired disease? If so, is a physiognomical resemblance an indication of a likelihood to the same constitutional affections, or the reverse?

The various aspects of resemblance by relationship are as follows:—

In general:—

1. Children resemble their mothers more than their fathers.

2. Males resemble their mothers, and females their fathers.

3. When children do not resemble their parents, but their grandparents, males resemble their maternal grandfather, and females their paternal grandmother.

Exceptionally:—

1. Children resemble their fathers more than their mothers.

2. Males resemble their fathers, and females their mothers.

3. Male resembles paternal grandparent, female maternal grandparent.

4. Offspring resembles male by whom female was previously impregnated more than its natural father.

I propose to discuss the laws of resemblance as laid down in the three first hypotheses.

Aristotle * teaches that in general children resemble their fathers more than their mothers, and Harvey † theorizes as to the cause. Ambrose Paré ‡ is of the same opinion, and advances as a reason, that "in concubitu" the mind of the woman is more fixed on the man than that of the man on the woman. This explanation may hold in a few exceptional cases, for we not unfrequently read of cases in which the female produces offspring resembling a male of whom she may have been enamored but who was not the father of the product. This influence of imagination or impressions on the mother is familiar to all, in the practice of Jacob, who placed rods of different colors before his ewes that they might bear speckled lambs. (Gen. chap. xxx., v. 37–41.) This view of the matter, however, is not to be taken as the rule, any more than the curious notion of Dr. Erasmus Darwin,§ who ascribed the large proportion of male births in Rome at a certain period to the prevalence of certain ornaments at the orgies of Bacchus.

Prichard ‖ says that "children resemble, in feature and constitution, both parents, but I think more generally the father. In the breeding of horses and oxen great importance is attached, by experienced propagators, to the male. In sheep it is commonly observed that black rams beget black lambs. In the human species, also, the complexion chiefly follows that of the father; and I believe it to be a general fact that the offspring of a black father and a white mother is much darker than the progeny of a white father and a dark mother."

‖ Researches into the Physical History of Mankind, vol. ii., p. 551.

The son is more likely to have the moral excellence of his mother, while his bent or inclination or genius (vocation best suited) will come from the father, modified in quantity and quality by the mother. The general mental qualifications will be of the type (kind) of the father, modified in quantity and quality by the mother. Sons are thus usually able to follow their father's vocation better than others of a different character.

Sir Anthony Carlisle says that a schoolmaster informed him that his scholars whose fathers were mechanics learned mathematics better than classics, while those whose fathers were classical scholars learned foreign and dead languages better than mathematics.

Those who maintain that children derive more of their qualities from their fathers than from their mothers have given no substantial reasons nor sufficient number of examples in support of their position to convince us that this is the general law. The truth of the matter seems to indicate that such cases as appear to conform to this view are exceptional, and often come from coupling unequally bred individuals, the male, in such cases, having the prepotency in transmission. In breeding animals this fact is often taken advantage of as a matter of economy. One well-bred male may transmit his superior qualities to a large number of offspring in a single season, while the female can give any qualities she may possess to but few, generally only one product.

In selecting animals for breeding, "economical purposes have made the male in general the most important, simply because he serves for a considerable number of females. The consequence of this has been that more attention has been paid to the blood or purity of race of the stallion, bull, ram, and boar than to that of their females; and hence it may be the case that these males more frequently transmit their qualities to the offspring than do the inferior female with which they are often made to breed. But this circumstance can scarcely be adduced as a proof that the male, caeteris paribus, influences the offspring more than the female."*

According to Mr. Louatt,† the relative influence of each parent, in breeding, on the offspring depends most upon the mother, where the parents are equally well bred, other things being the same; but the high-bred male pairing with the half-bred female will have a preponderating influence on the offspring.‡ Socrates and Coriscus are of the opinion that children generally resemble their mothers more than their fathers, and this appears to be in harmony with the teaching of our most eminent physiologists and scientists.

Linnæus conceived the character of the male parent predominated in the exterior parts both of plants and animals, and the same opinions have been generally entertained by more modern naturalists.

Mr. Knight § seems to differ somewhat from this opinion of Linnæus, "for I have observed," says he, "that seedling plants, when propagated from male and female parents of distinct characters and permanent habits, generally, though with some few exceptions, inherit much more of the character of the female than of the male parent, and the same remark is applicable in some respects to the animal world."

"Mr. Cline, the eminent surgeon, has observed," says Mr. Knight,* "in a communication to the Board of Agriculture, that if the male and female parent differ considerably in size, the dimensions of the fœtus, at the birth, will be regulated much more by the size of the female than of the male parent."

According to Earl Spenser,† Mr. Cline believes "that it is alway desirable that the male should be smaller than the female." The Earl is of the opposite opinion, and I think justly so, if we are guided by the fact that males are always naturally larger than females.

The comparative influence of the male and female in transmitting hereditary disease is one of great interest, particularly in regard to syphilis. In this last-named affection, authorities differ greatly,—from the view of M. Cullerier,‡ who believes that it is never transmitted from the father to his offspring, to that of Mr. Hutchinson,§ who is of the opinion that the father can transmit the disease in as severe a form as the mother. M. Cullerier is supported in his view of the relative power of transmission, by the one or the other parent, by MM. Notta ‖ and Follin.¶ Prof. Boeck ** and Mr. Morgan †† believe that the father rarely transmits the disease, and Dr. John S. Parry ‡‡ says, after a very careful review of these opinions, and well-weighed deductions from his own observations and experience: "I cannot but believe that the mother is much more likely than the father to transmit syphilis to the children, and that, as Mr. Morgan says, the influence of the father has been exaggerated."

Mr. J. B. Thomson, in his papers "On the Comparative Influence of the Male and Female Parent upon the Offspring,"§§ advances the opinion that it is the male chiefly who is concerned in the transmission of hereditary disease. This *opinion*, however, is not supported by facts which warrant us in accepting this view of the matter, and is directly opposed to the deductions from the many cases detailed by Mr. Sedgwick ‖‖ and others cited in this paper.

In hospital practice Dr. Garrod ¶¶ found gout to be hereditary in 50 per cent. of the cases observed, and in private practice the percentage was still higher. He cites a case in which it had been hereditary for upwards of four centuries (probably fifteen generations): the eldest son having been invariably afflicted with the gout when he came into possession of the family estate. Scudamore *** records 522 cases of gout, in 332 of which it was hereditary.

Rheumatism is also subject to hereditary transmission.

The writer knows of a case where a father died of Bright's disease at 56, his son at 35, and another son is threatened with it at the 35th year. Two daughters and three other brothers have not been affected. There

is still another case in my mind of a son who inherits the same disease apparently from his father.

When visiting the rooms of the Historical Society of Pennsylvania, my attention was fixed at the first glance on a portrait of one of our revolutionary generals of superior family, that bore such a striking and unmistakable likeness to a young acquaintance of mine that I was anxious to know the relationship, and have recently learned that it was his great-grandfather, and doubly so, for his father and mother were first cousins both of the same name, equally related to the gentleman represented in this portrait.

The strikingly characteristic feature in this family is the marked fulness of the lower eyelid, and arched eyebrows, which were intensified in this young man, because of the double descent through his father and mother. All the males and some of the females in this family die of apoplexy. I have not learned whether the characteristic features in this family are transmitted directly from male to male, or by atavic descent through the females; it certainly continues in the male line.

Dr. Tripe expresses his "belief that male infants are predisposed to disease in a far greater ratio than females, especially during intra-uterine life; that this predisposition, which in extra-uterine life is more marked during the first month, gradually diminishes after the child ceases to obtain its nutrition direct from its mother, and is almost removed shortly after the ordinary age of weaning, viz., at one year and a quarter. From these considerations we infer that the greater mortuary rate of males during the first years of life depends on some influence derived from one or the other or both of its parents, but most probably chiefly, if not entirely, from the mother. . . . . The greater longevity of females certainly points to another vital difference in the sexes; and it may perhaps be true that one cause (greater vitality of the female sex) induces the large differential mortality which we have shown to exist." *

This view is fully confirmed in the author's last paper on the "Relative Viability of the Sexes, particularly with regard to the relative liability to the inheritance of certain transmitted diseases—considered in relation to the selection of Life Insurance risks, with a view of exhibiting the unjustness of the practice of charging higher rates for women;" † also in his paper on "Statistics of Marriages, Births and Deaths in Philadelphia for the 11 years ending 1871." Penn. Monthly, September, 1873.

"There are family diseases, just as there are family likenesses, manners, and peculiarities; and what is remarkable, they are more liable to be communicated by the mother than the father, as if it were her special prerogative to impress her vices, as well as her virtues, upon her descendants." ‡ "Possibly diseases transmissible from either parent will be more likely to be developed in those children who partake most of the *vis insita*, as of the physiognomy of that parent; but we do not know that the observation of our readers will be found to confirm this statement of the author." §

Mr. Sedgwick observes that, "in many cases where the disease is limited in its appearance to one sex, its transmission is restricted to the other. From a careful analysis of a large number of cases, I am at present disposed to think that sexual limitation in the transmission of diseases is more common in females than in males. In several of the cases I have mentioned, where the appearance of the disease has been strictly limited to the males, its transmission has been quite as strictly limited to the female sex, occasioning the phenomenon of *double atavism*, as where neither sons nor daughters ever inherit their father's disease, but only the grandsons in the third and fifth generations, by transmission through the females of the second and fourth generations." * In a note he states that "in the report of a case of hereditary malformation of the hands, affecting ten generations of the same family, it is stated 'that it was the women only who had the misfortune of entailing this defect on their offspring.'" †

"Altogether, the male parent exercises more influence upon the irritability, and the female more on the sensibility. Fabricius is not therefore far from the truth ‡ when he says, that we inherit from our fathers the tastes and cachexies; from our mothers, the spasms, melancholy, vivacity, and intellectual faculties; or Gleichen, § in assuring us that the male determines the bony frame, and the female the eyes. Following Linnæus, in hybrid vegetables: the sexual organs resemble more the mother, the corolla and in general the exterior parts the father. In like manner, following the observations of Senff, gardener of Koenigsberg, the leaves are more like the father than the fruit. Girou says that the mother has more influence upon the plasticity, and the father upon the exterior vitality; ‖ this assertion does not rest on sufficient proofs. We have need of new facts before we can affirm that the mother determines more the viscera, as Vicq d'Azyr pretends having remarked, and that it is she principally who assures the longevity, as Sinclair ¶ contends." **

Cultivators and scientists have frequently called attention to the laws of resemblance which seem to prevail in the production of hybrid plants. Dr. Herbert,†† according to Sedgwick, "established it as a law with respect to amaryllaceous hybrids, 'that they resembled their mother in foliage and stem, or the organs of vegetation; and their father in flower, or organs of reproduction.'" Fries-Morel ‡‡ states that in carnations the hybrids resemble the mother in form and the father in color. According to De Candolle,§§ Gaërtner, Wiegman, and Knight have remarked that many vegetable hybrids have a tendency to return, after a time, to the maternal, but never, as a rule, to the paternal type." ‖‖ The views of Lindley seem to be opposed to those of Dr. Herbert, for he has it that vegetable hybrids resemble the male parent most in foliage and the female most in flower.

principal object of their life, have furnished me with frequent occasion to observe the resemblance of fathers and mothers with their products.

"The products of domestic animals resemble, in general, more the father than the mother, by the head, the members, the color, the character, in a word, by all that which belongs to the exterior life; nevertheless, under the same relations, the female, more than the male, resembles the father, and the male, more than the female, resembles the mother. The same products resemble in general also more to the mother than to the father, by the height, the length of the hair, the dimensions of the pelvis, finally by all that which is under the influence of the exterior life, or of nutrition; but under these relations the male, more than the female, resembles the father, and the female, more than the male, resembles the mother.

"The fœtus often resembles, by the exterior life, the paternal grandfather; and under the same relation, the daughter sometimes resembles the maternal grandmother; even when the father resembles his proper mother, and the mother her proper father.

"I have never seen a resemblance to the paternal grandfather in the grandsons, nor to the maternal grandfather in the granddaughters, when the father does not resemble his proper mother, or the mother her proper father.

"At some period after the epoch of birth, the sons who resemble from the first their mother, and the daughters who resemble their father, acquire sometimes from the resemblance, the one with her father and the other with his mother; that metamorphosis is more frequent and more pronounced in the sons than in the daughters.

"The sons never pass from the resemblance of the father to that of the mother, nor the daughters from the resemblance with the mother to that of the father.

"Several naturalists have recognized the general influence of the father on the exterior life and the mother on the interior life. In speaking of mules, Vicq d'Azyr said: 'It seems that the exterior and the extremities are modified by the father, and that the entrails are the emanation of the mother.'

"The chasseurs have adopted the proverb, *Chien de chienne et chienne de chien*, to express the fact that they find the qualities of the mothers in the sons, and those of the fathers in the daughters.

"A hunting bitch with a double nose, the issue of a father with a double nose and mother with the usual form of nose, was fecundated by a common dog, and of eight young, of the same pregnancy, four were males with double noses, and four females with a common nose.

"Of four colts by an Arabian mare, three males had the hair of their mother, and one female that of the father.

"As far as the size or stature of the offspring is concerned, it seems to be pretty well ascertained by facts known to the breeders of cattle and horses, that this depends in a great measure on the mother." *

According to Mr. Thos. Andrew Knight, an intelligent gentleman, who gave much time to experiments in connection with the breeding of cattle, we are told that "in viviparous animals the size of the fœtus is affected by the influence of the male parent, and in some instances not inconsiderably; but the size and form of the eggs of birds do not appear to be in any degree changed or modified by the influence of the male; and therefore the size of the offspring at birth must be regulated wholly by the female parent." *

In multiparous animals it is often observed that the influence of one parent preponderates in a part of the progeny, and of the other in another part of it. Thus it happens when a pointer and a setter breed together, it is not unusual to find part of the whelps almost perfect pointers, and the remainder as nearly true setters.† It being a fact, then, that brothers and sisters of the same pregnancy in multiparous animals do not resemble one another, it is not at all strange that products of uniparous animals, born at distant periods, should so frequently be dissimilar.

"It has long been a prevalent idea," says Carpenter,‡ "that certain parts of the organism of the offspring are derived from the male, and certain other parts from the female parent; and although no universal rule can be laid down upon this point, yet the independent observations which have been made by numerous practical 'breeders' of domestic animals (both mammals and birds) seem to establish that such a *tendency* has a real existence; the characters of the *animal* portion of the fabric being especially (but not exclusively) derived from the *male* parent, and those of the *organic* apparatus being in like manner derived from the *female* parent. The former will be chiefly manifested in the external appearance, in the general configuration of the head and limbs, in the organs of the senses (including the skin), and in the locomotive apparatus; whilst the latter show themselves in the size of the body (which is primarily determined by the viscera contained in the trunk), and in the mode in which the vital functions are performed. Thus the *mule*, which is the produce of the male ass and the mare, is essentially a *modified ass*, having the general configuration of its sire (slightly varied by equine peculiarities), but having the rounder trunk and larger size of its dam; on the other hand, the *hinny*, which is the offspring of the stallion and the she-ass, is essentially a *modified horse*, having the general configuration of the horse (though with a slight admixture of asinine features), but being a much smaller animal than its sire, and thus approaching its dam in size, as well as in the comparative narrowness of its trunk."

The same distinguished authority cites "a case in which a setter-bitch, having been 'lined' by a pointer, bore three pups; two of these (one a male) seemed exclusively to resemble the father, appearing to be perfect pointers in configuration, and growing up with the habits of that race; whilst the third (a female) seemed equally to resemble its mother, being apparently a true setter both in structure and instinct. Yet, notwithstanding this apparent restriction, it subsequently appeared that the pointer-pups must have something of the setter in their constitution, and the setter-pups something of the pointer. For one of the pointer-pups (a male) having been matched at the proper age with a pointer-bitch of pure breed, one of the pups borne by the latter was a *true setter*, exactly resembling its paternal grandmother, and another was *setter-marked*; and the setter-pup (a female) having been lined by a setter-dog of pure breed, there were among its litter of pups two *pointers* resembling their maternal grandfather. The same variety presents itself to even a greater degree in the human species. . .

"One of the most remarkable cases of this kind known to the author, is that of two sisters who seem to resemble each other in no one point of

configuration or mental character; but of whom one bears a most striking resemblance, both in person and in mind, to her father; whilst the other no less strikingly resembles her mother. The only peculiarities which at all indicate their relationship are a gouty diathesis which they both inherit from their father, and an idiosynerasy in regard to opium, of which neither is able to take even a small dose (in any form whatever) without violent vomiting." *

Mr. Orton † "refers to Mr. Bakewell's Dishley sheep, as deriving and maintaining their celebrity through the ewes. And he adduces an observation which, if well founded, is of great pathological importance, and of especial interest to members of the medical profession, as well as to the directors of associations for life insurance. It is this: that diseases of the vital organs (and it may be presumed, therefore, diseases primarily involving the vital functions of nutrition and secretion) are transmitted oftener, and in a more intense form and degree, on the side of the mother than that of the father. And he adds that, in the matter of life insurance, he has long been in the habit of judging of the value of a life by the family history on the female (mother's) side.‡ In perfect accordance with this position, and, if well founded, in their degree confirmatory of it, two observations may be cited: the *first*, that the daughters of a woman who has herself borne a large family, are often equally prolific as their mother, a fact, if it be one, not without interest to those to whom an heir-male of their own body is an object; the second, that the daughters of mothers that have borne twins oftener than other females give birth to twins.

"In connection with this branch of his subject, Mr. Orton draws a distinction between a part or organ, including its vital endowments, and the *quality* of the organ and its endowments. And while maintaining that the 'outer' structures are chiefly furnished by the male parent, he equally holds that the *quality* of these, as of all the organs, comes mainly from the female. By quality, he obviously means what the older physiologists included under the term *vis vitæ*, or what in ordinary language is called *stamina*. It is not, for example, the special endowments of the nervous and muscular systems, the powers of contractility and nervous agency, considered *per se*, which he says are given by the female, but the quality of these is now defined and may be good or bad. This allegation he illustrates by a reference to the 'short-horns,' and Mr. Bakewell's breed of sheep. But it will perhaps be best understood by a reference to the horse. 'The Arab,' he says, 'will let you have his stallion, but his mare at no price. He cultivates *endurance* and *bottom*, and the female gives them. He does not know the law we are promulgating; but he acts as if he did, for experience has taught him. The English breeder, on the other hand, values the stallion. He cultivates *speed*, and finds that the sire gives the locomotive organs; consequently his value, just the reverse of the Arab; his mare is easily got at, but his stallion is priceless.'"

Dr. Harvey,§ declining to give an opinion regarding it (Mr. Orton's theory), says: "It may be remarked in passing, that while *talent* is notoriously in the male line, it has often been observed of individuals that have risen to distinction among their fellow-men, either by their *power* of intellect or *force* of character, that they have owed their pre-eminence to their mother."

According to Dr. Harvey,* "Mr. Orton's argument is, that in the reproduction of the animal species there is no casual blending of the parts and qualities of the two parents, but that each parent contributes to the formation of certain structures, and to the development of certain qualities. And, advancing a step further, he maintains that the male parent chiefly determines the external character, the general appearance, in fact, the outward structures and locomotive powers of the offspring (*e.g.*, the brain, nerves, organs of sense, and skin, and likewise the bones and muscles, more particularly of the limbs), while the female parent chiefly determines the internal structures and the general size and quality, mainly furnishing the vital organs (*e.g.*, the heart, lungs, glands, and digestive organs), and giving tone and character to the vital functions of growth, nutrition, and secretion."

This, then, is the law which Mr. Orton, of Sunderland (a practical breeder of animals), claims to have worked out by independent observation, though he accredits the discovery to the late Mr. Alexander Walker.†

"It is an error to suppose that the male transmits certain characters and the female other characters; though, no doubt, from unknown causes, one sex sometimes has a stronger power of transmission than the other, ... for certainly they (the sexual elements) do not in ordinary cases differ in their power of giving character to the embryo."‡

Concerning the cause of the exterior or animal life following that of the father, and the interior or vegetative resembling that of the mother, the following may serve to explain:

"While the fœtus is developed from that part of the ovum called by physiologists the *germinal* membrane, this membrane itself consists of *two* layers, an outer and an inner, called respectively the *serous* and the *mucous*. Of these layers, each gives origin to a special set or system of organs; the outer (or serous) to the brain, nerves, organs of sense, and integuments, and likewise to the bones and muscles; the inner (or mucous) to the lungs, glands, digestive organs, etc.

"That is to say, the outer layer gives rise to the whole set of organs concerned in the strictly *animal* functions, while the inner layer gives origin to those concerned in the strictly *vital* functions."§

The heart and blood-vessels, according to this authority, "would appear to be either the joint production of the two layers or to originate in an intermediate layer subsequently developed and called the *vascular* layer. He suggests, however, that the vascular system may stand in the same subordinate relation to the vital organs and their functions as the osseous system does to the muscular.

The fact of the father influencing most the exterior organs, and the mother most the interior, is ascribed to the discoveries of Bischoff, Wagner, and Newport, that the spermatozoa do not appear to penetrate be-

* Op. cit., p. 785.

† Dr. Harvey's review of Mr. Orton's paper on the "Physiology of Breeding" (Newcastle Chronicle, March 10, 1854), in Edinb. Med. Jour., August, 1854, pp. 113–4.

‡ I have interpolated the word mother's, because I believe it makes the meaning of the author more explicit. He probably refers to the examination of *men*, who, according to the views advanced in this paper, resemble their mothers more than their fathers. But if he were examining women, it is probable that he would pay more attention to the father's side.

§ Op. cit., p. 114.

yond the *exterior* layer of the germinal membranes from which the exterior organs take their origin. Dr. Harvey says: "As the spermatozoon comes first into contact with the *exterior* of the ovum and disappears while lying there, it seems not unreasonable to suppose that its influence while extending to the outer layer may be in a great measure confined to it."

Dr. Mapother explains this phenomenon in much the same way. According to this authority "the influence of the male has been said to bear more upon the apparatus of animal life, as the spermatozoa do not probably reach deeper in the ovum than the serous layer of the germinal membrane, while the mother is more apt to share peculiarities in the organs of vegetative life." *

THE PHYSICAL EXAMINATION.

By a Medical Director.

The selection of lives for insurance may very properly be called an art, and therefore as such it is capable of cultivation and development. Looking at the question in the abstract, apart from all the hindrances which a dangerous spirit of rivalry has woven round it, it is evident that this art can only be acquired in a high degree by men of broad professional culture and experience, of decided integrity and firmness of character, and of keen insight into the dark and crooked ways of human character. Men that combine all these qualities are indeed rare. How very few there are, for instance, who can justly claim a satisfactory knowledge of even one of the things required, viz., auscultation and percussion! And yet, next to integrity, this knowledge is the gift most to be desired in a medical examiner for life insurance.

We have already spoken, in a previous number, of the careful manner in which the physician should sift the personal and family history of every applicant. The purpose of the present article is to say a few words in relation to the physical examination. We do not propose to set forth in writing how this should be done, for we assume that the examiner is already familiar with the subject. If he is not, we certainly cannot enlighten him by anything that we might write upon this topic, for it is pre-eminently a branch of science to be learned by actual observation and not from books. Our chief object is to discuss certain features of the subject from a life-insurance stand-point.

In conducting the physical examination of an applicant for life insurance the question presents itself, how thorough should this be? In private practice, if a man comes to you to have his chest examined, you request him to strip to the waist, and then percuss and auscultate every portion of the chest. Common sense would say that an examiner for life insurance should do the same thing; but we would ask, in all frankness, how often is this done? Very rarely, indeed, if the truth were but known. Now it is undoubtedly a fact that the time when a man is most likely to apply for insurance on his life is immediately after the manifestation of some symptom pointing, as he believes, to the development of a fatal disease. My family is unprovided for, he says to himself, and I must hasten to insure my life before the disease shall have progressed so far as to be readily recognized by the company's physician.

The writer was once present at the bedside of a friend who had but a few hours previously had a slight hemorrhage from the lungs. His physician, whose skill in auscultation and percussion was exceptional, instituted a careful examination, but was unable to find any dulness on percussion or any abnormal sounds except near the base of one lung, posteriorly. The pulse was but little accelerated, there was no appreciable heat of skin, no noticeable emaciation, and but little cough, except during excitement or after walking. If this man had chosen to give false answers to the questions put to him, I think there can be very little doubt that with the prevailing mode of examination he would have been accepted by almost any company to which he might have applied for a policy of insurance on his life.

The reader, unless he happen to be familiar with the ins and outs of the business, will very naturally draw the inference that there is a widespread negligence among the physicians of the different life companies. There is undoubtedly some truth in this inference, as every examiner will readily admit, but at the same time the larger portion of the blame lies with the executive officers. In the abstract they are supposed to instruct their physicians to employ every resource known to the art of medicine for the detection of the first beginnings of disease; in reality, however, they throw cold water upon every attempt to make anything but the most superficial physical examination. Here are the reasons given in justification of such a course: The applicant takes out a policy to please the agent, who is at the same time a personal friend. He must therefore be examined at his place of business, with the least possible loss of time and personal inconvenience. If the examiner were to insist that the man should come to his private office, or to the office of the company, and there be stripped to his waist, as if before a pension examiner, it is more than probable that the lukewarm applicant would not insure his life, or —worse still—that he would insure it in a rival company.

So eager is the competition for new business that not a single company has had the boldness to establish rules that would in a very great measure prevent all this. We are not sure how such a plan would work in the country, but in the larger cities it certainly would be to the advantage of the companies if they would establish the rule that all applicants must be examined at the office of the company or at the private office of the examiner. It would also from time to time save the companies a premature loss, if they would require at least a partial examination of the urine of all applicants who have passed the age of 40. The simple test by heat and nitric acid—though not a perfect one—would nevertheless suffice. It certainly is within the reach of all physicians, and requires but a few minutes' time.

One of the New England companies, if we are correctly informed, has put a rule of this kind into practice. It would be interesting to know how far they have found it practicable to enforce it, and also whether instances have occurred where applicants, who presented all the appearances of health, have been found by this test to have some affection of the kidneys.

Reforms of this kind could very easily be introduced if the more influential companies would act as a unit in the matter. The agents, from whom the chief opposition is to be expected, would then be compelled to acquiesce in the new order of things, and all the companies would in an equal degree enjoy the benefits of the greater protection.

* Physiology, p. 375.

ANNOYANCES OF MEDICAL LIFE INSURANCE EXAMINERS.

By WALTER B. CHASE, M.D.,

WINDHAM CENTRE, N. Y.

PROBABLY most physicians called upon to act as examining surgeons for Life-Insurance companies (removed from the home office of the company) have been annoyed by the officiousness, not to say the impudence, of Life-Insurance agents. The great question with certain of these agents, after a party has made a formal application for insurance, is, how they can secure a favorable certificate of examination from the medical examiner. If, after the examination is completed, the agent finds statements in the certificate calculated to impair the applicant's prospect for a policy, he at once sets himself to work to have such modifications made in the certificate as will overcome these objections.

Failing here, as he will with examiners who recognize and regard their responsibility, what assurance has the surgeon that the agent will not make such changes in the certificate as will deceive the company and render the examination not only of no value, but of positive harm, and at the same time abolish the very vital relation the surgeon is supposed to sustain to the company, viz., that of confidential adviser.

I ask, what assurance has either the company or the examiner that this very thing will not be accomplished?

Out of the half-dozen Life-Insurance Companies, for which I have acted as medical examiner, with but a single exception the certificate has at once passed into the hands of the agent to be forwarded to the home office.

To illustrate one of these annoyances, the following is an example: Several years since an agent of a prominent New England Life-Insurance Company called at my office with a young man who had given him an application for life insurance, desiring me to make the examination. The agent, at one time a clergyman, proposed that he should sit by the desk and record my examination as I should dictate it to him. This I declined to do. Not finding the certificate altogether suited to his purpose or fancy, he quite insisted on my making certain modifications in my statements concerning the applicant's condition. It is perhaps unnecessary to state in this connection that our parting was of such a nature that he never again requested my services, though he continued to receive applications for insurance in our town.

I would not wish it inferred that Life-Insurance agents are generally dishonorable men; on the contrary, I have in mind those who I know would not willingly be accessory to securing a policy through false representations or upon an unsound life.

For reasons of a professional nature the common method of delivering certificates of examination to Life Insurance agents direct is open to serious objections. In the event the examiner, in the discharge of an imperative duty, rejects the party as unsound or not entitled to a policy, the agent informs the applicant as to the cause of his not receiving a policy, and throws the whole responsibility upon the examiner, when justice to the examiner requires that neither the agent nor applicant should be allowed the privilege of knowing whether this responsibility rested with the surgeon or the company.

For prudential reasons, which will suggest themselves to any mind, pension examining surgeons are instructed to transmit their certificates of examination to the Pension Office under seal, without allowing the applicant any knowledge as to their import. I would therefore suggest that Life-Insurance companies have their medical examiners transmit directly to the home office their certificates of examination, both as a means of safety to themselves and as embodying a plan by which the medical examiner will be relieved from a possible and in some instances a real cause of annoyance.

Another cause of annoyance is found in the subject of "certificates of family physicians." This, however, has been most ably discussed and placed in its true ethical bearings in a late article, appearing in this journal, by Dr. Wey, of Elmira.

ON THE RELATION OF MEDICAL EXAMINERS TO LIFE-INSURANCE AGENTS.

By S. S. HERRICK, M.D.,

NEW ORLEANS.

THERE are some points in this subject which I have not seen treated in the literature of Life Insurance, and the importance of which I am sure is not duly appreciated by managers in general. While intelligent people fully understand the value of an independent judiciary, as a branch of government, and deplore that plan of selection which subjects judges to the debasing influences and conditions inseparable from party politics, Life-Insurance companies seem insensible to the danger that improper considerations may be presented to the minds of their medical examiners. This is surprising, considering the just importance attached to a due examination of applicants and the fact that this is in its nature judicial. In the body politic there is a crying want for an independent judiciary, and it is evident to my mind that complete independence on the part of medical examiners is quite as much a desideratum.

In too many instances the selection of the examiners is made by the local agent, and the result of the examination is usually open to his inspection. The agent receives commissions on the policies and annual payments, and is interested in securing the largest possible number of risks. It is natural that he should desire the medical examination to be as favorable as possible to his individual advantage, and the easy examiner is always sure to have his preference. Under this system the medical examiner finds his pecuniary interest in propitiating the agent, whom he finds a nearer, if not a better, friend than the distant managers at the home office.

However high an opinion we may set upon the moral advantages of a medical education, physicians are human to the last, and may not claim insensibility to a pecuniary argument. In common with the balance of mankind, we are enjoined to pray (not to prey) for our daily bread, and we ask not to be led into temptation. In a moral point of view the insurance companies do wrong in allowing their medical examiners thus to be tempted; and, like all other wrongs, in the long run, it is bad policy.

But, aside from corrupt pecuniary considerations, there is abundant room for injurious bias upon the judgment of the medical examiner. The agent is naturally inclined to give a lucrative appointment to his own physician, who may be on terms of intimacy or close relationship. A sense of obligation is ever present to the physician's mind, which is a colored medium to his scientific view and must perpetually embarrass, if not mislead, his judgment. Moreover, there are in this city conspicuous examples of physicians' signs at the doors of Life-Insurance offices.

Taken in the abstract, hospitality is undoubtedly a noble trait, and gratitude in a guest quite natural and commendable: but in the concrete it can readily be seen how costly the exercise of these virtues may be to other parties.

The obvious remedy for this abuse is to take away the appointment of medical examiners from the local agent, to bring all applicants before some duly appointed examiner of the company, and to report the result of the medical examination directly to the home office, without the inspection of the local agent. Let the examiner understand that he is responsible directly and solely to the central office, and let the agent be instructed that any interference or inquiry concerning the physician's report is an unwarrantable impertinence.

Such a plan, I am convinced, would prevent the acceptance of many doubtful and many improper risks; and by obviating undue losses, lighten the rates of insurance and thereby extend the benefits of an humane system to a large class who are now unable to bear its expense.

MEDICAL EXAMINERS SHOULD FORWARD THEIR CERTIFICATES TO THE HOME OFFICE.

By R. W. ERWIN, M.D.,

ATHENS, OHIO.

In addition to the suggestions on the examination of applicants for life assurance in recent issues of the RECORD, one other subject should be considered. I have had some experience as an examiner for different companies, and invariably the agent has taken my certificate and forwarded it to the company. This is wrong, for two reasons: 1st. He has no right to the secret history of the applicant, and a knowledge of his ailments, if there should be any.

2d. The certificate being in his possession is seen and read in nearly every instance by the applicant. If the latter is a patient of the examiner a fair statement of the risk may excite feelings of enmity against the physician, and he, to protect himself, signs a recommendation. This is more likely to be done in doubtful cases. It is true the acceptance of the office of examiner makes the obligation to the company's interest above that of self, but every one knows there are many who will not so value it, and why permit a measure, which does no good, to become a source of evil? Again, the opportunity is afforded the agent, by possession of the paper, to alter the certificate and correct a bad risk into a good one. There are not many who would do such a thing, yet straitened circumstances would make it a temptation to unscrupulous persons. The certificate of the physician ought to be confidential matter, known only to the officers of the company who grant or decline the policy. When the applicant is presented for examination the agent should be dismissed, and the certificate of examination sent directly to the office by the physician. Such a course would relieve the examiner of much embarrassment and in some cases insure against unfavorable risks. There should be three blank papers, one for the statement of the person wishing insurance; one for that of his physician, so long as companies continue the practice of taking the physician's statement; and a third blank for the examiner. The blanks that are used now will do, if the agents are instructed to get the applicant's and physician's statement *first*, and then place it in the hands of the examiner.

Miscellaneous.

BAD LIFE RISKS. Testimony from every quarter, and testimony of the most reliable kind, is constantly accumulating to the effect that our life-insurance companies are more and more frequently imposed upon by unsound and unsafe lives. The facilities for doing this are not wanting. The most alert and vigilant caution at the home office cannot detect deliberate fraud and perjury a thousand miles away. If a man is resolved to effect an insurance upon his life, and is willing, for the sake of so doing, to lie with a moderate degree of skill and persistency, the thing is not difficult of accomplishment. It is true that the medical examination is in the way. But aside from the fact that there are many diseases which can only be detected by the most experienced eyes and which will not be mistrusted or sought after unless indicated by the answers to the questions of the application, it must be remembered that a large majority of our medical examiners are necessarily the personal friends, and often the family physicians, of the applicants, and that with our estimable brethren of the lancet and the Latin, as with the best of us all, considerations of personal friendship are not without their weight and potency. We do not mean to say that the profession is venal; but we do mean to say that, between a village Galen, anxious to conciliate patronage, and a designing applicant, willing to commit fraud, a life-insurance company stands a poor chance of ascertaining the truth respecting the risk it is invited to assume.—*New York Ins. Chronicle.*

STATISTICS OF SUICIDE. The statistics of 1870 show an increasing tendency to suicide throughout the country. The percentage was 3.06 per hundred thousand. In 1860, it was 3.02, and in 1850, 2.01. Now it occurs to us that a comparison of these ratios, with the percentage of suicides occurring in our life companies, would go a good way towards settling the bearings of the suicide clause.

If the proportion of suicides bears no heavier on the insured than on the country at large, it is a pretty strong argument in favor of those who hold that no man in his right mind will destroy his life for the sake of the insurance. But if, as we are inclined to suspect, cases of self-murder are excessive among this class, the companies ought,—in the interests of society, as well as their own—to take away all mercenary motives to the crime.

As usual, the male sex greatly predominates among the victims; more than three-fourths are men. Suicide is rare among women who have reached maturity; the majority of the cases are confined to the romantic period of girlhood. Men, on the contrary, resort to this extreme remedy in numbers increasing with age. Ten suicides occur among the whites, to one among the blacks. The cheerful, contented disposition of the latter shows where lies the exciting cause of suicide. It is the product, not of mental rust, but of wear and tear. The rate is higher in the bustling communities of the North than in the more quiet South.

But the German and French minds, of all others, appear to be particularly prone to the disease. These nationalities stand nearly as three to one in the percentage of suicides, compared with the Irish, and four to one compared with the native Americans. The depressing effect of forsaking home and country is exhibited in the heavy ratio among all classes of our foreign population.—*Insurance Monitor.*

TABULAR VIEW OF THE PATHOLOGICAL ANATOMY OF YELLOW FEVER AND MALARIAL FEVER.

By JOSEPH JONES, M.D.,

PROFESSOR OF CHEMISTRY AND CLINICAL MEDICINE, MEDICAL DEPARTMENT UNIVERSITY OF LOUISIANA; VISITING PHYSICIAN OF CHARITY HOSPITAL, NEW ORLEANS.

The following comparison of the Pathological Anatomy of Yellow and Malarial Paroxysmal Fevers contains the general outline of the results which I have obtained by investigations conducted in various parts of the Southern States, and which were commenced in 1856. I have, upon several occasions, embraced opportunities of examining the bodies of those who had died from yellow fever and malarial fever, at the same time, as they lay side by side in the *Dead House*. Such examinations served to establish more fully the results of numerous post-mortem examinations of the subjects of each disease.

YELLOW FEVER.

Exterior.—Generally full and not reduced in flesh; features may even present a swollen, bloated aspect. Skin of face and upper portions of trunk of a golden yellow color. Dependent portions of body of a mottled purplish and yellow ecchymosed appearance. Black vomit frequently oozes from corners of the mouth, and trickles down the face and neck. When the muscles are cut a large quantity of dark blood escapes, which upon exposure to the atmosphere changes to a bright scarlet hue. Putrefactive changes take place rapidly after death. In some cases of yellow fever, especially when the functions of the kidneys have been arrested for some time before death, the putrefactive changes take place with great rapidity and energy, and sometimes even appear to commence before death, the body exhaling a disagreeable odor.

Cerebro-spinal Nervous System—Sympathetic Nervous System.—The post-mortem examinations of the brain, spinal cord, and sympathetic system have thus far revealed no characteristic lesions to which the aberrated nervous symptoms of yellow fever can be referred. Beyond congestion of the capillaries of the cerebro-spinal and sympathetic systems, which congestion appeared to be referable to the same cause as that producing capillary congestion in the internal organs, I have observed no structural lesion, as fibrinous effusion, hemorrhage, or softening of the cerebro-spinal and sympathetic nervous structures. Chemical analysis revealed the presence of urea, bile, and leucine in the brain, and to the effects of these substances, as well as to the direct action of the yellow-fever poison, must be referred the aberration of intellect, the restlessness, convulsions, and coma.

Heart.—Pale yellow and brownish yellow, as if undergoing fatty degeneration; structures of heart flabby and somewhat softened; numerous oil-globules deposited within and around the muscular fibrillæ of the heart. Cavities of the heart, in many cases, filled with dark fluid blood; yellow fibrinous clots sometimes present. Blood contains abnormal amounts of urea and extractive matters and ammonia. Fibrine of blood greatly diminished in amount.

MALARIAL FEVER.

Exterior.—The general appearance of those who die from the effects of malarial fever will depend upon the nature and length of time and the effects of the disease. When stout healthy men are suddenly destroyed by pernicious malarial fever, the body may present the fulness of health; and in such cases the superior portions of the body may, as in yellow fever, present a golden yellow color, whilst the dependent portions present a purplish and mottled appearance. The jaundice and mottling of the skin, however, is, as a general rule, present to a less degree than in yellow fever. In cases of protracted bilious fever, the body is frequently greatly emaciated. In chronic malarial poisoning, attended with enlargement of the spleen and cirrhosis of the liver, the belly and body and limbs generally are distended with dropsical effusion. The cut surface of the muscles presents a purplish hue, and the change to the arterial hue, upon exposure to the atmosphere, is much slower and less perfect than in yellow fever.

Cerebro-spinal Nervous System—Sympathetic Nervous System.—As far as my observations have extended in malarial fever, the dura mater was always normal; the arachnoid membrane pearl-colored, opalescent in some cases, in others perfectly transparent and normal in appearance; the blood-vessels of the pia mater congested with blood, but always without marks of inflammation. Subarachnoid fluid in almost all cases clear, transparent, and in some cases of a golden color; the amount varied in different cases, sometimes exceeding, but most generally falling short of, the usual amount. Blood-vessels of the brain generally filled with blood. The structures of the brain appeared, in acute cases, as a general rule, to be unaltered either in structure or appearance; in chronic cases the nervous structures sometimes presented a deeper and more grayish color, from the presence of pigment granules.

The structures of the brain and spinal cord, in malarial fever, were therefore, as a general rule, altered neither in consistence nor appearance, and the same is true also with reference to the sympathetic nervous system.

Heart.—Normal in color, presents the deep purplish red muscular appearance of the healthy heart. Muscular fibres of the heart firm and of normal appearance under the microscope. No deposits of oil in the muscular structures.

Cavities of the heart frequently distended with dark blood. Firm laminated, fibrinous concretions very common; and in some cases of pernicious fever, the formation of these heart-clots during the cold stage without doubt causes death, and renders unavailing the action of remedial agents.

The fibrinous concretions are not only attached to the carneæ columnæ and chordæ tendineæ, and auriculo-

YELLOW FEVER.

LUNGS.—Dependent portions greatly congested; otherwise normal. In some cases circumscribed effusions of blood in textures of lungs.

STOMACH.—Mucous membrane of stomach in many cases intensely congested, softened, and eroded. Stomach often contains large quantities of black vomit. Reaction of black vomit often *alkaline* from the presence of *ammonia*, resulting from the decomposition of *urea*, eliminated by the gastro-intestinal mucous membrane. *Ammonia* and *urea* present in the black vomit ejected during life, and also when examined almost immediately after death. The presence of ammonia in the stomach and black vomit was not the result of post-mortem putrefactive changes. In many cases ammonia was present in such large amount, that when a rod, dipped in hydrochloric acid, was held over the mucous membrane of the stomach, or over the black vomit, dense fumes of chloride of ammonium were formed, as if the rod had been held over a bottle containing liquor ammoniæ. Chemical analysis revealed the presence of ammonia and also of urea in the black vomit. Under the microscope the black vomit was seen to contain colored blood-corpuscles, and cells of the mucous membrane of the stomach, and broken capillaries. In some cases vibriones and fungi were numerous in the black vomit; in others they were absent.

INTESTINES.—As a general rule dark-colored and distended with gas. In some cases the reaction of the intestinal contents was strongly alkaline from the presence of ammonia.

LIVER.—Yellow color and bloodless, resembling this organ in fatty degeneration, but firmer and denser in structure. Under the microscope, textures of the liver infiltrated with oil; secretory cells of liver contain much oil. The liver of uncomplicated yellow fever, as far as my observations extend, and according to the observations of Louis and many others, is of a bright yellow color. It is probable that this color, as in the case of the malarial liver, varies with the length of the attack and the effects of previous diseases. Thus Dr. Samuel Jackson, of Philadelphia, found the livers of those who had died in the early stages en-

MALARIAL FEVER.

ventricular valves, but they also frequently send forth long branches into the pulmonary arteries. The formation of these concretions is rare in yellow fever, and when formed they are much smaller and softer than in malarial fever. The blood of malarial fever contains more fibrin, fewer colored corpuscles, and changes more slowly to the arterial hue, upon exposure to the atmosphere, than the blood of yellow fever.

LUNGS.—Dependent portions congested with blood; otherwise healthy.

STOMACH.—Mucous membrane often presents a normal appearance; sometimes ecchymosed; rarely inflamed or softened; sometimes discolored with bile; rarely contains black vomit (altered blood). Reaction of mucous membrane of stomach and intestines acid. The pathological alterations of the stomach, observed after death, do not correspond, as a general rule, with the severity of the symptoms, the vomiting and pain on pressure during the progress of the fever. The injection of the blood-vessels, and the mottled, purplish-brownish red color, after death, appear to be indicative, not of inflammation, but rather of stagnation and accumulation of the blood in the capillaries, consequent upon the disturbance of the relations of the blood to the capillaries. The distressing vomiting, so often a troublesome symptom in malarial fever, appears to depend upon the contact of the altered bile and the irritation of the nervous centres, which supply the stomach with nervous force, by the altered blood and by the malarial poison.

In cases where there has been chronic inflammation of the stomach before the appearance of the fever, and in cases of long standing, where the solids and fluids were permanently altered, decided lesions of structure were found in the stomach. It may be asserted, however, that there is no constant or characteristic lesion of the stomach in malarial fever.

These remarks apply also to the SMALL INTESTINES. The mucous membrane frequently presented a purplish, irregularly injected, mottled appearance, especially after the administration of purgatives, and it was frequently observed that the injection of the blood-vessels was greatest in the dependent portions of the intestines. In several cases Brunner's glands in the duodenum were enlarged and distinct. The solitary glands of the small intestines appeared in many cases enlarged and distinct. Peyer's glands were uniformly free from any well-marked morbid alteration. In some cases they were distinct and well defined in their outline, and presented a honey-comb surface, dotted with dark points; but they were always free from marks of inflammation and even of irritation, and in their pale, white color contrasted strongly with the surrounding mucous membrane, discolored with bile and often irregularly injected with blood.

LIVER.—The weight of the liver is increased in malarial fever above the standard of health. This increase of weight is due in part to the stagnation and accumulation of blood in the capillaries and blood-vessels, and to the deposit of pigment matter in the structures of the liver. This observation applies to the liver in the acute stages.

In all the different forms of malarial fever, intermittent, remittent, and congestive, which had continued longer than five days, and in which there had been no previous alterations of the structures, as in cirrhosis and fatty degeneration, I found the ex-

YELLOW FEVER.

gorged with blood. The decoction of the yellow-fever liver is of a golden yellow color, whilst that of the malarial liver is of a brownish yellow color. The golden yellow color of the yellow-fever liver can be extracted both by alcohol and water. The yellow-fever liver is firmer and harder than that of malarial fever, contains much less blood, and is much less readily acted upon by liquor potassæ and acids. Liquor potassæ readily dissolves the malarial-fever liver, and the decoction presents the appearance of venous blood, while no such effect is produced by the action of this alkaline solution upon the yellow-fever liver.

Chemical analysis reveals the presence of urea and fat in abnormal amounts; animal starch and grape sugar are also present in the yellow-fever liver. As a general rule grape-sugar is absent from the malarial liver.

GALL BLADDER.—The gall bladder in yellow fever is, as a general rule, contracted, flaccid, small, and contains little or no bile. The amount of bile generally does not exceed 100 grains. In malarial fever, on the other hand, the gall bladder is, as a general rule, distended with dark, greenish, black bile. In yellow fever the vomiting is rarely bilious, unless in the commencement of the disease; and the black vomit contains little or no biliary matter.

The small intestines are rarely if ever discolored by bile in yellow fever, whilst in malarial fever it is common to find the gastro-intestinal mucous membrane discolored by bile.

SPLEEN.—As a general rule but slightly enlarged. In many cases normal in size and appearance. In many cases of yellow fever the spleen is neither enlarged nor softened, nor altered in appearance, either upon the exterior or within. There appears to be no special alteration or destruction of the colored corpuscles in the spleen of yellow fever as in that of malarial fever. The enlargement of the spleen in fevers does not, from these observations, depend upon the diminution of the fibrin, because this element of the blood is diminished to a much greater extent in yellow fever than in malarial fever, and at the same time the spleen is enlarged to a great and marked degree in the latter. Another fact worthy of consideration in this connection is, that in yellow fever the colored blood-corpuscles are not specially diminished in amount, whilst in malarial fever they are rapidly destroyed, and this destruction appears to be greatest in the liver and spleen. In malarial fever both these organs are loaded with the altered blood-corpuscles and with the pigment granules resulting from the alterations of the colored corpuscles, whilst neither the spleen nor the liver in yellow fever affords any evidence of alterations of the colored blood-corpuscles.

MALARIAL FEVER.

terior of a slate color, and the interior of a bronze color. In that form of cirrhosis of the liver which is directly induced by the prolonged action of the malarial poison, the liver is in like manner of a slate color upon the exterior, and olive green within, and loaded with dark pigment granules. The change in the color appears to be very persistent, and in several cases I have observed the liver to retain shades of light slate and light bronze several weeks, and even months, after the relief of the attack of malarial fever, the patients having been destroyed by other diseases or by violence. The liver, especially in the peripheral portions of the lobules, contains pigment granules, resulting from the alteration of the colored blood-corpuscles and the hæmatin. The pigment granules are frequently distributed uniformly through both the portal and hepatic systems of capillaries. There is no accumulation of oil globules, as in the yellow-fever liver. If malarial fever precedes or succeeds yellow fever, the liver may contain both oil globules and pigment granules.

The peculiar color of the malarial liver can to a certain extent be extracted by boiling-water, and the filtered decoction presents a brownish mahogany color, from the presence of the dark coloring matters of the pigment granules; the decoction of the yellow-fever liver, on the other hand, presents a golden color. The blood issuing from the cut surface of the malarial liver presents a dark purplish hue, and does not change to a brilliant scarlet, as in the yellow-fever liver. Upon chemical examination, the malarial liver contains animal starch, but no grape-sugar; the yellow-fever liver contains both substances.

GALL BLADDER.—In most cases distended with more than 1,000 grains of thick, greenish black bile, having frequently a specific gravity ranging from 1.030 to 1.037. The bile is more abundant in malarial fever and is of a deeper color, and frequently contains concretions of epithelial cells, from the coats of the gall bladder and biliary ducts, and casts of the biliary tubes. In thin layers, and when added to water, it presents a deeper shade of green. The yellow-fever bile presents a golden color in thin layers and when added to water.

SPLEEN.—Enlarged, softened, and loaded with altered blood-corpuscles and pigment granules; of a dark slate color upon the exterior; the blood of the spleen does not change to the arterial hue upon exposure to the atmosphere. In many cases the spleen is so soft that it ruptures when the attempt is made to remove it from the cavity.

YELLOW FEVER.

KIDNEYS.—These organs, as a general rule, present a brownish yellow color, much lighter than that of health. They, in common with the heart and liver, contain much free fat. When thin sections of the kidneys are examined under the microscope, the Malpighian corpuscles and tubuli uriniferi are found to be filled with granular albuminoid and fibroid matter, excretory cells detached, and oil globules. As far as my observation extends these structural alterations of the kidney have escaped the notice of preceding observers. The importance of these changes in the kidneys cannot be overestimated, for upon them apparently depends the suppression of the urinary excretion, which is an almost universally fatal symptom. The changes in the kidneys may depend upon several causes, amongst which may be mentioned as of prime importance the alterations induced in the albumen and fibrin of the blood by the febrile poison, and the congestion of the capillaries induced by derangement of the vaso-motor system of nerves and by the altered blood.

URINARY BLADDER.—As a general rule the bladder contains little or no urine in yellow fever. The urine is of a light yellow color, without any crystalline bodies, and loaded with albumen, granular fibroid matter, urate of ammonia, casts of the tubuli uriniferi, excretory cells of the kidney. In many cases the urine is entirely suppressed for as long a period as 48 hours before death. So long as the kidneys perform their functions freely and regularly the patient may recover, even though black vomit may have appeared, but if the action of the kidneys has been arrested by structural changes, death is inevitable.

MALARIAL FEVER.

KIDNEYS.—Normal in appearance and structure, except in malarial hæmaturia, when the textures are congested, and dark colored in some cases. Occasionally slate-colored spots appear upon portions of the kidneys.

URINARY BLADDER.—Often distended, with high-colored urine, free from albumen and casts. In malarial hæmaturia the urine contains casts and blood-corpuscles, and desquamated cells of the tubuli uriniferi. Casts high colored, and often contain colored corpuscles.

493 ST. CHARLES STREET, New Orleans, La., June 4, 1873.

CHILDREN'S CLINIC.

CASES FROM THE CLINICS OF DR. J. LEWIS SMITH, BELLEVUE HOSPITAL MEDICAL COLLEGE, MAY AND JUNE, 1873.

NERVOUS COUGH.

THIS boy, aged six years, presents rather a cachectic appearance, but his appetite is good and his evacuations seem to be normal. During the last six months he has been subject to a cough, not severe, and attended by little or no expectoration. The cough of late has been more frequent than at first; pulse 88 and temperature normal. Were the cough due to a lesion in the respiratory apparatus, it is probable that now, after the lapse of half a year, careful auscultation and percussion would detect something abnormal; but the result of the examination is negative as regards any lesion, and the cough is therefore, doubtless, purely nervous.

A nervous cough is not infrequent in weakly children, between the ages of three and ten years. It may result from disease of the brain; from second dentition; from some irritant in the intestines, as worms; from spinal irritation; and also, I think, independently of any local ailment, from a state of anæmia or cachexia, the function of the respiratory organs being modified or affected as that of the heart often is from the deteriorated state of the blood. In this case I am unable to discover any local cause.

In most cases of nervous cough, as I have observed it, the state of the patient was such as to indicate the need of iron, even when there was a local cause of the cough. The following example, which came under my notice several years since, shows the benefit which may be expected from the use of this agent in certain cases of this form of cough. A pale and spare boy of 11 years, who had had a troublesome cough several months, and had passed through the hands of different physicians, one at least of whom diagnosticated advanced phthisis, was taken to the late Dr. Cammann. The doctor, detecting the nature of the ailment, wrote the following prescription, and in a surprisingly short time the cough entirely ceased:—

℞ Ferri sulphat. } ℥ ss.
Acid nitric. }
Aquæ destillat. ℥ ss.

Misce.

Dose gtt. iij. four times daily, in sweetened water.

In certain patients there is no apparent local cause and no decided anæmia; and yet the cough is troublesome. I have in these cases obtained good results from belladonna and bromide of ammonium. In 1871 I was asked to see a German boy, 8½ years of age, who had suffered from a nervous cough for two months, and which latterly had been frequent and annoying. Within six days the cough entirely ceased from the use of the following prescription:—

℞ Tinc. belladonnæ. ℥ i.
Ammon. bromid. ℥ i.
Syr. simplic. ℥ ss.
Aquæ cinnamomi ℥ i.

Misce.

One teaspoonful morning and evening.

This mixture may, of course, be given alternately with the iron in cases which require that tonic.

ADHESION OF LABIA MAJORA.

In this infant, who is one year old, there is complete

adhesion of the labia majora to each other at their bases, and the vulva is occluded except at the orifice of the urethra, where there is an opening about two lines in diameter. The mother states that she has never observed any soreness or discharge from these parts, but in all probability there has some time been a vulvitis sufficient to cause excoriation of the opposite surfaces, so that they were agglutinated by lying in contact. It is fortunate that this state of the parts was discovered, for it is now easily remedied; whereas, had it continued, the union would no doubt have become firmer, and would have proved at puberty a serious obstruction to the flow of the catamenia. By drawing apart the labia gently, you observe that the adhesions separate, leaving a raw surface on either side, from which a little blood exudes. The length of the excoriated surface on either side measures three-fourths of an inch, with a width of about two lines. The mother will dust this frequently with powdered oxide of zinc, to prevent reunion, and within a week the cure will be complete.

INTERMITTENT FEVER.

This infant, now 10 months old, contracted the ague on Long Island, where the parents reside, and has had occasional attacks of it since the age of 6 weeks. I have notes of 36 cases of this disease occurring under the age of 3½ years. Several of the cases were treated in private practice, and the rest in the institutions with which I have been connected. In children above the age of 3½ years intermittent fever differs but little from that of the adult, while in those under this age it presents certain peculiarities or differences, which I trust will render the examination of these records interesting and profitable. Of these cases 19 had the quotidian form, 10 the tertian, 2 the tertian becoming afterwards quotidian, 1 the quotidian becoming afterwards tertian, while in the remaining 4 cases the form of the disease is not stated. In quotidian ague the malaria has been supposed to act more powerfully on the system, or the system is more susceptible to its influence than in the tertian form, and hence the fact that the quotidian is the prevailing type of ague in tropical regions, where vegetation is luxuriant, marshes extensive, and the heat intense. If this theory is correct, the feeble resisting power in the system of the infant explains the fact that it has quotidian more frequently than tertian intermittent, although the latter is much more common in the adult in this climate.

Facts demonstrate that infants sometimes receive intermittent fever from their mothers. If mothers during gestation have malarious cachexia, their infants, whether born at full time, or, as often happens, prematurely, are apt to be small, thin, and feeble, and occasionally they have soon after birth distinct paroxysms of the ague. Dr. Stokes related the case of a pregnant woman with ague, who believed that she noticed periodical tremors of her fœtus, but I suspect that she was mistaken, at least as regards the cause, for the paroxysm of intermittent in young children is not ordinarily accompanied by a chill.

The youngest infant in my practice who apparently derived the ague from its mother, and probably through the fœtal circulation, had the following history: Its mother had occasional attacks of tertian intermittent during the two years preceding her confinement, and her baby when one week old was observed to have the same disease, occurring also each second day, the coldness and blueness in the first stage of the paroxysm lasting from half an hour to one hour. In certain instances it has seemed to me probable that infants who were nursing had received the ague from their mothers through lactation, but I have not been able to determine this positively.

The period of incubation in the infant varies greatly, as in the adult. When the malaria is concentrated and unusually active, or the condition of system is favorable for its reception, the disease may commence soon after exposure. Thus in tropical regions travellers exposed for a single night have been known to sicken within twenty-four hours; but in our cooler latitude a longer incubative period is the rule. In the infant, however, in our climate, intermittent fever often begins in a very short time after exposure, though there may be an incubative period of some weeks. The following have been my observations relating to this point: A. M., female, 8 months old, remained two days on Long Island, in October, 1870, and three days after her return to the city a quotidian commenced. P. S., male, 11 months old, remained three days on Long Island, and a quotidian commenced four days after his return. K., 9 months old, remained on Staten Island one week, and eleven days after his return a tertian commenced. G. K., aged 3 years, remained a day and night on Staten Island, in 1870; three weeks afterwards intermittent fever commenced, preceded by a week of languor. A. U., female, aged 2 years and 2 months, had the first paroxysm of a tertian two and a half weeks after returning from a visit of one week in Hoboken. As there was no malaria in the portion of the city where these infants resided, the incubative periods are nearly ascertained.

It is well known that the paroxysm of intermittent fever in an infant ordinarily differs in certain respects from that in an older child or in an adult. The cold and sweating stages are less pronounced, while in the second stage there is an active febrile movement, lasting from two or three to six or eight hours, or even longer. In 24 of the cases of infantile intermittent which I have treated, my notes describe the character of the paroxysms. In 16 of these there was no chill or trembling in the first stage, but blueness and coolness of the extremities and features, and sudden prostration. This stage lasted from ten minutes to one hour. In the 8 remaining cases the infants were observed to tremble or shake as in adult cases. The perspiration of the third stage was in nearly all cases slight and of short duration, and in some was not observed.

In this climate intermittent fever in the adult is almost never attended with any danger unless from the cachexia which its long continuance may produce. In infants, on the other hand, the paroxysms are often dangerous, mainly from clonic convulsions, which are apt to occur in the cold stage. Convulsions increase greatly the passive congestion of the cerebro-spinal axis already present in this stage, and if not speedily relieved they may end in transudation of serum over the surface of the brain, and perhaps meningeal apoplexy, causing fatal coma. This has occurred twice in my practice.

Sometimes in young children the diagnosis of intermittent fever is doubtful, either because the disease has not continued sufficiently long, or there has not been the characteristic paroxysm. The patient may be feverish and fretful, with anorexia, and evidences of headache, but without the usual distinctive symptoms. I have sometimes in such cases been able to establish the diagnosis by detecting enlargement of the spleen. In examining for the "ague cake," the child must lie quietly on its back, and the fingers, placed midway between the epigastrium and umbilicus, be carried gently but with firm pressure outward in the direction of the spleen, when the anterior edge of this organ will be felt, if it be enlarged. It is impossible

to make the examination when the child cries, on account of the contraction of the abdominal muscles. In 1872, when a considerable number of young children with ague were brought to the children's class in the Outdoor-Department, I detected enlargement of the spleen in about one-half of the cases.

It is evident that no time should be lost in applying appropriate remedies in a case of infantile ague; for although the first paroxysm may be mild, the next may be more severe, and attended by danger. Moreover, the sooner the disease is cured the less liable it seems to be to return. Therefore we prescribe at once the sulphate of quinia or cinchonia, one and a half grains of the latter producing the effect of about one grain of the former. Our experience in the children's class in the Outdoor-Department has been chiefly with the sulphate of cinchonia, on account of its cheapness, and there has yet been no case of ague which it has failed to control. A recent writer has published statistics showing his success in curing intermittent fever by this agent, but nothing in therapeutics is more easy than to cure this disease in our climate by either of the sulphates mentioned. The chief difficulty consists in preventing a return. To an infant of two years I prescribe one grain of sulphate of quinia or the equivalent of sulphate of cinchonia, three times daily, till all symptoms of the ague have disappeared; then twice a day during the subsequent week, and afterwards once a day for some days; and finally twice or thrice a week. It is only by the protracted use of the drug in occasional doses that the return of the intermittent can be prevented.

It is important in administering these sulphates to infants to employ a vehicle which will, so far as possible, disguise the bitterness. I have found nothing so good for this purpose as the syrup of one of the berries, as in the following formula:—

℞ Cinchoniæ sulphat .....gr. xvi.
Acid. sulphur. dilut.....gtt. xxiv.
Syr. rubi idæi (raspberry)..... ℥ ij.

If the patient, when presented for treatment, is pallid from the long continuance of the ague or from other cause, physicians are in the habit very properly of prescribing iron in addition to the specific remedy. By producing a better state of the blood through this agent, and by hygienic measures, the ague is in my opinion more easily controlled, and less likely to return. The citrate of iron and ammonia dissolved in simple syrup, or the officinal Vinum ferri, are the preparations which I usually prescribe for this purpose to young children.

A MINORITY REPORT ON FOUNDLINGS AND FOUNDLING INSTITUTIONS.

(READ BEFORE THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.)

BY JOEL FOSTER, M.D.,

NEW YORK.

It will be remembered that a report was read by Dr. Jacobi, Chairman of the Committee on Foundlings and Foundling Institutions, at the last session of this Society; that, after some discussion, the whole subject was referred back to the committee, to report to the Society at its session of 1873; and that my name was added to the committee. Having waited in vain for the committee to be called together by the chairman, until within a week of the meeting of the Society, I hastily offer a few remarks on the subject, regretting that it was not in abler hands. The ablest authors on social philosophy and political economy agree that provision should be made for the care and protection of newly-born infants, and boldly protest against the policy of providing facilities for the easy abandonment of them. That asylums for the care of illegitimate and abandoned infants should be established and maintained, is now conceded by all who have thoroughly investigated the subject. Political economy has long since fixed the pecuniary value to the State of each healthy child saved to grow to manhood and womanhood. Practical statesmanship has recognized the correctness of this principle, and in various ways sought to give it effect. Hence, institutions having for their object the saving of infants which are without parental care or support, should be established. The object is worthy of commendation, viewed from the low standpoint of political economy; and the foundling asylums, and similar institutions of European states, must be regarded as among their noblest charities.

But charities of this kind which attach a merely commercial value to the life to be saved are liable to be organized on imperfect plans: while seeking to save the individual life in point, they adopt methods which lead to the sacrifice of this very life, and foster the evil which they should aim to prevent.

Foundling hospitals or asylums, as hitherto conducted, in many instances proved not only expensive failures, but they have been the nurseries of the crime of foundlingism.

Parentage has been ignored, and the crime incident to foundlingism has been carefully covered or concealed. The *twig* has been clipped from the parent *stem*, and every effort has been made to rear it by artificial means.

The methods of rearing hitherto adopted, whether by artificial feeding or farming out, have practically proved unsuccessful; at least that degree of success has not yet been obtained which we believe our enlightened and progressive age demands.

The whole subject of foundlingism should be regarded and studied from a much higher standpoint than political economy, which is but one feature of this great evil. Practical christianity, as well as practical statesmanship, in this country recognizes in the illegitimate not only a life to save, but crime to be prevented, maternal instincts to be cherished and fostered, and parental duties to be inculcated and enforced by moral and religious means.

We believe that the genius of Christian civilization demands of us—1. That we regard the infant as a human being, and as such entitled to all the privileges and immunities attached to our common race. 2. That whatever may be the accidents of its birth, it has an inherent right to be nursed and cared for by its mother. 3. The mother is entitled to our protection and care, while she discharges the incumbent duties of maternity. 4. That when released from such duties, she still is entitled to our sympathies and our efforts to save her from a life of crime.

No physician can doubt that if this class of infants were nursed by their mothers, under suitable regulations, the mortality would be very slight compared with any other method of rearing them. "The *mother's breast* is the infant's *birthright*," and suckling a *sacred duty*, to neglect which is prejudicial to the mother and often fatal to the child.

The mother supplies something more to her infant than food, and that something, which may be designated as love, tenderness, or sympathy, is an essential

element in the child's health. The hired wet-nurse cannot supply all that the child derives from the nursing and the care of its mother.

But while it may be admitted that these views are in general correct, can they be reduced to practice? We are prepared to show that the plan is both practical and economical.

The New York Infant Asylum is based on the following principles: 1st. The illegitimate child is entitled to the care of its mother. 2d. If for any reason the mother cannot nurse her child, it is entitled to the care of a competent wet-nurse. 3d. The mother of the illegitimate, presumed to be at heart virtuous, having been deluded by false promises, is entitled to protection and sympathy. This Institution has now been in active operation between one and two years, and has demonstrated the correctness of the above principles. The deluded mother, on learning that she can find refuge for herself and child, gladly accepts the offer to enter the Asylum and nurse her infant, where she is kindly treated, besides saving the life of her infant. She is protected and saved from a life of infamy and disgrace. To save the life of the newly-born requires the skilful care and love of the mother, without which few survive three months.

That breast-milk is not only the appropriate food to save life, but to produce proper development, to form the constitution of the child, and to lead it in the paths of health, it is necessary to commence our management of it from its birth; for it is too true that the system is influenced by the agency of external power, with which, from the moment of its birth, a child comes in contact by the inheritance of a robust or weak organization. That the chances of life are very much greater when nursed by the mother, is shown by the records of hospitals for diseases of children, especially in the reports of the Clinical Hospital for Diseases of Children in Manchester, England, carefully prepared by Doctors Morei and Whitehead. A few of these results will be quoted. 1st. The direct and baneful agency of want of good breast-milk may be inferred from the tables given below, from which it appears that the larger the supply of breast-milk and the more extensively it is given the better is the child developed, and *vice versa*.

Results observed in 1041 children, first and second years: 1st. Children having had breast-milk alone to the ninth month or longer, some to the fifteenth month: Of 150 children, 94 well developed, or 62½ per cent.; 35 medium, or 23 per cent.; 21 badly, or 14 per cent.

2d. Those who have had breast-milk up to the sixth, eighth, or ninth month, after which they were partially weaned, about 20 per cent. of them receiving for some months longer other food besides the breast, there were, in 113 children, 65 well developed, or 57.4 per cent.; 29 medium, or 25.6 per cent.; 18 badly, or 19.7 per cent.

3d. Those having breast-milk moderately abundant, and bread-food along with it from birth or early age: of 216 children, 110 well developed, or 51 per cent.; 54 medium, or 25 per cent.; 52 badly, or 24 per cent.

4th. Children who from birth, or the age of two or three months, besides an abundance of breast-milk (as stated by mothers), had received additional food, generally boiled bread and milk, or merely with sugar, water, and arrowroot: of 105 children, 55 well developed, or 52 per cent.; 29 medium, or 28 per cent.; 21 badly, or 20 per cent.

5th. Children who have had from the earliest infancy a moderate or small supply of breast-milk, some for a few months only, others up to nine, twelve, to fifteen months, with other food from birth: of 407 children, 100 well developed, or 26.8 per cent.; 107 medium, or 20 per cent.; 191 badly, or 45 per cent.

6th. Children fed entirely by hand, and no breast-milk: of 50 children, 5 well developed, or 10 per cent.; 13 medium, or 26 per cent.; 32 badly, or 64 per cent.

Thus, taking the extreme points of the table, we have in the former case 62.6 per cent. well developed, and only 14 per cent. badly developed; in the latter case, 10 per cent. well developed, and 64 per cent. badly developed. It was likewise noticed that those nursed exclusively on breast-milk rapidly advanced in dentition and ossification of the skull, and the early facility of walking; many were able to walk in from 10 to 12 months. From a reference to the annuaries of mortality in Paris, Dr. Quetelet obtained nearly everywhere the same results—that in the first three months after birth, twice or three times as many children die as in the other months of the first year.

Other authors have made the same observations. M. Bonoiston de Chateauneuf says: "It is true that, to preserve the life of a child, care does *everything*, and climate *nothing*, or very little."

"Switzerland and Holland are the countries where the smallest number of infants die, owing to the fact that all the mothers nurse their children." The chances of infant life under various kinds of care is very interesting. In the houses of well-to-do people it is estimated that from 80 to 85 survive their first birthday.

In all the city of New York, about 76 per cent.

In all Massachusetts, 81½ per cent.

In the rural neighborhood, 87½ per cent.

Of the foundling infants on Randall's Island, until recently bottle-fed by others than their mothers, about 10 per cent. lived to the age of one year; bottle-fed by mothers, 70 per cent.; wet-nursed by others than their mothers, 27½ per cent.; nursed by their own mothers, 80 in 100 were saved.

In the last-mentioned institution is found ample proofs of the great importance of the maternal instinct and affection in the care of the infant, even in low life. This is seen even in the cases where the child is reared upon artificial nourishment.

Experience in the Foundling Institution of the "Sœurs Gris-es," or Gray Nuns, in Montreal, as taken from the report of the Montreal Board of Health for the last six years, ending January 1, 1871, is as follows:—

Year.	Received.	Died.	Alive Jan. 1, 1871.	Percentage alive.
1865	729	656	73	10
1866	624	581	43	6.9
1867	652	598	54	8.3
1868	678	637	41	6.1
1869	670	633	41	6.3
1870	700	662	38	—5
Total	4059	3767	292	—7

Thus it appears that when deprived of the care which the maternal affection alone can insure, the hired wet-nurses and bottle-feeders, all in the rural districts near Montreal, failed to save even 8 in 100 of all the babies they received and farmed out. The Foundling Asylum under the care of the Sisters of Charity in New York tried the experiment of farming out infants in the rural districts of Long Island,

Westchester, and adjoining counties, and were obliged to recall their children on account of the greatly increased mortality, being very much greater than within their institution, although they kept a constant surveillance by people employed to look after them.

It has been before stated that care is everything in the early nursing of the infant, and it is well known to all physicians who have practised in the country, that very little attention is paid to sanitary science, and that the most absurd ideas prevail among the greater portion of the common people concerning the ventilation of sleeping apartments, or the quantity of pure air necessary for the welfare of the infant, to produce proper development and insure its life by proper feeding. The absence of a mother's care is manifest, especially in early life.

The plan adopted by the New York Infant Asylum, and now in full operation, is as follows: The house of reception is always well ventilated, with plenty of sunlight, and an abundant allowance of room for each child; always under the care of a competent superintendent and an educated nurse. The infants are in all cases wet-nursed by their mothers, if possible; they are then transferred to a branch of the institution in a rural district, with a southern exposure, with perfect drainage, and an abundance of pure water. It is a State institution, every county having equal privileges as New York. The children are kept scrupulously clean, as likewise their mothers or nurses. The bed clothes are changed frequently, and with the mattresses are thoroughly aired every day. Fresh air is allowed to pass freely through the nurseries every day; but when the currents of air from the windows and ventilators are too strong, the children are carried into another ward during the ventilation.

When the weather will permit, the children are carried into the open air, and continued in it for a considerable length of time. When the children arrive at a suitable age they are adopted out to respectable foster-parents. Applications are almost daily received from worthy, and often wealthy, people, to adopt children. The asylum is visited daily by one or more of the lady managers.

The lying-in department is in the city of New York, and when completed will have all the modern improvements suggested by the best sanitarians.

The success of the Asylum since its inception has demonstrated the truth of the principles before stated, that seventeen per cent. only died where they were nursed by their mothers, while twenty-three per cent. died where they were nursed by hired nurses, under the eye of the head-nurse. It must likewise be taken into account, that in several instances the infants, when received into the institution, were in a very unhealthy condition, never having nursed, and some of them dying in a few hours after reception. When the unfortunate female about to become a mother applies for admission, she, in most instances, readily consents to remain after her confinement and nurse her child, thus saving the expense of a hired wet-nurse, and saving the life of her child.

During the last year applicants have been received from seventeen counties in this State, who, but for this institution, would have resorted either to the vile abortionist, or to some of the numerous private establishments advertised in the daily papers, usually kept by a class of quack-doctors or immoral women, who care little for the life of either mother or child.

In conclusion, we have endeavored to show that it is the duty of society to provide asylums for illegitimate and abandoned infants, likewise to adopt the best and most humane methods of saving the life of the newly-born; and last, but not least, is the sacred duty of saving the unfortunate mother, and to prevent the perpetration of fœticide, infanticide, and abandonment; that the former can be accomplished by inducing the mother to nurse and care for her child; that the proper food for the young infant is the *milk from the mother's breast* and her *tender care*; that we have shown, by statistics from the Montreal Board of Health, the utter failure of the farming-out system in the country around that city, and likewise the experiment of the Foundling Asylum under the care of the Sisters of Charity in the country around New York; that infant asylums organized and conducted on the plan recommended by this report should be encouraged, and receive material aid from the State; that the system of farming out by the State would be neither economical nor humane, but unwise; that it would have a tendency to create numerous foundling bureaus in every large town in the State, with paid superintendents, agents, and clerks, with a central distributing reservoir, and would soon become a political engine—an asylum for worn-out politicians, instead of a refuge for the unfortunate and despairing mother and her helpless infant.

THE RATIONALE OF PERMANENT DRESSINGS.

By A. B. CROSBY, M.D.,

PROF. ANAT. BELLEVUE HOSPITAL MEDICAL COLLEGE, N. Y.

The subject of permanent dressings is one which has attracted much attention from surgeons, especially in this city, during the past few years. Extended clinical observation has demonstrated that this appliance of the surgeon is susceptible of a much wider application than was formerly supposed. The results have been all that could be desired, and there is no likelihood that permanent dressings will lose the high favor in which they are at present held by the profession. It is sometimes well, after the clinical utility of a surgical dressing is fully demonstrated, to interrogate ourselves as to the reason for the faith that is in us. It is in this view that I shall venture to offer, very briefly, a few thoughts on the rationale of permanent dressings.

The primary and cardinal benefit of a permanent dressing is, that it gives to the affected part *absolutely perfect rest*. Hence it has come to be used in fractures, in diseased joints, in sprains about joints, in any condition, in fact, where rest is the *sine qua non* of the treatment. In a fracture the surgeon seeks to coaptate the fragments and then to retain them in their normal relations; and long ago observed that, in order to treat fractures most successfully, the splints must represent a perfect mould of the normal contour of the affected limb, so that the muscles of the affected part might be subjected to *equable lateral pressure*. It needs little observation to show that a straight splint applied to a curved surface must make *unequal* pressure, and therefore not only fail to completely control the muscles, but, by the very inequality of the pressure, interfere with the circulation and cause more or less swelling. A permanent dressing well applied gives an exact mould of the limb, and so preserves its normal contour—a condition absolutely essential to the perfect restoration of a fractured bone.

I had for a series of years used permanent dressings in fractures of the leg with excellent results. In August, 1870, I saw a young Boston girl who, while on a visit to some friends in Vermont, was thrown from a wagon and got an oblique fracture of the left femur in the middle third. The accident occurred

some eight miles away from the house of her friends, and the intervening roads were very rough and hilly. As she had been carried into a farm-house situated on an inaccessible mountain-road, it was desirable, on all accounts, that she should be transported the above distance, to where she might have necessary care and appliances of comfort. I accordingly put the limb up in a well-adjusted plaster-cast dressing. Adhesive strips were previously applied to the sides of the leg, secured by a roller, and Surgeon Warren Webster, U. S. A., who happened to be with me, made firm extension on the leg and held it in a normal position while I applied the permanent dressing. The limb was drawn out to its full length, and maintained there until the plaster had firmly set. The patient was then placed on a mattress in the bottom of a wagon, and transported eight miles without pain or displacement of the fragments. On arriving at her destination no shortening could be detected. I saw the patient again in eight-and-forty hours and there was still no shortening. The attending physician subsequently reported to me an excellent recovery without appreciable shortening.

In diseased joints, it is a matter of common observation that the disease itself acts as a stimulus, and thus excites reflex contractions in the muscles about the joint. Spasmodic contraction of the muscles, occurring at short intervals, subjects the articular cartilages to constantly recurring concussions, and so the mechanical violence constantly increases the disease until disorganization of the joint is the result. What the affected joint requires to insure recovery is *absolute* rest. It was formerly the practice to resort to tenotomy in such cases, in order to give the joint rest; but the object was only partially attained in this way. A permanent dressing gives to the joint *perfect rest*, preventing all flexion and extension; entirely controls muscular contraction, and so prevents the articular surfaces from contusing each other. Clinical experience has demonstrated, moreover, that the permanent dressing may be used with advantage at any stage of the disease. For instance, in acute inflammation of the knee the permanent dressing keeps the diseased surfaces at rest, and the equable compression to which the swollen joint is subjected promotes rapid absorption of the fluids effused into the joint, as the result of the inflammation.

It is claimed by the advocates of this plan that in case of much suffering in an acutely inflamed knee, it is only necessary to apply cold outside of the permanent dressing, and give opiates freely, in order to insure a favorable result at an early period. If the case is chronic, the same dressing answers equally well. Even if there are fistulous openings, the dressing can be fenestrated so as to permit free discharge, while perfect immobility of the joint can be maintained. The value of this dressing cannot be overestimated in connection with diseased joints.

In cases of severe sprains about joints, there is likely to be, in addition to the tension of the tissues and the extravasation of blood into the soft parts, an irritable condition of the muscles set up, which may contuse the articular surfaces, and so excite arthritic irritation, if not actual inflammation. The *immediate* and *equable* application of a permanent dressing after a sprain will give the part rest; will promote the absorption of extravasated blood; will prevent muscular contraction, and will so prevent the joint from becoming either irritable or inflamed.

The above facts, which clinical observation has abundantly demonstrated, are quite sufficient to show the advantages that may accrue from the use of permanent dressings. Of the various substances employed in these dressings, such as starch, gum and chalk, dextrine, flour-paste, silicate of potassa, glue, and plaster-of-Paris, the latter is by far the best, by reason of its cheapness, the rapidity with which it becomes solid, and the ease with which it may be adjusted.

Of the different ways of applying plaster, I very much prefer, myself, surrounding the limb with two thicknesses of Canton flannel, drawing them smooth, and cutting the edges so that they will just meet. These now, being saturated in a basin of fluid plaster, can be spread smoothly one upon the other, applied around the limb (held in a proper position), and be secured by a single roller-bandage carried around the whole. If the layers of flannel just meet around the limb when dry, they will not, when saturated with plaster, meet to within from half an inch to an inch. As is well known, the equable compression of the plaster-cast speedily empties the superficial vessels, and so reduces the size of the limb, leaving the dressing loose. The outside roller can now be easily peeled off, the edges of the cast sprung together, and a new roller applied so as to again equally compress the limb. Thus all necessity of cutting open the dressing—always a troublesome matter—and applying a new one, is done away with.

I have heretofore alluded to the fact that a permanent dressing, if properly applied, will prevent muscular contraction, and so prevent deformity in fractures, on contusion of articular surfaces in cases of arthritis, and after sprains. This admirable effect is, in my judgment, brought about by the *firm, equable, lateral pressure* to which the muscles are subjected.

Recalling now something of the anatomy of the voluntary muscles, we may know that the ultimate fibrillæ make up the proper contractile tissue of the organ. These are flattened cylinders, about $\frac{1}{1\,8\,0\,0}$ of an inch in thickness, and marked by transverse striæ. Each fibrilla is made up of a series of quadrangular particles termed sarcous elements. Carefully examined, these seem to be made up of pellucid particles, having a rectangular outline, but a dark centre. So it is possible that the sarcous elements are, after all, nucleated cells having a linear arrangement. The striæ may thus prove to be the line of junction between the cells. It is proper to state, moreover, that some observers consider "the sarcous elements as artificial products occasioned by the breaking up of the fibril at the parts where they are thinner." There seems good reason to believe, moreover, that, when a muscle contracts, its sarcous elements change their form, the transverse diameter increasing at the expense of its longitudinal measurement.

If a whole muscle is examined when in a state of contraction, it is found to be shortened at the same time that it is swollen and hard. The surface of the muscle is manifestly wrinkled, and its fibres frequently oscillate or vibrate from alternate contraction and relaxation. It is this vibratory motion in the fibres of a contracting muscle that gives rise to the sound heard on the application of a stethoscope. Every muscle augments in thickness during its contraction, and, in connection with my topic, it becomes an interesting question whether the whole mass of a muscle increases or diminishes during a contraction. Schwamerdam tried the experiment with an insulated solid muscle, not yet dead, by immersing it in a tube full of water and then irritating it until it would contract. He found that the water descended in the tube, but the result was not uniform. A simple experiment may be made by immersing an arm in a properly constructed tube containing water. The level of the water

while the muscles of the arm are relaxed should be noted on the tube. On contracting the muscles, the water will be found to descend considerably below the mark on the tube; but we are not to forget in this experiment that the diminution in the bulk of the arm, during muscular contraction, may be accounted for, partially at least, on other grounds. When all the muscles of a limb are in a state of contraction not only is the ingress of blood into the limb retarded, but the veins are largely emptied by the pressure, so that the diminished size of the limb may be partially due to a diminution in the amount of blood contained in the part. Nevertheless, Etmann is credited with having immersed an eel entirely in water, and then having excited muscular contraction, he found that the water descended. In this experiment, if correctly reported, there would seem to be no element of fallacy. From such an experiment, it would seem to be a fair inference that a muscle does diminish in bulk during the period of contraction. The fact, however, is patent, that the transverse diameter of a muscle increases during contraction.

If, now, we seek definitely for the rationale of permanent dressings, we shall find, I think, that they accomplish the purpose for which they are designed in at least three different ways. In the first place, permanent dressings bring about the desired result by making *firm and equable lateral compression of the muscles*. Such compression of the muscles ought, theoretically, and does *de facto*, prevent contraction and consequent shortening in fractures, concussion of articular surfaces, etc.

It is well known that in violent puerperal convulsions, or other muscular spasms, immediate relaxation can be induced by carrying a cord around the limb, crossing the ends, and then jerking them violently. Every boy who suffers from crural cramp instinctively seizes the offending muscles and compresses them with the utmost firmness. In both cases speedy relaxation is the result: here firm lateral compression induces the desired end. I am equally sure that a firm lateral compression of all the muscles of a limb will entirely quiet their irritability, and that they will thus continue as long as the above conditions are carefully maintained. To attain the best results, especially in fractures, it is desirable that the dressing should always be firmly in contact throughout the limb, and hence the necessity of tightening it whenever it becomes loose. Firm lateral compression, then, affords mechanical support to the muscles; moreover, under this condition the transverse diameter of the muscles cannot increase, without which contraction is impossible.

In the second place, permanent dressings have an important influence on the blood-supply of the part to which they are applied. The first effect of equable compression of the limb is to mainly empty the superficial veins, and compressing it ultimately retards the afflux of blood into the limb. The amount of blood then circulating through a limb is manifestly diminished by a firm permanent dressing. In order that muscular tissues should contract, it is necessary that there should be a certain activity of nutrition and a certain degree of temperature. It is especially in warm-blooded animals that these conditions are most essential. It is a well-established fact that if the supply of nutrient material is cut off from a muscle, as when the blood is prevented from circulating through it, its contractility will diminish and soon cease altogether. By allowing the blood to again permeate the muscle its contractile power may soon be restored. This experiment, first performed on dogs by Struonits, has been repeated on the cold-blooded animals by Engelhardt and Valentine, with the same results.

The nutritive process and the expenditure of force is, of course, most rapid in warm-blooded animals. The maintenance of irritability in them is directly dependent on the supply of blood and the influence of oxygen; when the latter are cut off, the former soon fails, and ultimately ceases.

From these facts it legitimately follows that if a permanent dressing diminishes the amount of blood in a part, it will proportionately diminish the part so compressed—will, in fact, prevent contractions, by cutting off from the muscular tissue a considerable proportion of its essential stimulus, the blood.

It is important, also, to mention an important corollary in this connection. Clinical observation has abundantly demonstrated the fact that in fractures treated by permanent dressings, irritation, pain, heat, swelling—inflammation, in fact—is exceedingly rare. Permanent dressings, by arresting all muscular contraction and giving the part absolute repose, obviate the tendency to morbid action in the part. But beyond this, the equable compression of the limb, by diminishing the amount of its blood and by retarding the ingress of the vital fluid, directly and mechanically prevents the hyperæmia which is the necessary condition of inflammation. So evident is this principle, that some surgeons of our time and city are accustomed to resort to this dressing as a prophylactic against anticipated inflammation. Thus, after forcibly breaking up an anchylosis of the knee-joint, some surgeons not only resort to firm permanent dressings, but, in order to still further prevent the further ingress of blood, they add a graduated compress over the main artery of the limb.

In the third and last place, the good effects of permanent dressing are due in no slight degree to the accurate relation that exists between the cast and the configuration of the limb. About the ankle, the knee, the wrist, the elbow, etc., there are certain prominences or processes alternating with depressions. These offer points of support when covered by an accurately fitting mould of the part. Moreover, we may notice that the forearm, arm, leg, and thigh, each constitute a truncated cone. A permanent dressing forms a tightly-fitting conical case, by which extension and counter-extension are equably diffused over the whole surface of the affected part. The advantage to be derived from the conical form of the thigh, in treating fractures of the femur, has been realized by surgeons. In Latta's splint for fractures of the femur, a conical zinc case, properly padded, is buckled firmly around the thigh, and the upper end of the long splint being attached to it, the counter-extension is equably diffused over the whole surface covered. The counter-extension can thus be effectually accomplished without any pressure upon the perinæum, and without any irritation of the skin covered by the zinc case. To sum up, then, it follows from the foregoing considerations that the rationale of permanent dressings may be—1. In the principle of *equable lateral compression* preventing muscular contraction. 2. Diminution in the blood-supply, with proportionate loss of contractility; and 3. The conical form and irregular configuration of the extremities, by which extension and counter-extension can be equably diffused. We have learned clinically that permanent dressings prevent deformity and insure absolute repose in an injured part. There can be no doubt that they are among the most valuable dressings of the modern surgeon. It has been my purpose to show that the use of this valuable surgical appliance is not only empirical, but rational.

Progress of Medical Science.

Inoculability of Pyæmic Blood.—Raynaud inoculated two series of rabbits with blood taken from a woman suffering from pyæmia. In the first series, ten drops of blood taken from the woman's hand were injected subcutaneously into a rabbit. It manifested a slight illness, which soon passed away. One drop of its blood killed a second rabbit in seven days. Immediately after death of the latter, blood was taken from its heart, which, in the dose of a thousandth part of a drop, killed a third rabbit in 20 hours, and a millionth part of a drop of this animal's blood killed a fourth in 30 seconds. The section showed nothing noticeable in either case save ecchymoses.

In the second series, the first rabbit was injected with 10 drops of the woman's blood, in the axillary vein. The rabbit sickened and died on the fourth day. A fresh peritonitis and a metastatic abscess in the lung were found. From this animal, as in the first series, a second was inoculated subcutaneously; from this, again, a third, and so on through eight generations, with constantly minuter doses. The millionth of a drop injected into the seventh rabbit killed it in less than three days, while the eighth escaped uninjured after injection of a trillionth of a drop.—*Gaz. hebdomad.*, No. 14, 1873.—*Centralbl. f. d. med. Wissensch.*, No. 31, 1873.

The Influence of Carbolic Acid in Preventing Pyæmic and Septic Infection in Animals.—Rosenbach injected dogs and rabbits with purulent fluids, and others with the same matters, but with the addition of a portion of carbolic acid. The animals were injected subcutaneously with fresh but unhealthy pus obtained from a congestive abscess and a carious humerus. The result was, that after injection of the purulent matter alone, a phlegmonous inflammation followed in each case, from which four of the animals died in a few days, while one recovered. In the four fatal cases—of which three ran their courses with violent fever—the death was in each instance occasioned by extension of the phlegmon and destruction of the tissues. In seven cases similar pus, from the same source, was injected, to which 5 p. c. carbolic acid had been added. In all these cases the only result was the formation of local abscesses. The temperatures in these cases exceeded the physiological maximum but in one instance. Experiments to determine the minimum of carbolic acid necessary to produce this result showed that ½ p. c. of the acid was insufficient, and 1 p. c. afforded no certain protection. Some experiments with septic purulent matters, kept for two months in a warm temperature, indicated that the influence of carbolic acid on decomposed pus was less than with fresh septic matter. Finally, experiments with healthy pus—pus *bonum et laudabile*—showed that the addition of carbolic acid entirely prevented the local infection as well as the general intoxication which were otherwise produced.—*Habilitationsschrift, Göttengen.—Berl. Klin. Wochenschr.*, No. 27, 1873.

Hydrochlorate of Apomorphia.—This new emetic has been recently subjected to a series of trials by Mörz, with results which indicate that it has a decided superiority over the emetics in common use. The dose employed varied from 0.006 to 0.012 of a gramme. Emesis occurred from 3 to 17 minutes from the time of administering the drug. The method of administration adopted by preference was subcutaneous injection of the arm. The injection occasioned no pain, and but little local irritation. The immediate effects were as follows: After a few minutes a slight sensation of heat was felt, a little dizziness, a slightly apathetic disposition, moderate or scarcely noticeable change of color in the face, increased secretion of saliva, one or two efforts at vomiting, and then a sudden discharge of the contents of the stomach. If the nausea continues, another emesis follows, after which the patient invariably falls into a brief, quiet slumber, and awakes afterwards without the slightest unpleasant symptom.

The advantages of apomorphia are summed up as follows:—

(1.) Convenience of administration.

(2.) Employance of smaller doses than other emetics require; for adults 12 centigr. may be regarded as the amount which will induce vomiting under all circumstances.

(3.) Harmlessness, a quality which, in an equal degree, can be attributed to neither tartar emetic, ipecacuanha, nor sulphate of copper.

(4.) Certain and speedy accomplishment of desired effect.

While the same indications applicable to other emetics apply to apomorphia, it is especially recommended for children's affections, particularly in threatened attacks of laryngitis. Four milligrammes are often sufficient to avert the danger of suffocation. It is also recommended in the treatment of the insane, but its most brilliant results, it is claimed, are exhibited in cases of acute poisoning. Attention is finally called to its value as an expectorant, where, in conditions of great debility, it is desirable to clear the air-passages, as in pneumonia, as well as in feeble individuals and the aged.—*Prager Vierteljahrschr.*, Bd. 115—*Oesterr. Zeitschr., f. Pr. Heilkde.*, No. 24, 1873.

Treatment of Salivation by Atropia.—Heidenheim has recently investigated the action of atropine on the salivary secretion, and has shown its effect to be (1) to annul the influence of the corda tympani upon the secretion, but (2) not to interfere with its influence upon the circulation, nor (3) to prejudice the secretion by irritation of the sympathetic, thus not destroying the gland-cells. Following H.'s investigations, Ebstein has applied atropine to the treatment of a case of salivation with remarkable success.

A patient was admitted to the hospital at Breslau, who some months previously had suffered an attack of hemiplegia. At the time of admission traces of the paralysis still remained, with some drooping and partial immobility of left half of the mouth. From the corner of the mouth saliva flowed profusely, and was too copious to be accounted for merely by the paralysis of the orbic. oris. According to the patient's statement, this discharge had persisted for about a month, coming on some months after the occurrence of the hemiplegia. Some drooping had accompanied the paralytic stroke at first, but afterwards this ceased.

The atropine was administered at first in pills, each containing 0.0005 atrop. sulph. From one a day the dose was gradually increased to 4 pills (0.002 pro. die). The discharge of saliva was at the beginning 300 c. c. daily. With the increase of the dose the discharge gradually diminished to 275, 100, and 90 c. c., though it did not cease entirely. On stopping the drug the saliva flowed as at first. The atropia was next administered subcutaneously over the submaxillary gland of the paralyzed side; 0.0003 gramme so injected had no effect. The dose was increased to 0.0006, and by degrees to 0.0016. One or two minutes after injecting 0.0006 the patient noticed that his mouth was drier, and in from 5 to 7 minutes the flow had ceased entirely. After the dose of 0.0016 there was no saliva from 4 o'clock P.M. till 6 the next morning. Afterwards the

flow recurred. When the injection was made over other parts of the body the effect was delayed to about twice the length of time. This was also the case when the atropine was dropped into the conjunctival sac.

The writer believes that the proper narcotic for salivation is atropia, and in conclusion thinks he can "recommend its use in the treatment of salivation to his colleagues with good conscience."— *Wilh. Ebstein, Berl. Klin. Wochenschr.*, No. 25, 1873.

Tracheotomy in Diphtheria.—During the years 1861–1872 inclusive, there were performed in the department of Prof. Wilms, in Berlin, 330 tracheotomies on diphtheritic patients under 16 years of age. Up to 2 years of age there were 6 operations, and all died. In the ages of 2–3 years, there were 56 operations, 15 recovered; 3–4 years, 69, 22 recovered; 4–5 years, 74, 18 recovered; 5–6 years, 57, 20 recovered; 6–7 years, 33, 15 recovered; 7–8 years, 21, 5 recovered; 8–14 years, 19, 8 recovered; total, 103 recoveries (31⅓ per cent.)—boys, 36⅓ per cent., girls, 24⅓ per cent. In the first two years, and between the ages 11–14 inclusive (of each 6), not a case recovered. The constantly unfavorable result in the later periods of childhood is accounted for by inferring that the relatively more capacious air-passages must suffer from a higher grade of disease before they afford sufficient indications for operation. In operating, chloroform is usually employed, all bleeding vessels, veins or arteries are tied, and as a rule the interior tracheotomy is preferred. As a rule, the canula could be removed between the 5th and 8th days. Practically, the indication for its removal was inferred if within 4–6 days the morning temperature was somewhat higher than upon the previous evening, and the respiration a little more frequent. When the indication was not regarded, the discharge soon became reddish—an evidence of irritation.

A pulse of over 152, a few hours after the operation, renders the prognosis unfavorable, and with a pulse of 170, the patient is sure to be lost; if less than 130, the prognosis is, with few exceptions, favorable. A high temperature soon after the operation (39° C. and over) is unfavorable; a normal temperature upon the following day is very favorable. Sudden rise of temperature usually points to complications or a relapse.— *Bartels. Jahrb. f. Kinderhlkde.*

A Case of Syphilitic Enteritis.—A well-developed child, six weeks old, was attacked by a macular syphilide of the skin. Under treatment it disappeared in three weeks, and the child remained well till its fourth month. It then began to suffer from an apparently slight intestinal catarrh, which, however, obstinately resisted all treatment. The stools were copious, at first of greenish mucus, with here and there streaks of blood, finally of rice-water appearance, and vomiting became frequent. The diagnosis enteritis follicularis was made, and from the child's debilitated condition a bad prognosis was inferred. After two months' duration of this affection, an extensive ulcerative syphilide broke out. Antisyphilitic treatment was adopted, and the syphilide rapidly receded with, at the same time, a marked subsidence of the intestinal symptoms, and in three weeks the child was recovered. That the intestinal affection was due to the syphilis was presumed from the coincidence of the syphilide upon the skin, and its ready yielding to antisyphilitic treatment after a symptomatic treatment had failed.— *Orvosi Hetilap*, 1873, No. 18.

Ligation of the Arteria Innominata.—Dr. E. S. O'Grady, of Mercer's Hospital, England, recently ligated the innominate artery for an aneurism of the subclavian in a patient nearly sixty years of age.

THE ABUSE OF MEDICAL CHARITIES.

Our relations to the community as dispensers of medical charity have always rendered us liable to every sort of imposition. This is no more than could be expected, verifying the truism of a general principle, that there is never a use without an abuse. We always expect to find unprincipled individuals, who are ever ready to take a mean advantage of the good intentions of others, and by false representations are willing to appropriate benefits which they know belong to others. In matters of charity this is pre-eminently the case, from the lazy, lying mendicant at the street-corner to the base miser who sneaks into the free ward of a hospital and prostitutes the very name of poverty by the meanest of all pretensions. A great deal has already been said concerning this abuse of medical charity, and many propositions have been advanced with a view of checking the evil, but with little avail. The very civilization of the human race which has made charity necessary, has stimulated the growth of the abuse, so that, as an evil, it has taken root into every grade of society.

To blame the profession for much of this state of things appears at first rather startling, but we believe that the charge can be fairly substantiated. We would be outraging the finer feelings of our humanity were we to assume that no real charity is performed by our profession, that no benefits are conferred upon the poor for the sole pleasure and satisfaction derived from their performance. There is a great deal of this charity, a great many services having a right to the name which are as conscientiously rendered as those of the true Samaritan of old. All this is well enough as far as it goes, but we are sorry to say that too many have gone further in the use of their privileges and in the performance of their duties, and have laid themselves open to the damaging suspicion that too much is done for show and selfish interest.

It has often occurred to us that there is altogether too much said by ourselves about the charity of our profession; that if the public is not aware that we possess and exercise the virtue, it has certainly been no fault of ours. The public hear so much of our charity that they are beginning to think that they are conferring a favor upon us by giving us an opportunity to exercise our propensity in that respect. We not only tell them of our Samaritan virtues, but are too much inclined to force their exercise upon the people. This disposition is seen in the struggle for hospital and dispensary appointments. If a new dispensary is founded, or a new hospital projected, the most strenuous efforts are made to secure a place on the medical staff, and the trustees are at once impressed with the belief that of all the services that can be rendered to the institution, the purely professional ones are the cheapest. The public are not backward in having the same idea. No sooner are these institutions opened than every facility is offered to the public to avail themselves of the privileges; and if all other means fail to make a show of patronage, regular advertisements are issued for patients. These institutions must make a show of a number of patients treated, else there will be no reasonable excuse for their establishment, and no encouragement to the benefactors. It is easily seen that this very system encourages an abuse of charity which the medical profession directly abet by the very eagerness with which they serve these so-called charities.

Many medical men go still further, and, we are sorry to say it, under the cover of charity, found institutions for the study of a specialty and advertise for patients in the daily papers. We have known of more than one institution of this sort where patients were actually coaxed to come, that the number of applications might prove it to be prosperous, and offer an excuse for seeking an appropriation from the legislature. In view of this state of things, is it right to assume that none but the pure charity-patient was treated? Is it fair to presume that, under the circumstances, even ordinary measures were taken to guard against fraud on the part of the applicants?

It is laudable to use every legitimate means to study disease, to enlarge observation and increase experience; but the manner in which practice is carried on in many of our public institutions is not legitimate. A few who may hold positions are, in reality, advancing themselves by damaging the pecuniary interests of the majority of their brethren. Many do so thoughtlessly, but the results are none the less detrimental. In a medical centre such as New York, there is always a struggle to develop an interest in clinical teaching, and a desire to have the clinic rooms of the various colleges well filled with interesting cases.

This is as it should be, and so far as due care is taken to exclude the unworthy applicant, nothing but good can come of it. But is this care always taken when a particularly interesting case presents itself?

In view of this, is it a matter of surprise that the unprincipled class of the community will be backward in availing themselves of advice so freely, in fact gladly, bestowed? We have known of gross impositions being practised in this way. Not infrequently patients of other practitioners—patients well able to pay a fee—will apply to dispensaries, clinics and infirmaries, and get advice and operation without any hindrance whatsoever. Especially is this the case with well-to-do patients living out of town.

Not long ago, in conversation with a patient upon whom an operation for artificial pupil had been performed by a celebrated oculist in New York, we were surprised to hear that the said operation had been performed for charity at the Eye Infirmary. When asked why he did not consult the surgeon privately at his office, the simple reply was, that it was not necessary when he could so easily obtain the same advantages for nothing at the Infirmary. We have heard of several cases of this sort, who, having capital operations performed for nothing in New York, are exceedingly reluctant, when returning, to pay the ordinary and modest fees of the rural practitioner. The surgeons, by want of care in treating the cases at the institutions, are thoughtlessly offering a premium on dishonesty. We are aware that there is often considerable time consumed, and trouble to be taken, to separate the fraudulent from the worthy recipient of charity; but this time and trouble should be taken in the cause of charity, and in the true interests of the profession. The majority of the gentlemen connected with our clinics and infirmaries have substantial incomes from their practice, and to them personally the occasional cheating of a fee does not amount to much; but they should look beyond this, and, as a matter of honor to the young and struggling practitioner, take ordinary pains to prevent fraud. The young physician is, after all, the real sufferer; the fee which might be scorned by his well-to-do brother would be a godsend to him. He is contented with a little; and why cannot the dispensary and infirmary attendants make an effort to throw that little into his hands? The connection with a hospital, infirmary, dispensary, or college clinic has many advantages, which to the holder are more than counterbalanced by the disadvantages of a forced attendance at certain times. Personally the advantages may perhaps be incalculable, but each gentleman holding such a position is bound in the discharge of his duties to consider somewhat the interests of those who may not be so fortunate. The advantages of the very name of being connected with a hospital, the opportunities for experience and practice which such a connection may give him, are great, and if properly used science can be advanced, charity served, and the best interests of the profession promoted.

Although the profession can do much to prevent fraud, they cannot do everything when unaided by the authorities of the institutions. In many instances the action of members of the medical staff, in refusing to attend to certain pretenders, is upheld; but in many other instances what is conventionally styled "the interests of the institution" interferes. It is true it is intended to be understood that none but paupers are admitted, or such as are only able to pay a certain stipend for board; but, generally speaking, no objection is made to a patient if he conforms to all the pecuniary requirements made of him. The fact is, that many of the hospitals are too much in want of money to refuse any one who is willing to pay the required board; for some reason best known to the authorities, no further questions are asked. Every medical man can recall cases in which patients are able to command the best rooms and the most expensive luxuries, private nurses, and the like, and so long as they pay for these they have the advantage of medical services gratis, under the cover of charity. These are cases in which the attempts to cheat the profession of legitimate fees are too open to admit of question. And yet the practice is tolerated in all our large institutions, the authorities of which appear, by this open defiance of ordinary justice, to own the medical staff body and soul, by compelling them, on pain of jeopardizing their positions, to attend these patients the same as if they were deserving paupers. Now we claim that there is in this way of doing things a little too much of institution and too little of doctor. But can we expect anything more of managers who are made to believe that medical men are so eager to give their services to these charities that they will resort to all sorts of intrigues for influence to obtain positions, and all manner of subterfuges to retain them afterwards? The supply of medical men is so much greater than the demand, that directors and managers can afford to be independent. Such is the only explanation for the paradox that the most useful men to the institution are the ones who have the least to say in its general management, and are servants to all.

Some of the hospitals, not satisfied with making their expenses in this way, have dared to go farther in their unfair dealings towards the medical staff. Not only have they received patients well able to pay medical fees, but they have made an extra item in the patient's bill for medical services, which services as an institution they received gratis! As an offset to such a practice it is the rule that no physician or surgeon shall use his position in the hospital for the sake of making money. Under the circumstances just mentioned we fail to see where the justice of the arrangement is. The doctor is not a hireling of the house, but in the relation to it of a benefactor, and if any attempt b

made to remunerate for medical services, pure and simple, to whom do they legitimately belong? If the doctor dare not expect such rewards, what interpretations can we give to the right of the hospital to demand them?

In view of a state of affairs like the above, it is in vain to look for much help from hospital authorities towards correcting abuses of medical charity: all we can do in a professional way lies in ourselves. We cannot cure the evils, but we can do a great deal towards preventing them. It may not be possible to overturn the present hospital management, but there is much to be done to make the managers feel the worth, influence, and power of the medical staff, and by the right sort of action, desirable reforms can be instituted. In dispensaries, physicians are in a more independent relation to the authorities, and can exercise an almost absolute right to refuse aid to the undeserving. Much more is this the case in our college clinics. We are by no means jealous of the amount of real charity done to the poor of New York, but we do not care to have it overdone. When a profession can claim to treat gratuitously three hundred thousand paupers annually in New York city, not counting those in hospital, and it knows at the same time that one out of every ten of the young medical men in that city can barely earn a living, we think it is about time to look into the matter, to consider whether the occasion is not opportune for proving the force of the proverb, "Charity begins at home."

INDEPENDENT JOURNALISM.

Few medical journals have been started without professing at the outset to be entirely free and untrammelled by any undue or unethical influences.

It is notorious, however, that there are few in this country which do not derive some pecuniary support from giving whatever influence they may possess, directly or indirectly, to some college or prominent physician or physicians; few which consider they can afford to refuse a profitable advertisement, when they can obtain it by bestowing upon its subject a laudatory editorial, or insert somehow in its columns a commendation of it.

From time to time we have noted this growing evil in medical journalism, and now desire to call the attention of the profession, and particularly of editors, to the advertisement of "Cincho-quinine," to be found in so many medical periodicals at the present time. A condition the proprietors of this article attach to its advertising is, that the journals with which they contract shall insert quite a lengthy extract from the *Boston Journal of Chemistry* (published by them), descriptive, etc., of the preparation. Of "Cincho-quinine" itself we have nothing to say, for or against; our desire is simply to protest, for the respectability and purity of the medical press, against *selling* their columns, with their advertising pages, to any person or for any purpose, good, bad, or indifferent.

MEDICAL LIBRARY AND JOURNAL ASSOCIATION.

Dr. John C. Peters, President, in the Chair.

CANCER OF THE FEMALE BREAST. ITS CHARACTER, DIAGNOSIS, PROGNOSIS AND TREATMENT.

Professor Willard Parker remarked as follows:—

In the latter part of the last century the man who was particularly connected with the study of this subject, cancerous tumors, was Dr. John Abernethy. Previous to his time, our knowledge upon this subject was in a state of confusion. So completely and successfully did he study this subject of tumors, that, in his time, the results of his investigations were regarded as the *ultimatum*. They were so generally accepted by the profession, that whoever was familiar with what Mr. Abernethy said upon the subject, was supposed to know all that could be known about tumors. These results of the investigations of Mr. Abernethy continued to control the minds of the profession, to a very great extent at least, until perhaps the last twenty-five years. Since that time great changes have taken place, which have grown more particularly out of investigations arising from the use of the microscope and from the researches of the histologists.

The first great departure was introduced by Bichat.

Bichat was the father of general anatomy, and was one of the brightest examples of a thorough scholar that France has ever produced. It was by the influence of his study that the human body was divided into its different systems—the muscular system, the vascular system, the nervous system, etc. In connection with his great work, the study of general anatomy, he took up the study of tumors. In his studies upon that subject, he observed that tumors were growths in the body, abnormal in character, that some of them had a character analogous to the original natural tissues, and that others varied somewhat from the original natural tissues. He observed, therefore, that there were two classes. One *like* the original normal structure, and the other *unlike* the original normal structure, and had a structure *sui generis*.

Bichat died in the year 1802. His pupils, Dupuytren, Andral, Cruvelhier, and others, seized upon this idea which Bichat had advanced, and made the two great classes of tumors with which the profession has been so familiar since their time. They divided tumors into two great classes, one which embraced that class of tumors which were composed of a structure analogous to the natural structures of the body, which they called homologues or homoplasts, and another which embraced that class of tumors which were composed of a structure which found no analogy in the body, which they called heterologues or heteroplasts. They farther observed that the first class were almost always mild in their effects, easily controlled by treatment, and they received the additional name of benign. They also observed that the second class were very apt to destroy life, sometimes very rapidly, were not easily controlled by treatment, and they received the name of malignant. This division of tumors was persisted in for a long time by the French, and it has been in France that the strong advocates of this classification have arisen. In the latter part of the life of Velpeau, that great surgeon began to question this matter of homology and heterology, as the terms had been used in this connection, but his studies and researches

assumed no definite shape. The next class of men who attempted to give a solution to the question, What is cancer? were the chemists of France, and of these there were Thenard, Lassaigne, Vauquelin, and others of equal ability. These men made a careful analysis of cancer, with the view of discerning, if possible, something peculiar to cancer: something which perhaps might receive the name of *carcinomatine*, a distinct and fixed substance, the presence or absence of which might always enable us to say whether cancer was present or absent. After a long and careful research, they found that their labors were unsuccessful, and the work was allowed to pass from their hands, and it fell into the hands of the histologists. This class of observers have been diligent in their study, and faithful in looking for some change or modification of the cell-products, shape of cells, or presence of peculiar elements, by which they could distinguish cancer. For a long time it was thought that they had succeeded in making the desired discovery, and the announcement was made that the essential element in cancerous growth was the presence of a certain shaped cell, which was immediately denominated the "cancer-cell." This announcement was very generally accepted by the profession as a solution to the long and vexing problem. It is only a few years since we all had faith that the so-called "cancer-cell," or morphosis, something distinct and definite in its character, which had been found, would enable us to determine whether any given growth was cancerous in its nature, or whether it was not cancerous in its nature. But the truth is, we now know that no one cell at present can be fastened upon as absolutely representing cancerous disease.

The "cancer-cell" theory belonged to the French.

The Germans, on the other hand, never acceded to this proposition, and for some time there was considerable discussion between French and German scholars upon this question. Among the Germans who engaged in this discussion were Virchow, Rokitansky, and others, who have since become preëminent in their profession. The study of this subject, however, has been followed up by Virchow particularly, and now we have the result of his investigations formulated and presented to us in his great work upon the pathology of tumors.

First of all he lays down the proposition that everything proceeds from a cell—

"*Omnis cellula e cellula.*"

For a time his opinion was that the embryonic connective-tissue cell had the power of proliferating the cancer-cell, that is, that the connective-tissue cell could produce a cell like itself, and also a cell of a different character, which was the cancerous product. But it now seems to be settled that like only begets like, and the doctrine that the connective tissue is capable of proliferating a cell of a distinct character, which can be the cancer-cell, is regarded as not being tenable.

The doctrine is now, that the true cancer, so far as we rely upon the cell, is made up of cells which are of the epithelial type.

Failing to discover a peculiar cell by which cancer was to be recognized, both histological and pathological observers have at present settled down upon the point that true cancer is to be recognized by certain peculiarities in its anatomical structure. That is, we have in the first place a stroma made up of connective tissue; that in the interstices of this connective tissue, denominated alveoli, are deposited cells; that these cells are of the large, nucleated variety, and have for their prototype the epithelial cell. The presence of this anatomical arrangement is now regarded as evidence of the presence of true cancer. In other words, that nearly all cancers, if not all, have their origin in epithelial structure. This portion of the subject is one of great interest, and it is to be hoped that, at some future period not far distant, the histologist and the pathologist, by aid of the microscope and other means which they have at their command, may be able positively to determine and settle the question as to what changes have taken place in the growths which we now call cancerous. Virchow, pursuing the study still farther, as relating to the clinical history of these growths, has given us several stages.

1. The stage of development or local irritation.
2. The stage of granulation.
3. The stage of differentiation. That is, from being an apparently homogeneous structure, some of the cells go on to make muscular tissue, epithelial structure, etc.

Of these varieties of cells he distinguishes four; that is, cells which are to appear in four different kinds of structure.

1. Connective tissue.
2. Nerve structure.
3. Muscular structure.
4. Epithelium.

Continuing the stages he makes

4. The stage of maturity.
5. The stage of retrograde metamorphosis, or the stage when it has attained its maximum growth, and begins to retrograde and die.

This process may take place by ulceration, suppuration, adipose change, and so on.

This embraces all the general remarks I have to make on the question, What is cancer?

Now, with regard to cancer of the female breast. There is hardly any organ in the human body so frequently the seat of this disease as is the female breast. Of course when cancer involves any important organ in the body it becomes the object of great solicitude on the part of the patient and the friends, and on the part of the surgeon a source of great anxiety, and, I am sorry to say, without any satisfactory results attending his efforts to give permanent relief.

In the first place, with regard to its frequency. Upon this point we have some very instructive tables furnished us by a French surgeon, who made his collection of cases during the eleven years immediately subsequent to the year 1830. The whole number of cases he collected, of all kinds, was 9,119.

Of these 4,222 occurred in organs peculiar to the female sex, and only 48 occurred in organs peculiar to the male sex. This is in the proportion of 88 to 1. The reason for this extreme difference in frequency in the two sexes is not known.

Of the 4,222 cases which occurred in women—

2,996	cases	occurred	in	the	uterus.
1,147	"	"	"	"	mammæ.
64	"	"	"	"	ovaries.
15	"	"	"	"	vagina.

Of the 48 cases which occurred in men—

21	cases	occurred	in	the	testes.
10	"	"	"	"	penis.
7	"	"	"	"	scrotum.
5	"	"	"	"	prostate.
5	"	"	"	"	pap.

A remarkable feature of these observations is that so few occurred in the ovaries.

I propose now simply to refer to the cases which have fallen under my own observation. These are

cases which I have either treated myself, or have seen in consultation. These observations and notes extend over a period of about 40 years, but the larger portion of these cases have occurred within the last 20 years.

I have upon my tables the record of 295 cases.

In making up these tables I have taken into consideration the following points:—

(1), Date; (2), name; (3), age; (4), civil condition, married, single, or widow; (5), No. of children; (6), which breast was involved; (7), family history; (8), personal history; (9), diagnosis, prognosis, treatment; (10), subsequent history.

First, with regard to age:—

Average age	$48\frac{7}{10}$ years.
Oldest	86 "
Youngest	28 "

CIVIL CONDITION.

Married	190
Widows	53
Single	34
Unknown	18

NUMBER OF CHILDREN.

Mothers	186

BREAST.

Right breast	107
Left breast	130
Axilla involved	71

It will be noticed that there is a difference of 23 in favor of the right breast. I have also found that the same result has been obtained upon this point by other observers. I can assign no reason why its occurrence should be so much more frequent in the left breast than in the right.

FAMILY HISTORY.

Cancer taint	28
No cancer taint	208
Consumption	35
Consumption and cancer taint	5
Unknown	36

It will be noticed here that by far the larger portion occurred in persons who had no history of cancer taint. So far, then, as my tables go, they prove that cancer is not a hereditary disease, which is contrary to the opinion I had always entertained previous to a more thorough examination of the question.

PERSONAL HISTORY.

Blows	38
Injury from breastpump	1
Injury from tight dress	2
Inverted nipples	2
Uterine sympathy	19
Mental anxiety	45
Commencing benignant (op. 17)	31
Commencing malignant, but living long (op. 14)	15
Sloughing and living long (op. 3)	6
Cystic (av. age, 57¾; oldest, 72; youngest, 33)	9
Metastatic	3

With regard to the 19 cases which occurred from uterine sympathy, they belonged to that class of cases which formerly were called the irritable tumor of the breast. These cases not uncommonly occur in connection with dysmenorrhœa, and the leading symptoms are swelling and pain in the breast and nipples before menstruation.

I wish to call special attention to the 45 cases marked mental anxiety as a cause for their development. I believe this to be an important point in connection with the development of cancer in the female breast. I believe it is very rare for cancer to present itself where everything passes pleasantly and prosperously in life, and cheerfulness at all times surrounds the individual. I find, in many cases, that the development of cancer dates at something which has caused mental anxiety, such as loss of property, loss of friends, long-continued sickness in families, giving rise to great mental solicitude and physical fatigue, etc., etc.

In addition to the above general features, I find that I have the record of 31 cases which began as benign tumors. In this class of cases the tumors had been carried from 10 to 30 years without inconvenience, but suddenly, from some cause, mental anxiety being a prominent cause, these tumors commenced to grow rapidly and assume a malignant form. One of these cases I now recall, in whom the tumor had existed from early womanhood. That lady was married when 20 years old, bore two children, her husband was prosperous in life, but suddenly distress in life came from reverse in fortune; and during these dark hours in her history, the tumor took on changes which developed into a rapidly advancing cancerous growth. The tumor was twice removed, but no permanent relief ensued.

Another case was one in which the patient carried the tumor 35 or 40 years without inconvenience, when suddenly the tumor took on new action, and the woman died from the effects of cancerous disease within six years from the time of the manifestation of this new action.

I have another group of cases which began as malignant. They are 15 in number. Of these cases, 14 were operated upon, and remained non-progressive for a long time. These are the cases which have afforded the greatest success in treatment. The following is a condensed statement of the history of these cases subsequent to the operation:—

1. Lived 12 years, and died with cancer of liver.
2. At the end of 27 years was in fair health.
3. Lived several years, and died from accidental injuries.
4. Patient well 22 years after operation. The patient had an issue made in the arm.
5. Lived 36 years, and died of other disease.
6. Patient well 5 years after operation.
7. Patient well 8 years after operation.
8. Patient well 10 years after operation.
9. Patient was operated upon in 1856, disease returned in 1873, but is not active.
10. Living and well 20 years after operation.
11. Living and well 3 years after operation.
12. Lived 7 years after first operation. This patient had the second operation.
13. Patient living in 1873, 10 years after first seen, and she had no operation.
14. Disease returned 2 years after operation, after great depression of spirits.

I have another group of cases which took on the sloughing process; those in which ulceration and sloughing took place rapidly and continued.

In this group are six cases. Of these, three were operated upon and three were not.

Of the cases in which no operation was performed—

1. Three years' duration, and patient lived 6 years after the sloughing commenced.
2. Nine years' duration, had been ulcerating 3 years, general health unimpaired.
3. Thirty-eight years' duration, and had been sloughing for 10 years.

Of the cases in which operation was performed—

1. Lived 5 years.

2. Operation 12 years ago, patient still living.

3. Patient well 10 years after operation.

This last case was indeed a most remarkable one. When first called to see the lady, I found her in what was apparently an exceedingly unfavorable condition. There was a large sloughing, cancerous mass upon the thorax, which filled the house with the most terribly disgusting odors which emanate from such sloughing masses. The glands in the axilla were not involved. There was no trouble above the clavicle. Operation was resorted to, simply to relieve the patient of the presence of this mass of death. There was no promise whatever of hope in the case. The operation was performed ten years ago, and the patient is still living and in good condition. These sloughing cases, when the surrounding parts are not involved, are to be regarded as favorable cases for an operation, rather than unfavorable. The fact of sloughing should have but little weight in deciding for or against the operation, but if anything, it is to be regarded as favorable.

Another group of cases of which I have taken note belongs to the so-called cystic variety.

Of these cases I have nine. Three of these cases were operated upon, but only one is now known to be living. In that case, cancer taint was present in the family. The patient is now living, ten years after the operation. What is meant by cystic cancer is, that they are tumors containing fluid, and the walls of these cysts or the walls of the tumor contain cancerous structure.

These cases are quite favorable for operation. The common cause for their occurrence is blows.

There is another class which has been denominated metastatic cancer. Properly speaking this term does not express what is understood by these cases. What is understood by the term is, that the disease has ceased its activity in one organ of the body and made its appearance in some other organ of the body. The organs most commonly affected in this way are the uterus and the mammæ.

One case I call to mind, as illustrating this change, occurred in a woman who had cancer of the breast at the age of 54, which subsided in its growth, and at the age of 76 it appeared in the uterus, and was there the immediate cause of the patient's death. I have seen two of these cases in which the transition of the disease was from the breast to the uterus, and one in which the transition was from the uterus to the breast. As a general rule, the constitutional disturbance in these cases is but little, and the patients are generally able to attend to the common duties of life apparently in a very comfortable condition. I will now say a few words with regard to the

FORMS OF CANCER.

Of these we have, speaking particularly of the breast—

First.—Those beginning as a tubercle in the skin.

Second.—Those beginning as an ulcer on the nipple. These begin very much as does the epithelial cancer of the lip.

Third.—Circumscribed. This form occurs more commonly in young persons, usually in fat persons, and is of rapid development. Sometimes this form involves one lobe, sometimes several lobes of the breast, and is something corresponding to the so-called encephaloid form.

Fourth.—The infiltrated form, or schirrus. This usually returns very soon after operation, very rapidly involves the lymphatics, and is seen very often in the skin. The disease makes its appearance in the skin in the form of small lenticular masses, sometimes called tubercles in the skin.

Fifth.—Cystic. This form is usually found in persons past the middle period of life.

Sixth.—The sloughing variety.

DIAGNOSIS.

Under this head I shall say but very little, for the manner of arriving at a positive diagnosis in these cases you are already familiar with.

I will simply remark, in passing, that the first form, the tubercle, is sometimes mistaken for syphilis. In the skin the appearance is very much like the epithelioma of the lip. The third form is very apt to be mistaken for *fungous hæmatodes*. It is perhaps as near to fungous hæmatodes as occurs in the breast. The fourth form is usually recognized by the pain and retraction of the nipple. The fifth form might raise the question of hydatids of the breast. Hydatids of the breast are exceedingly rare. I have never seen a case. When I find a smooth tumor in the breast filled with fluid, I regard it as being either of the encephaloid or cystic variety of the disease, and the diagnosis between these two is sometimes difficult. The presence or absence of fluctuation and the microscopical evidence are the most reliable.

PROGNOSIS.

First.—Prognosis is always unfavorable.

Second.—In tumors commencing benign, prognosis is most favorable.

Third.—In sloughy tumors prognosis more favorable after an operation.

Fourth.—In cystic tumors prognosis is more favorable for an operation, and removal of the tumor is advised.

Fifth.—In tumors which commence malignant the patients usually die within two years. Sometimes they continue a little longer. Yet of tumors commencing malignant I have 14 cases where the patients lived many years after amputation of the breast.

Sixth.—Prognosis may be affected somewhat by the method of treatment employed. Hence we have prognosis after compression, electrolysis, caustics and internal treatment, and these will be more particularly spoken of under the head of

TREATMENT.

With regard to treatment, again, I have not much to say. The methods employed may be embraced under the following heads:—

1. Amputation; 2. Caustic applications; 3. Compression; 4. Electrolysis; 5. Medication; 6. Moral treatment.

In the superficial cancer of the breast it is very well to use caustics. The same thing may be said with regard to cancers upon the face. The treatment with caustics in that region is good surgery. When the tumor is situated to any extent below the surface, the idea of caustics is bad surgery.

In two cases which have come under my observation, one died within four days, poisoned by the material used for the caustic application, and the other never reached her home alive.

With regard to the treatment by the use of compression, compressed sponges being usually employed, I have seen no good from it.

With regard to electrolysis, I have seen nothing in it yet to give me any confidence whatever in its use. I have nothing, however, to say against its use. There may be something of value in it, and it should be thoroughly tried. The day was when no knowledge was

had with regard to a successful method for the treatment of syphilis, but now we know that by the proper use of proper remedies, that disease can be cured, and charlatanism has left that field almost entirely. With regard to the internal treatment of cancer, I believe very much in it.

INTERNAL REMEDIES.

I believe that the day must come when something will be accomplished by the aid of internal remedies. Of the remedies now used, arsenic is perhaps the one which commands my confidence more than any other. There is another point in the treatment of cancer which I conceive to be of great importance, and that is the moral condition of the patient. I believe that it is impossible to cure our patients of cancer unless they are buoyed up by hope. Their surroundings should be of a character that will give them the greatest possible amount of comfort and happiness. Keep them in the sunlight of enjoyment, for darkness is the soil in which cancer flourishes.

THE QUESTION OF OPERATION.

Now we come to consider an important question: Do we accomplish any good by operations?

There are some who say, never operate. I think this opinion comes from the older members of the profession, who are inclined to look beyond the simple performance of the operation. The younger men, many of them, say operate. Upon this question I perhaps can do no better than to refer you to the opinions of two men who are among the most experienced of the profession, and who have had abundant facilities for making observations. I refer to Paget and Sibley, both of London.

Mr. Paget has shown, from his statistics, that the average length of life after an operation is 43 months, and that the average length of life without an operation is 55 months. Mr. Sibley has shown from his statistics that the average length of life after an operation is 53 months, and that the average length of life without an operation is 32¾ months. Here are the results of observations made by two distinguished authorities. I think all that I am justified in saying upon this point is, that every case must be taken by itself, looked at with all its surroundings, before a decision is given either for or against an operation.

The dangers in an operation are not great, if it is decided to perform it.

The following may be regarded as the indications, when attempting to decide upon any given case.

The older the patient, other things being equal, the more favorable for operation. If the cancer has extended so that we have secondary cancer, it is not surgical to operate. Therefore, when the axillary glands are involved, or when the skin is involved, and we have the local and constitutional disease both existing, I regard it as unfavorable for an operation. When the tumor is isolated, and there are no secondary manifestations, the conditions are favorable for an operation, and the sooner it is performed the better is the chance of preserving the life of the patient.

If a patient comes complaining of an irritable tumor of the breast, apparently connected with some disorder of menstruation, I should recommend, first, careful attention to the general health; and second, if found increasing in size, to remove it at once. There is another condition in which I would operate, and that is in the sloughing cases. Then it is done simply to make the patient more comfortable. Practically speaking, these cases do not belong to secondary cancer, and the operations are not unfavorable. But with all these cases we must use our own discretion. Select the cases, and give them the benefits and advantages of an operation.

Now a few words with regard to the hereditary character of cancer. In the cases which are found in my tables, the cancer taint was present in only 28 of the whole number, 236, whose history upon this point was obtained.

Within the last year I have been examining the Register's Bureau of Statistics in this city, and I find, in a period of time extending over about 70 weeks, there were only 532 deaths from cancer of all kinds and in all organs, while from pulmonary consumption alone there were 6,219 deaths, or as 1 to 11½. When compared with Bright's disease it is found that about three times as many die from that disease as from cancer. From the statistics of the Register's office for the last five years, the following proportion of Americans and foreigners who died of cancer are found:—

Americans, 68; foreigners, 154; negroes, 5. Savages rarely have the disease.

It would seem as if this disease of the breast is found in certain conditions of life, and that in these conditions it is upon the increase.

Without pursuing the discussion of this subject farther, I will close by saying, that the conclusions to which I have arrived are chiefly as follows:—

1. That the disease is not hereditary, or if so, only in a very limited degree.

2. That the disease begins as a local disease positively and purely. It becomes constitutional, just as syphilis begins a local disease and becomes constitutional.

3. That the disease occurs in those of vigorous health, instead of being connected with those conditions in which consumption occurs.

4. That cancerous parents may beget tuberculous offspring. That is, feeble constitutions arising from the effects of cancer will not beget cancer, but the diseases which follow in their line are tuberculous.

5. That the moral condition has a powerful influence on the development or the prevention of the development of cancer.

6. I am very forcibly struck by the parallelism and analogy existing between cancer and syphilis. Both begin by local irritation. Syphilis is inoculable, but cancer has not been proven so to be. In this respect they differ from each other. We have secondary syphilis, and we have secondary cancer. We have tertiary syphilis, but perhaps it cannot be said that we have tertiary cancer, unless it can be said that cancer is tertiary when it affects the bones, as it sometimes does.

In conclusion, I have to say, that we must not give this subject over as an unprofitable one for study and observation. Many diseases have run rampant which finally have been made to yield to treatment, and we may hope that the same thing may yet be accomplished with reference to cancer. The work of the histologist and pathologist may yet bring us into the light, and the day may come when we can say of cancer, as we now can say of syphilis, It can be cured.

DR. FORDYCE BARKER: Mr. President, my apology for departing from my usual rule with regard to surgical questions and operations is, that I may perhaps suggest some new fields for inquiry and observation, and perhaps bring out some new ideas in the course of the discussion by these suggestions. In regard to surgery, I am no expert. I do not pretend even to interfere with it, and it is therefore somewhat embarrassing to speak upon a subject which really belongs to the surgical department. I have, however, had occasion to study the subject of cancer with great interest, and perhaps with a large experience, and have, therefore, for many years

taken every pains to inform myself with regard to the progress of science, and have felt an interest in its bearing upon the question of its manifestation in the form in which it occurs secondarily, which in its most frequent form is in that of cancer of the breast.

In alluding to certain points in connection with the general subject, I will refer to one or two cases in connection with my own personal experience. Previous to my coming to this city, I was obliged to practise more or less in general surgery, and in the course of that time I was called upon to amputate the breast thirteen times, for what I supposed to be cancer of that organ. I have listened to the statistics from the gentleman who has already occupied your attention, with great interest and with great pleasure, because, in almost every point, while they have not corresponded with published statistics as we now have them, they have corresponded with my own. In four of these thirteen cases in which I operated for cancer of the breast, I know nothing of the results. Two of the thirteen cases are still living. All of the seven remaining cases died at periods varying from eighteen months to four years after the operation. A curious point in relation to them was, that the one who lived the longest—and this point I have not seen alluded to by any author—was the patient who was the oldest. That patient was 71 years of age when I operated, and had been afflicted with the disease some four or five months when I first saw her.

There was no apparent return of the disease until several months afterwards, and then there was probably a return of the disease to some internal organ. The point is this: whether the progress of pathological changes is not exactly in the same ratio as the metamorphosis of tissue in relation to age; whether in persons of advanced life we may not account in this way for the longer exemption from a fatal termination of the disease than when the disease occurs in those who are less advanced in age.

In 1858, although I had refused to have anything to do with general surgery, and confined my operations entirely to the obstetrical department, I had one patient who absolutely refused to permit any one else to operate upon her except myself. I accordingly removed her breast. The axillary glands were not involved, but the disease returned within a very few months, and the patient died eleven months after the operation.

The second case which I will refer to is a rather curious and rather exceptional one. It occurred in the year 1860, in a lady 43 years of age, and she had had the disease for several months when I first saw her, and in what I regarded as a very malignant form. That person, again, utterly refused to have an operation performed unless I would perform it myself, and I accordingly performed the operation, assisted by Dr. Foster Swift and Dr. Charles Phelps. In that case acupressure was employed, as I believe, for the first time in this city, and I was very much interested and pleased with the effect of acupressure in diminishing the amount of suppuration, which in that case was very slight indeed. That patient was operated upon in April, 1860. In my own belief, and in the belief of the microscopist, it was one of the most malignant forms of this disease of the breast, and yet the woman was alive in 1871. I simply mention this case as a small contribution to the number of successful operations, in the sense of curative, in cases of carcinoma of the breast. That specimen was afterwards presented at the New York Pathological Society, and the minutes of the meeting, which were published in the MEDICAL RECORD, represented it as being presented by Dr. Swift, and that the operation had been performed by Dr. Parker, which is a fair illustration of the uncertainty of surgical glory. With regard to statistics in determining whether a surgical operation shall be performed or not, most modern writers agree that operations do, in a certain proportion of cases which are judiciously selected, absolutely and positively prolong life, relieve suffering, and in some cases actually save life. The diametrical opposition which the statistics of some surgeons have to those of other surgeons who are equally well situated for making observations, may perhaps be explained in this way. One surgeon may be of the opinion that the disease is, primarily, always a local disease, and that its constitutional character is secondary to the local disease, which manifests itself differently in different cases. If this theory be correct, the proper method of treatment is the early extirpation of all suspicious-looking growths. On the other hand, other surgeons are of the opinion that the disease is a constitutional disease; that operations are deleterious in their effects, and should not be resorted to until all other means have failed to arrest its progress.

Again, some surgeons who have a greater fondness for operations than others, will remove a suspicious-looking growth much earlier than those surgeons who are less fond of operations, so that in some cases it may be that the delay in the performance of the operation has permitted the disease to make such extensive ravages upon the general system, that the operation, if performed at all, can only be performed with the expectation of giving some relief from distressing symptoms.

I began in early life as a most enthusiastic believer in the numerical system, regarding it as a most efficient means for advancing our knowledge of disease. But my experience has proven to me that statistics which ordinarily receive publication are extremely unreliable, and that they form a most unstable foundation upon which to predicate future action, whether it shall be for the formation of an opinion or made the basis of an operation. The statistics which the author of the paper has given us relative to the comparative frequency of cancer of the breast singularly accord with the statistics taken from the cancer hospitals in the city of London. Out of 7,800 cases which were under treatment in that city between the years of 1851 and 1861, 4,388 were cancer of the breast. This is from an entirely different sphere of observation, and yet the result of the observation shows that the female breast is one of the most favorite places in the human body for the development of this disease. It seems to have an elective affinity for the female breast, and perhaps in the progress of etiology and the science of physiology the reason for this elective affinity will be discovered.

The next point which I will notice in connection with the paper, is with regard to hereditary predisposition to the disease. I feel quite confident that I should never have read a paper which I did read, and which was published by the Academy of Medicine, upon "The Clinical Study of Cancer of the Uterus," had I not been thoroughly convinced upon this point. When I came to study my own observations, I found that some of them were so different from the published statements in published works that I felt doubtful about reading them without consultation with some of my personal friends. My own statistics with regard to hereditary predisposition to cancer of the uterus almost exactly correspond to the observations of the author of this paper with regard to hereditary predisposition to cancer of the female breast.

Another very interesting point to me was, that the

author of the paper has found so much larger proportion of cases of cancer of the breast where hereditary predisposition to cancer was entirely absent, but where hereditary predisposition to tubercles was present. The results of his observations upon this point give the same relations which are found in my own statistics, and I believe that the idea of hereditary predisposition to cancer should be denounced, and that this denunciation should be pronounced boldly by physicians.

There were a few points to which no allusions were made, and concerning which I wish to make some inquiry.

What is meant by a cancerous cachexia? In my earlier experience I was always looking for something like a cancerous cachexia, but my later experience and observation have taught me to become a non-believer, and I do not now believe at all in cancerous cachexia, as the term is commonly used. I have seen patients in the most advanced stages of cancer of the uterus, and in almost all its various phases, when they presented the appearance of robust health. The cachexia, when it does appear, is to my mind not a measure of the influence which has been produced by the simple presence of cancer in the system, but rather from associated lesions of the various organs of the body.

These are my observations with regard to cancer of the uterus, and I should like to know whether the same thing has been observed with regard to cancer of the breast.

Another point which was not alluded to, and concerning which I should be pleased to gain some information—and that is, with regard to the value of pain as a symptom in cancer. I am of the opinion that it is a symptom of uncertain value in aiding us in determining the existence or non-existence of cancer of the uterus. I have seen patients in the advanced stages of the disease without the slightest suspicion having been raised with reference to the presence of the disease by any pain. My own opinion is, that pain is simply a measure of the influence which the disease has had upon the contiguous and adjacent tissues. Cancer may occur so as to interfere with the functions of the uterus, or affect the subperitoneal tissues; and when these tissues are affected we are sure to have pain, and in some of these cases the pain is most atrocious. In other cases, where the disease presents more malignancy, the pain is sometimes very trivial. Whether the amount of pain is in relation to the amount of influence which the disease has upon the adjacent and contiguous tissues, I am not able to say, but simply throw it out as a question for consideration.

From time immemorial there has been an attempt made to destroy cancer by the use of every variety of known caustics. It has been a favorite resort of empiricism, and the most successful and perhaps the most lucrative of all charlatanism has been seen in the use of caustic agents to destroy the local manifestations of cancer. As a consequence of this, of course, a great majority of the surgical world have been satisfied with regard to the uselessness of such attempts. My own prejudices have always been against this method of treatment. I once attempted to make some observations respecting this plan of treatment as it was then adopted in St. Bartholomew's Hospital, and the whole process was so revolting that I did not pursue my investigations farther, and the result of my observations was not at all favorable.

In the year 1870, however, I was consulted by a lady who had a tumor in the breast which was very suspicious in its character, and which I watched for some weeks, when I regarded it as cancer, and urged upon my patient the importance of having it removed at once. But that patient utterly refused to have any cutting operation performed. At that time I had been studying up the subject somewhat, and among other works which I had read was Marsden's work upon the use of caustics in the treatment of cancer.

The same summer, while abroad, I visited the hospital in which Dr. Marsden had made his observations and applied his treatment, and saw the results of this treatment. I became so much interested in this plan of treatment, and was so highly pleased with it, that, upon my return, I recommended to my patient to submit to the treatment by the use of caustics. After some delay she consented. The form of cancer from which she was suffering was apparently of the most malignant type, and at the time I commenced the treatment the mass was about two inches in diameter, which is the extreme limit in size permissible to be treated by this method. In the course of eighteen days after the first application was made the mass came away, the process of cicatrization was completed in a short time, and there has not been the slightest appearance of return up to this time.

Another case to which I wish to make reference was in a patient who had had two sisters die with cancer of the breast, but her father and mother were still living at the time she consulted me. Not the slightest suspicion of cancer could be traced in either member of the family. One sister died some six or seven years ago from cancer of the breast. The other sister I was called to visit, and I found the axillary glands involved in the disease; there were evidences of what is known as the cancerous cachexia, and I called for counsel. Dr. Van Buren was called in consultation, but the case was regarded as utterly hopeless, and the patient died without an operation.

The third sister came under my observation for epithelioma of the uterus. That patient I operated upon in 1866, removing the cervix uteri by amputation. It is now seven years since the operation was performed, and she remains in the most perfect health.

About five years ago a lady consulted me with regard to a suspicious-looking tumor in her right breast. She was under my observation for about two years, and received treatment, but I never was of the opinion that the growth was malignant. At the end of two years it entirely disappeared. In Feb., 1873, that patient came back to me with a tumor in her left breast, which I regarded as true cancer of the breast. The tumor had been observed for more than a year, and when I saw it, the nature of the case seemed clear and positive. Its removal was recommended. Consultation was held to satisfy the patient with regard to its nature, the propriety of its removal, and if decided to remove it, how it should be removed. It was decided to remove the tumor by Marsden's treatment, and the treatment was accordingly commenced upon the first day of April. The amount of pain which the patient has suffered during the course of the treatment has been very insignificant indeed. She has been up most of the time, has been able to be out riding some of the time, and it is now eighteen days since the first application, and the slough is just ready to come away. The treatment of this case thus far has been very pleasant. What the result of the case may be it is impossible at present to decide.

I will now describe the plan of treatment as given by Dr. Marsden—the plan which he professes to have derived great success from, not only in a very considerable number of cases of cancer of the breast, but in the treatment of cancer of various parts of the body and even of cancer of the neck of the uterus.

This method of treatment is limited to cases in which the surface of the tumor does not extend over two (2) inches. Care must be taken that the paste is of sufficient consistence so as not to flow beyond the point to which it is applied. The general formula for the preparation of the caustic is to combine arsenious acid and mucilage in such quantities as to make a thick paste, and the formula commonly employed for this purpose is—

℞ Arsenious acid ..... ʒ ii
Mucilage ..... ʒ i

This paste is spread over the surface of the tumor, and two or three layers of lint spread over that. The lint absorbs all the surplus paste and protects from farther cauterization. The first application is left on for twenty-four or forty-eight hours, according to the extent of surface, and then removed by gently soaking it with warm water. After the old paste has been removed in this way, one judges from the impression made with regard to a farther application of the caustic. These applications are to be continued until a line of demarcation entirely surrounding the diseased structure is shown. Then the lint is soaked and removed, and a bread-and-water poultice applied, and changed every few hours. At first there is sometimes considerable inflammatory action set up, but the amount of pain is very inconsiderable as compared with the use of the knife, and the process of cicatrization is equally painless and satisfactory.

The shock to the system, as a rule, is very much less. The constitutional effect of the arsenic in this case was very slight, lasting only a few hours, and then passed away. Indeed, the moderate constitutional effect of arsenic I have long believed to have a certain positiveness in the treatment of cancer, in that it retards the proliferation of cancerous tissue. I mention these cases with the hope that it may contribute something to our knowledge of means by which we may meet this most terrific disease.

Dr. Sands: Mr. President, I shall merely call the attention of the Association to a few points in connection with the nature of cancer, the classification of cancer, the etiology of cancer, and the treatment of cancer. I am more and more convinced, until surgeons can have the aid of the pathologists, until they can work together in the investigation of malignant growths, that but little advance can be made with regard to the important subject of the therapeutics of cancer.

It is a fact with which we are all familiar, that at the present time various kinds of tumors are removed from the body, and the most varying opinions are expressed with regard to these cases. It is not long since that I removed a female breast, and one surgeon who was present expressed the opinion that it did not need any microscope to enable him to determine that it was cancerous; but a microscopical examination proved it to be a case of pure adenoma of the breast. I think that most surgeons, as well as pathologists, are willing to give an anatomical rather than clinical meaning to the term cancer. The term cancer can no longer be considered synonymous with malignancy. All cancerous tumors are malignant, it is true; but, on the other hand, there are many tumors which are malignant in their nature, to which the term cancer cannot be applied, because they have not the anatomy of the tumors described under that term. Among these we have the sarcomata, myxomata, epitheliomata, lymphomata and some others. If we are to make any progress in our investigation of this subject of tumors, each tumor should be examined immediately, with the view of determining the true anatomical elements of which it is made up.

With regard to the etiology of cancer, of course it is very interesting and important to determine whether cancer is, or is not, a local disease, whether the condition of the patient is always consequent upon a constitutional taint, or whether it is simply a symptom incident to a local morbid state. Different views have already been given upon this point; and in favor of its being a local disease primarily, there is a degree of plausibility, when we go a certain distance. The occurrence of cancer secondarily can be explained in this way, when it occurs in or near the original seat of the disease. But it does not so easily explain the occurrence of cancer in parts *remote* from the original seat of the disease. In illustration of this point is the following case:—

I had a patient under observation who was suffering from primary melanotic cancer of the lymphatic glands in the axilla. The diseased glands were removed, and the patient had a good recovery, but afterwards suffered from secondary cancer of the scalp. In the latter situation the disease was identical with that of the lymphatic glands in the axilla.

Another case illustrating the same point occurred in a person from whom I removed, about eighteen months ago, a small epithelioma of the face. Dr. Parker had removed a similar growth from the same situation before. This gentleman made a good recovery, but he now is suffering from epithelioma of the rectum, and is rapidly declining in health. I have still another case, where it is yet more difficult to explain the secondary occurrence of the disease upon the theory that cancerous tumors are transplanted. That case was seen in St. Luke's Hospital, and was a small tumor which occurred in the left ventricle of the larynx. The tumor was removed, and the patient made a good recovery. The disease was never reproduced in the original locality. The nature of the tumor was determined by microscopical examination to be cancerous. About eighteen months subsequent to the operation, the patient again entered the same hospital, and died twenty-two months after the original operation. When post-mortem was made, cancerous disease was found in the suprarenal capsules of both sides and one ureter. It would seem hardly possible to explain this case upon the theory that secondary cancers are always the result of primary cancers; and all these cases which I have mentioned go very much to show that cancer is a constitutional and not a local disease. Some surgeons go so far as to say that all tumors are expressions of constitutional disease. It is a well-known fact that, in some cases, benign tumors are so numerous, that their occurrence in such numbers can only be explained upon the theory that they are dependent upon some constitutional cause.

With regard to hereditary tendency of cancer, Dr. Parker's statistics are very gratifying; but there are some facts which I think show that in some cases at least cancer can be inherited. Cases like the following would seem to indicate that the disease has a hereditary tendency. In that case autopsy demonstrated that the gentleman died from cancer of the stomach, and not long afterwards a son of the same gentleman died with cancer of the same organ. I have already in mind several cases equally as well marked which it seems to me clearly indicate that the disease has a hereditary tendency. With regard to the treatment of the disease, I have had no experience with reference to the use of caustics. I have, however, a very decided conviction that the knife is the remedy

so far as there is a remedy in this disease. I do not believe that cancer is purely a local disease, yet if the knife can be applied early, and remove not only all the tissue of the disease, but the tissues about the disease, there may be a chance for a long interval before a return of the disease, in some cases.

The reasons why I would advocate the treatment of cancer by operation with the knife are chiefly threefold. One is, that the nature of the tumor cannot be determined prior to its removal.

Another reason is, that it now and then happens that a tumor of undoubted malignancy is cured by this surgical operation. Finally, I think an operation is justifiable often upon the ground of expediency. The chances are increased, if the patients die from cancerous disease, that they will die not from the external progress of the cancer, but that they will die from cancer of some of the internal organs. It is very well known that the return of the disease is very often upon the internal organs after the external disease has been removed, especially upon the lungs, and a death from cancer of the internal organs is not so painful and not absolutely loathsome, as when permitted to pursue its ordinary course externally.

Dr. Buck related the history of a case of cancer cured in the person of a lady about 40 years of age. The tumor was in the breast, and possessed all the characteristics of schirrus. It was removed, and more than 30 years after the operation it was ascertained that the patient was yet living and in comfortable health.

Another creditable case was in a lady who was very timid and despondent. One determining point in this case was, to perform an operation in order to infuse hope into the mind of the patient with regard to her recovery. She did make a favorable recovery, and subsequently returned to France. That lady was well for two years, and I was fully convinced that she would not have survived as long as that without the operation. In these days of anæsthetics, we may more readily advise an operation, for the patients are entitled to the respite of hope and comparative comfort which may be more than an equivalent for the fears and sufferings which they may experience without the operation.

With regard to operating for the removal of cancerous breasts in very corpulent persons, my experience has been very discouraging. I always dislike to perform an operation upon such patients, for in some cases which I have seen their life is drained away, as it were, from the wound.

Dr. Thompson: Mr. President, upon perusing the records of the New York Pathological Society, from 1845 to the present time, I find that 55 cases of carcinoma of the stomach have been reported by various surgeons, of which Dr. Parker reported four. The first case was reported by the President of this Association, Dec. 24, 1845.

Of those 55 cases, 23 were males, and 18 females. In fourteen cases the age of the patient was not reported. The average age of the cases reported was 9¼ years, which is a little above the average age of Dr. Parker's cases, which he reports at 48⅞ years.

Remarks by the President.—Gentlemen and Associates: We may well congratulate ourselves upon the results of this evening's investigations and discussion. We have become better acquainted with the real nature of cancer of the breast, and with those hygienic, therapeutic, and operative means which will not only delay its progress and mitigate its dire effects, but which may in a certain number of cases remove it entirely.

The time has now arrived when its treatment is removed from all empiricism, and the regular profession is in possession of means which will accomplish vastly more for the sufferer than any boasted specifics, or any irregular or mysterious practice.

We now know that cancer of the breast is generally a simple and local, not a constitutional or hereditary affection. It is a mere excessive growth and proliferation of normal epithelium. The first change is a large accumulation of epithelium within the ducts of the gland, just as in ordinary adenoma. But soon the walls of the ducts are not only invaded by epithelium, but this is also found outside the ducts amongst the inter- and peri-glandular connective tissues, which in their turn are thrown into a state of active proliferation, and become infiltrated with small round cells. Now, we have every reason to believe, from the vast experience of Weeden Cooke, that the muriate tincture of iron and other mineral astringents will arrest these processes in their incipiency, and much delay them in their advanced stages.

We also know that the epithelial cancer-cells are not cemented together by any intercellular substance, and that the lymphatics communicate with the alveoli in which the loose and detached cells are contained. The mineral astringents will prevent the absorption of the infecting cells into the lymphatics and the further contamination of the system.

If the disease be farther advanced, we have every reason to believe that Marsden's and Cooke's pastes will accomplish more than any caustic vaunted by quacks.

Finally, with proper precautions, it has been proved that the knife may often be used very successfully. There is an active and passive stage of cancer; and when the tumor is removed in its active condition the constitution resents this premature interference, and the disease returns rapidly after the operation. The local soothing measures recommended by Weeden Cooke should be used until the tumor has ceased to grow, and then exsection may be performed with safety.

Correspondence.

CARD FROM DR. REESE, OF PHILADELPHIA.

To the Editor of the Medical Record.

Sir,—In a couple of foot-notes to an article by Dr. Chew, in your issue of July 15, pp. 335, 338, some errors occur, which, although to be expected, perhaps, *under the circumstances*, had better be corrected. The writer says, in reference to diagnosticating the case in question as one of strychnia-poisoning solely by the *symptoms*,—that "the opinion expressed above was controverted by Dr. J. J. Reese, who stated in his testimony that 'there is not a single poison that can be determined exclusively by the symptoms; if you could not distinguish by the symptoms, there would be only one other means of distinguishing: that would be a chemical analysis of the food.'"

The error here consists in not quoting my testimony correctly. It is unquestionably my opinion, and so I have always held and taught, that, in medico-legal cases, "there is no single poison that can be determined exclusively by the symptoms;" (then I added), "for if so, there would be no necessity for making a chemical analysis." Then I went on to testify, that in a case of suspected poisoning *which did not prove fatal*, the only certain method of proving the fact was—not only "by a chemical analysis of the food,"

but also, "of the excreta." I particularly emphasized the *urine* in cases of suspected *mineral* (tartar-emetic) poison. The clever *ruse* here consists in making me say that the only alternative in determining a poison, after a failure of the symptoms, was "a chemical analysis of the *food*;" whereas the real point of the case was that, *when the patient recovered*, this "analysis of the food," together with a chemical examination of the excreta, and especially of the urine, was the true alternative.

Now, this was precisely the condition of things in the case on trial. A sick gentleman was alleged to have been poisoned by several different articles—among them tartar-emetic. The State's "experts" relied *exclusively* upon the "symptoms," in order to sustain the theory of poisoning. *No analysis was made of the food or medicines administered; nor of the matters vomited or purged; nor of the urine.* Under such circumstances, I am free to say that the allegation of poisoning could not be *proved*.

Then comes in the second error. This writer endeavors to show, though not with the effrontery of his friend "the Attorney-General of Maryland," that in giving the above "opinion" on the witness-stand, *I was going back upon myself*, inasmuch as, in a certain case of strychnia-poisoning in which I was concerned, some years ago (the results of which were published in the *Am. Jour. of Med. Sci.*, Oct., 1861), I had testified that the chemical proof was not indispensable *in every case*, in order to prove the administration of poison, and for various reasons. In this instance, a careful analysis failed to discover the poison after death; and I stated, in the words of this writer,—"yet, all the moral circumstances connected with this case" (such as proof of purchase of strychnia, the conduct of the prisoner towards his wife—the victim—his subsequent actions; together with the violence of the seizure, the death, the post-mortem, etc.), "*as well as the symptoms*, clearly pointed to poisoning by strychnia." This is precisely my opinion still,—an opinion perfectly in accordance with what I have previously stated. While I have never said or believed that, *in every case*, the chemical detection of the poison was absolutely essential to establish the proof, I do hold that where this very important factor is absent—either through ignorance or negligence in a non-fatal case, or from some unavoidable contingency where the case has terminated fatally,—the other methods of proof should be made out so clearly and satisfactorily that there could be no possible mistake.

One other error, or rather *blunder*, of your correspondent occurs in the last foot-note. While laboring to account for Dr. Taylor's unfortunate difference of opinion from his own and that of his colleagues, he slyly suggests *an explanation* as to "how Dr. Taylor may have received a one-sided account of the testimony in the trial," viz.: "the fact that the new edition of his work on Medical Jurisprudence is edited, in America, by Dr. J. J. Reese"! Here the *blunder* consists in trying to reconcile the fact that "Dr. Taylor certainly received a report of the first trial of Mrs. Wharton,"—in which everything was made perfectly clear and distinct,—with the other ugly fact that, although arrived at mature age, and possessing some distinction as an author, he should presume to exercise his own judgment, and actually have the weakness to come to a conclusion different from that held by Dr. Chew and his colleagues! But there is still a loophole left for this simple-minded, immature Dr. Taylor: "a third supposition,"—that, "having read the trial, he had forgotten or overlooked the fact referred to;" and this, be it remembered, is affirmed of a distinguished author who deliberately prints the objectionable *opinion* in the "new edition" of his great work on "The Principles and Practice of Medical Jurisprudence,"—of which work Dr. Reese is *not* the American editor.

Your readers will observe that I confine myself exclusively to noticing the errors in the *foot-notes* of your correspondent's article. If I deemed it at all worth while to reply to those connected with myself personally, in his text, I would simply refer them to my original "Review of the Wharton Trial," as containing, as Paddy might say, *my reply in advance*.

Thanking you for your courtesy, I am,

Very respectfully yours,

JOHN J. REESE, M.D.

1840 GREEN STREET, PHILADELPHIA.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from August 5, 1873, to August 18, 1873.

SIMPSON, JNO., Surgeon.—Granted leave of absence for three months on Surgeon's Certificate of Disability. S. O. 163, A. G. O., August 9, 1873.

SIMONS, JAS., Surgeon.—Leave of absence extended thirty days. S. O. 45, Division of the South, August 5, 1873.

ALEXANDER, C. T., Surgeon.—Granted leave of absence for thirty days. S. O. 162, A. G. O., August 8, 1873.

WOLVERTON, W. D., Assistant-Surgeon.—Relieved from duty in Department of Dakota, to proceed to New York City, and report by letter, upon his arrival there, to the Surgeon-General. S. O. 158, A. G. O., August 2, 1873.

TILTON, H. R., Assistant-Surgeon.—Granted leave of absence for thirty days, to take effect September 1, 1873. S. O. 151, Department of the East, August 11, 1873.

SMART, CHAS., Assistant-Surgeon.—Assigned to duty at Fort Bridger, Wy. Ty. S. O. 129, Department of the Platte, August 5, 1873.

LAUDERDALE, J. V., Assistant-Surgeon.—Assigned to temporary duty at Fort Wadsworth, N. Y. H., during absence of Assistant-Surgeon Tilton. S. O. 151, c. s., Department of the East.

CLEARY, P. J. A., Assistant-Surgeon.—Relieved from duty in Department of Texas, to proceed to New York City, and report by letter, upon his arrival there, to the Surgeon-General. S. O. 160, A. G. O., August 6, 1873.

WIGGIN, A. W., Assistant-Surgeon.—Granted leave of absence for thirty days, with permission to leave limits of Department, and apply for an extension of thirty days. S. O. 95, Department of the Columbia, July 28, 1873.

DEATH OF DR. HENRY S. HEWIT.—It is our painful duty to announce the sudden death of our esteemed friend Dr. H. S. HEWIT, which occurred August 19th. We shall give a sketch of his life in our next.

BELLEVUE HOSPITAL MEDICAL COLLEGE.—Dr. W. A. Hammond has resigned his professorship. Dr. Janeway is to give the course on Materia Medica and Therapeutics, in addition to the course on Pathological Anatomy. The diseases of the nervous system will be treated of by the Professor of the Principles and Practice of Medicine.

Original Lectures.

A CLINICAL LECTURE UPON SORE NIPPLES AND MAMMARY ABSCESS.

By FORDYCE BARKER, M.D.,

CLINICAL PROFESSOR OF MIDWIFERY AND DISEASES OF WOMEN IN BELLEVUE HOSPITAL MEDICAL COLLEGE.

(*Phonographically reported for* THE MEDICAL RECORD.)

GENTLEMEN:—All of you may obtain a great reputation by performing some important surgical operation; but the unfortunate fact with regard to such reputations is, that they are not easily secured, because the opportunities only rarely present themselves for such operations; and, indeed, you may pass a lifetime in an active practice without once being called upon to perform an ordinary amputation of the thigh or arm.

Your reputation, however, may be very much jeopardized, if not ruined, if you are not able to treat successfully a case of sore nipples or mammary abscess, and these are the cases you will see perhaps every week in your life. In these cases the responsibility will always fall upon the doctor, and unless he is familiar with their management the weight may prove more than he can well bear.

In text-books in general there is a sad deficiency with regard to description of the different forms of these troubles, the proper management, and the exact and appropriate treatment for each definite form.

Various articles, with which every practitioner is more or less familiar, are recommended for their cure, without any definite rules being laid down, where one or another will be applicable. These remarks apply with equal force to both sore nipples and mammary abscess. The forms of sore nipples are these: First, inflammation. This generally occurs in those cases where the nipple is naturally contracted, or in those cases, which are not at all infrequent, where the nipple is almost completely absent.

The child when placed at the breast has great difficulty in getting hold of the nipple, especially when the breast is distended, which renders the nipple still more retracted; it pulls away at it, and as a result of the irritation to the breast an inflammation of the nipple takes place. This inflammation of the nipple may by propagation pass into the lacteal ducts, and we may have mammary abscess as a consequence of that.

Second, fissure or erosion of the nipple. These fissures of the nipple are of two forms. One comes from inflammation of the nipple, but there is another form which exists just at the base of the nipple, and gives the most intense pain and suffering, the patient, perhaps, bursting out into a profuse perspiration as the child is placed at the breast.

The next form of sore nipple is the ulceration which I have referred to in connection with the case now before you. The surface of the nipple is red, and denuded of its cuticle; the nipple is very much retracted, and in this case there is a fissure at the top. The pain is very intense, and it may be that the woman experiences as much suffering from this as from anything else during the entire puerperal period. The process does not generally confine itself to the nipple alone, but the areolar tissue around the nipple becomes inflamed, and as the inflammation becomes more intense, perhaps one-half or two-thirds of the nipple becomes entirely destroyed in the process. These three forms are distinctly and easily recognized; and now a few words with regard to the treatment of these different forms.

In the first place, for drawing the nipple out. There is a great difference among authors as regards the propriety of applying the child to the breast immediately after the confinement has been completed, and also as to the proper time when it should be done. Some writers recommend that it should be done as soon as possible after delivery. The reason given for this early application of the child to the breast is, that the child by nursing stimulates the breasts, which excites reflex action in the uterus, thereby producing uterine contraction, which renders the woman less liable to post-partum hemorrhage.

With reference to that point, I can say I do not consider it to be sound practice. I adopted it for some years, but have given it up entirely. You can procure uterine contraction, which will place the woman out of all danger from post-partum hemorrhage, by means which are far less exhausting for the patient than the resort to the troublesome efforts of the child at nursing. I now advise to get the woman completely restored after the fatigue of confinement before applying the child to the nipple.

The first stage after parturition is that of exhaustion. The whole effort of the system has been used to accomplish this result, and so complete is the exhaustion, that it is very commonly manifested by nervous chills. If the woman is permitted to get a few hours of sleep, her exhausted nerve-power will be restored, and *then* is the time to direct that the child should be placed to the breast.

The main reason for this is, the breast is not now distended, and the nipple is easier drawn out. The traction excites the more rapid secretion from the breast, and the first secretions from the breast are of great benefit to the child as a laxative, being its first proper food. It is then that the nipple can be more readily grasped by the child, and properly formed. If, however, you wait until the secretion of milk has taken place, and the breast has become distended, before applying the child, the distension itself causes obstruction to a free flow through the ducts, and the nipple and breast may become a very great source of irritation.

There are some cases in which the nipple congenitally is so short that the child cannot get hold, and it must be drawn out by some mechanical appliance. The most common method resorted to for accomplishing this is the old-fashioned application of a bottle, which has been filled with hot water and emptied, and the use of the breast-pump.

A few words with regard to breast-pumps. Most of them are constructed upon principles utterly devoid of common sense. Most of them have so small an opening in the part applied to the breast that the nipple is constricted, and the milk cannot flow at all after the first two or three exhaustions of the instrument.

The essential requisite for an efficient breast-pump is a large bell-shaped extremity, so that the nipple is not at all constricted by the narrow diameter which is applied over it.

The pump which meets the indications most satisfactorily, and which has come to my notice, is what is called Mattson's breast-pump, and it is a most excellent instrument.

With regard to treatment of the sore nipples, the following are the rules which chiefly govern me in the management of these cases: If the nipple is inflamed, apply a poultice until the inflammation is subdued, and then apply a solution of nitrate of lead in glycerine, ten grains to the ounce. This is also the most com-

plete and perfect prophylactic against the occurrence of sore nipple that I know of. This solution should be applied immediately after nursing, having first washed the nipple perfectly clean.

The application must also be washed off every time before the child nurses. It is almost a specific, when properly used, against excoriations and ulcerations. If the tendency is quite strong to sore nipples, the solution may be used of the strength of 15 grs. to the ounce, or even ʒi; but as a rule the 10 gr. solution is sufficient. Next, where the cuticle is denuded, and we have a raw surface, or it becomes so irritated that there is a tendency to an abrasion, the indication is to form an artificial cuticle, which will entirely protect the parts, and yet permit the milk to pass through it.

For this purpose collodion has been extensively used. The objection to the collodion is this, that it contracts as it dries, and thus itself becomes a source of superficial irritation and discomfort, and does not readily permit the flow of the milk. I have used for this purpose, and with the most satisfactory results, the Compound Tinc. of Benzoin. Wipe the nipple dry after the child has nursed, and with a camel's-hair brush apply four or five coats of this tincture.

The first application may produce some burning, but when once applied this will be entirely overlooked, and the woman will desire its reapplication. This forms a most excellent artificial cuticle, and at the same time permits the flow of milk without obstruction. Cicatrization will take place under this coating, and the patient will thank you for the benefit received. When the fissure is at the base of the nipple, very small it may be, but accompanied by the most severe and agonizing pain, the most satisfactory method of management is to touch the fissure with a fine point of nitrate of silver, and apply over this the Comp. Tinct. of Benzoin as before.

When the inflammation and ulceration have gone on to such an extent as to destroy the surface of the nipple, and there is danger of the inflammation extending back to the mammary gland, do not allow your patient to torture herself by allowing the child to nurse. Remove the child entirely, and empty the breasts by the breast-pump or by rubbing.

I then use as an application in these cases the following:

R. Rose Ointment	ʒi.
Carb. Magnesia	ʒi.
Calomel, grs	xxx.
M.	

These ingredients should be rubbed together very carefully, and it should be freshly prepared, perhaps every twenty-four or thirty-six hours. If the child is permitted to nurse at all, it should be done entirely through an artificial shield, and the best shield is one made of the cow's teat. The objection to the india-rubber shield is, that there is an offensive odor emitted from them, and they are very apt to make the child's mouth sore.

If, however, it becomes necessary to use the shields which are in the market, in selecting them get a broad base, what is called the L-shaped glass, in the same manner as in the selection of the breast-pump. The ordinary nipple-shields seen in the stores are simply abominable.

The next subject which is immediately connected with the one just under consideration, is a very troublesome complaint, viz.: mammary abscess. This woman who is now before you has been confined about one month, yet it is only three days ago that she began to complain of her breast, and since that time suppuration has taken place.

This is an important point, and one which is often overlooked in the books. It will be seen that the whole surface of the gland about the nipple is inflamed, the woman had a chill, has a fever, &c., &c. This is probably one of those cases which is the effect of the peculiar poison which develops puerperal fever in some cases, puerperal peritonitis in others, and mammary abscess in others. There are three different forms of mammary abscess. First, inflammation of the cellular tissue surrounding the nipple and external to the breast; second, inflammation of the substance of the gland itself; third, inflammation of the areolar tissue between the gland and the thorax. The first form may result from irritation, and is nothing more than a pure simple phlegmon, requiring the same treatment. It usually terminates rapidly, is not attended with the constitutional shock which accompanies glandular inflammation, and is to be treated the same as phlegmonous inflammation elsewhere. As soon as fluctuation is detected, the question may arise whether the escape of the pus should be permitted to take place spontaneously, or whether the breast should be opened by the surgeon. The amount of constitutional disturbance is to decide that, and if it is decided to open it, the incision should not be made within the areola, because the retraction which is incident to cicatrization will spoil the nipple for future use. The sooner this discharge takes place, the sooner the healing process will be completed, and the breast restored to a healthy condition.

In case the gland itself becomes inflamed, it is attended with more constitutional disturbance. There is headache, chills, fever, full pulse, high temperature, etc., and yet even greater constitutional disturbance if there is a tendency to the formation of multiple abscesses. If these cases are seen at a very early period of their formation, when there is great tenderness, high temperature, fever, etc., pulse 108, perhaps 120, it may be well to try to abort the inflammation. For this purpose I give the woman ten grains of Dovers powder, with an alkali, paint over the surface of the gland with Tr. Iodine, and cover it with a warm poultice or cotton padding covered with oil-silk. Empty the breast with a pump, and in most cases you will arrest the whole thing at once.

The trouble is, that the patient does not see the physician until this period has passed, and then suppuration must be favored by poultices. Internally the patient must be ordered as full doses of quinine as she will tolerate.

As soon as fluctuation is detected, open the breast at the lowest point, because otherwise pus will burrow between the tissues of the gland, become a source of irritation, and produce another inflammation.

The third form is called the sub-glandular, and is attended with still greater constitutional disturbance. It has none of the external redness present in the other forms, because it is situated between the gland and the thorax.

The gland sometimes becomes very prominent. The inflammation is attended with intense, severe pain, rigors, chills, and yet upon the external surface there may be no special intimation of its existence. The most significant symptoms are that the patient complains of difficulty of breathing on account of pain produced, and, when present, the prominence of the gland. These cases are generally exceedingly tedious, and sometimes dangerous, because the inflammation is so deep-seated that the pus between the gland and the thorax burrows about, forming sinuses and extensive fistulous tracts, which may be exceedingly troublesome and exhausting from the profuse discharge and constitutional irritation which is produced.

My hour has already passed beyond its limits, and further remarks upon this subject must be postponed until some future date.

Original Communications.

ILLUSTRATIONS OF POTT'S DISEASE OF THE SPINE IN THE CERVICAL REGION,

AND OF ITS SUCCESSFUL TREATMENT BY DR. CHARLES FAYETTE TAYLOR'S METHOD.

By THOMAS M. L. CHRYSTIE, M.D.,

SURGEON TO THE NEW YORK ORTHOPÆDIC DISPENSARY, N. Y.

THE Case-book of the Orthopædic Dispensary shows that, from April 1, 1869, to Feb. 1, 1873, there were admitted to the dispensary 280 cases of Pott's disease; and further, that 62 of these—over twenty-two per cent.—had the disease in the cervical region. It will thus be seen that the cervical vertebræ are as liable to injury and disease as any division of the spinal column. It is also true in our experience that disease in this location, when left without interference, runs a more rapid course and more frequently has a fatal termination than is the case when the lower divisions are attacked—a statement which is well supported by the fact that we seldom meet on the streets with examples of the characteristic deformity which is produced by disease in the cervical region, although we have shown that this division is as frequently attacked as any other.

Our experience does not lead us to consider one portion of the spinal column more likely to be exempt from disease than another, but the prognosis is much modified by the location of the affected part. Disease of the cervical vertebræ, when left to unrestricted progress, is considered most likely to terminate fatally. Disease in the lumbar and lower dorsal region is also considered more unfavorable, when left to itself, than disease in the middle dorsal region. The latter is rarely fatal, and even when allowed to progress without interference will generally terminate favorably for the patient's life. There will be deformity, of course; but the shortening of the stature is partly compensated for, so far as the lungs are concerned, by lateral and antero-posterior expansion of the thorax.

The reason why disease in the middle dorsal region progresses more slowly, and generally terminates in recovery, is undoubtedly owing to the fact that the ribs and their attachments act as constant supports, preventing, to a certain and important extent, the weight of the body above from pressing with its full force on the diseased parts. The pressure from above gradually expands the chest, and the upper portion of the spinal column is thus let slowly down without the same amount of injury to the diseased section or the shock to the whole system as would exist were the disease in the lumbar or cervical regions, which have no such natural protection. But, on the other hand, when mechanical interference is attempted, we find that the cervical and lumbar regions are much more amenable to treatment than the dorsal. The very conditions—such as the absence of support furnished by the ribs to the dorsal vertebræ, which make the progress of disease in the cervical and lumbar vertebræ more rapid and dangerous—render it also much more amenable to successful mechanical interference. The dorsal vertebræ are always subject to the constant motion of respiration, while their costal attachments, which afford a natural protection to the diseased bodies, are equally instrumental in preventing the establishment of complete relief from pressure and motion by artificial means. Leaving the consideration of disease of the lumbar vertebræ, which has many interesting peculiarities, to a future time, the object of the present writing is to call attention to the successful treatment of disease of the cervical vertebræ. I am led to believe, by many inquiries and remarks, that physicians in general have no recognition of the frequency of Pott's disease in the cervical region.* I have already shown how frequently it is to be met with, and I hope to show that in this locality the disease is even more amenable to treatment than it is in any other, and more uniform success is obtainable. By "uniform success" I do not mean the removal of an anchylosed kyphosis; for anchylosis, when the disease has gone so far as to destroy the bodies of the vertebræ, is but another word for cure, and no one would propose to interfere with the conservative results of this natural process. But need a case proceed so far as to render the best result of treatment to be an arrest of the disease and anchylosis, with no further deformity than that occasioned before the treatment was commenced? This question will be answered when we consider the early diagnosis of the disease. Give the inflamed part rest (not seeming or partial, but complete and long continued), and if the constitution be not too depraved, either in consequence of hereditary tendency or because the disease has been neglected too long, the inflammation will subside and the patient get well. The patient will not recover merely because he has an instrument on his back; but he will recover, all other things being equal, if in the first stage the treatment is successful in giving absolute rest to the injured parts, and this rest is maintained for a sufficient length of time. Here it may be remarked that we must not be content with simply applying an instrument. We must constantly watch him and "treat" the disease by means of the instrument. This constant attention to the mechanical treatment is absolutely necessary to secure the object of the apparatus.

Cases have recovered in the recumbent position; but I think it will be found on investigation that these were very recent and very favorable cases in which a strong tendency to recovery was united to more than ordinary ability to bear confinement. So, too, there are many cures by many instruments when in judicious, *patient* hands. The only virtue claimed for Dr. Taylor's method is that it seeks—first by a very perfect mechanical appliance contrived for the purpose of carrying out a well-defined principle of treatment, and secondly by patient, persevering watching and

* Rokitansky says: "The most common situation of the disease is the lower dorsal and upper lumbar regions, though it does occur also in the cervical and the lowest part of the spine." Philadelphia, 1855, vol. iii., p. 181. Prof. S. D. Gross (p. 147, Gross's Surgery—same): "It is met more common in the dorsal region than in either the cervical or lumbar, the second, third, and fourth pieces being especially prone to suffer. It is generally stated that the lumbar vertebræ are more frequently affected than the cervical, but this I believe to be an error." Dr. Henry G. Davis also says that "the disease is much more common in the dorsal region than in either the cervical or lumbar." Several other authorities consulted say nothing in regard to the relative frequency of the disease in different regions. It should be remembered that Rokitansky's opinion is derived from examination of cases *dying in hospital*, and is therefore, in reference to this question, less trustworthy than statistics derived from observing living cases. Our private cases, which are very carefully recorded, show even less difference in location of vertebral disease than do those of the Orthopædic Dispensary. I think the number here reported sufficient to establish that there is very little selection of vertebræ which are more likely to be affected by disease.

adjustment of it—to actually insure the needed rest for the injured vertebræ; and that in carrying out this method the confinement to the recumbent position, except for a short time in acute cases, is unnecessary. Where the recumbent position, without the spinal assistant of Dr. Taylor, is unable to afford relief to the diseased vertebræ, we are able to give the required support with entire success. To those cases which are either incurable from the start—such as occur in highly strumous constitutions—as well as those which have passed beyond the curable stage, we are able to offer a sure amelioration of suffering, a probable arrest of the destructive process, and, to many, a positive diminution of deformity. The treatment, then, consists of simply answering the prime indication presented in all inflammations, no matter where situated—in giving the inflamed part rest.

How important it is, then, that an early diagnosis be made, and the treatment begun before the morbid process has advanced to the production of irreparable mischief. The early symptoms of Pott's disease of the spine, which Dr. Taylor was the first to point out in complete form to the profession nearly ten years ago,* have proved of the greatest importance in determining the existence of that disease long before it could have been detected by any physical signs. Pain nearly always characterizes the early stages of cervical disease. It may be located in the abdomen, but more frequently extends up the back of the neck to the base of the skull. A steady pain, often severe in character, in the neck, extending to the shoulder and down the arm, is quite common. A disposition to stammer is sometimes noticed. This and paroxysms of an asthmatic character existed very marked in one case of cervical disease where there could be no mistake in the diagnosis; for there was a sharp projection of the fourth and fifth cervical spinous processes, and the "asthma" and stammering disappeared after a short period of treatment. The origin and course of the spinal accessory nerve, and its connection with the pneumogastric, suggest the cause of these symptoms. They had existed for nearly a year before the projection was noticed, but their cause was not suspected. Hiccoughs, followed by pain, are sometimes noticed as a prominent symptom, though it is more often met with when the disease is at the dorsal vertebræ. When the disease is at the seventh cervical or first dorsal vertebræ, the respiration may be somewhat short and jerky, owing to an instinctive dread of a too full and rapid expansion of the chest, which might produce a motion at the vertebræ, and pain. The same instinctive dread of motion causes the patient to hold the head fixed at one position; and should this position happen to be with the head rotated and flexed, it should not be mistaken for ordinary torticollis. Too much stress must not be laid on the inability to find the exact point of disease, or a commencing projection in the neck, which of course would not be apparent until a certain amount of tissue had been destroyed by the disease. The natural lordosis in the neck and the prominence of the muscles, together with the short and nearly vertical cervical processes, make it difficult to reach or to see the spinous processes of the affected vertebræ, except in the lower portion, where the normal but variable prominence of the seventh spinous process enters as an uncertain factor. But a little study of the movements and attitude of the patient, which are among the most valuable indications of the presence of disease, together with the physical signs which have already been enumerated, are, in most instances, sufficient for a clear diagnosis long before the vertebral articulation is destroyed. Let no one fail to carefully watch the patient's attitude and movements when disease of the cervical vertebræ is suspected. The carrying of the head thrown backward; the sideways posture often mistaken for lateral curvature; the supporting of the head by the hands and the leaning heavily against whatever gives support, or a simple tendency to any or all of these, are among the more prominent physical signs of commencing cervical disease. In one child, three years old, thickset and well covered with adipose, the lowering of one shoulder was the only observable malposition. Several careful examinations, made by watching the child while she moved about the room naked, revealed that the real seat of distortion was a tilting of the neck to one side, and that the compensating lateral deviation of the spine, made in order to retain the head in a vertical position, caused the shoulder to droop. It was impossible to obtain the child's co-operation in making a diagnosis, and hence the above procedure. Efficient antero-posterior support furnished to the cervical vertebræ removed the drooping of the shoulder in a few months. The child remained under our observation for six or eight months after the spinal assistant was removed, and was perfectly well during that time.

There can be no deviation from the natural position in one part of the column without the production of corresponding changes in other portions. The slightest dropping forward of the head, from a loss of substance in the bodies of the cervical vertebræ or the intervertebral bodies, is instantly followed by a depression of the spinal curve between the shoulders and a flattening of the back at this point. This is caused by a straightening of the dorsal curve of the spine, and is a sure indication of loss of substance in the bodies or intervertebral cartilages of the upper cervical vertebræ. This change is seldom symmetrical, and there is generally some slight lateral deviation of the dorsal spine, which, I repeat, must not be confounded with lateral curvature of the spine.

It is no uncommon event for two points of disease, separated more or less widely, to develop in the spinal column. Both may be developed at the same time; or, what is more commonly the case, there may be an interval in the setting up of the morbid processes at the different points; and, generally, the cause of the second is of a similar nature to that of the first, when it cannot be traced to the same cause. In cervical disease it is so common for another point of disease to follow lower down, that we are now on the lookout for it. This second development is always in the same place, about the last dorsal and first lumbar vertebra, and occurs in perhaps forty or fifty per cent. of all cases of cervical disease—a serious complication if timely precautions are not taken. There is no doubt in my mind but that it is due to the peculiar attitude the patient is forced to assume when the cervical vertebræ are the seat of disease. This attitude is shown at Fig. 1. The vertebral or intervertebral bodies are kept constantly impinging on each other, and the constant pressure produces their partial absorption, and ultimately becomes equivalent to a traumatic cause of their disease. The head may be thrown back or it may drop forward, but in either case the trunk inclines forward in such a manner as to make a bend in a posterior direction, at a certain point below the disease, at which point there is a great increase of pressure. This is especially the case when no appropriate antero-posterior support is provided, and the tendency of the lumbar part of the spine to bulge backwards is not always fully prevented even by a well-arranged instrument; although it may prevent

* See *Transactions N. Y. State Medical Society*, for Feb., 1863.

this second point from becoming affected with actual disease. But as the disease at the cervical region subsides, the spinal muscles regain their strength sufficiently to give the spinal column its natural contour. Feeble children in arms, before one year old, often have this disease produced in the lower dorsal region, in consequence of being habitually kept in the sitting position. The muscles of the back are not sufficient to sustain the child, and hence the whole force of the upper portion of the trunk impinges on two or three vertebræ in the centre of the spinal column. We have many cases of Pott's disease in infants, and the disease is always in the same place, and often we are able to trace its causation to the fact that the patient has been kept in the sitting position very constantly without proper support by the hands.

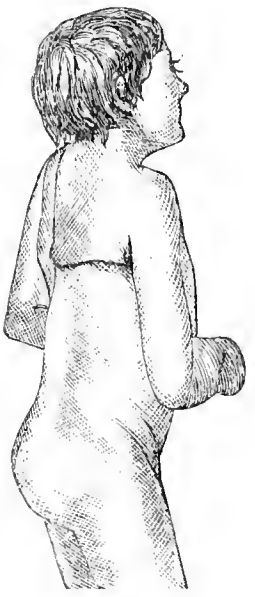

Fig. 1.

In a later stage of disease of the cervical vertebræ paralysis is a frequent complication—relatively more frequent than when the disease is situated in the dorsal or lumbar region. Perhaps the more rapid progress which cervical disease is apt to make, and its more frequent fatal termination, may be due to the fact that the arrangement for the many motions of the head affords less natural protection in case of injury than is the case with the dorsal and even with the lumbar vertebræ. At any rate, we know that disease in cervical vertebræ, when the vertebræ are not protected, is peculiarly liable to the formation of abscess, and paralysis ensues as a consequence. The holding of the hand to the chin, which the patient is apt to practise, is a poor substitute for adequate support, though an important diagnostic sign. The shortening of the neck and the resting of the occiput between the shoulders is frequently seen in children, and are important symptoms, especially in very young children, when there is so much adipose as to increase the difficulties of physical examination.

I now pass to the consideration of the means of treatment and the results as exemplified in practice.

The apparatus used for protecting the vertebræ, when they are diseased in the cervical region, is figured in the accompanying engraving (Fig. 2). It consists of a hip-band (D), two uprights, having each near the top a diverging strip fitting and resting on the trapezius muscle close to the neck, and from the end

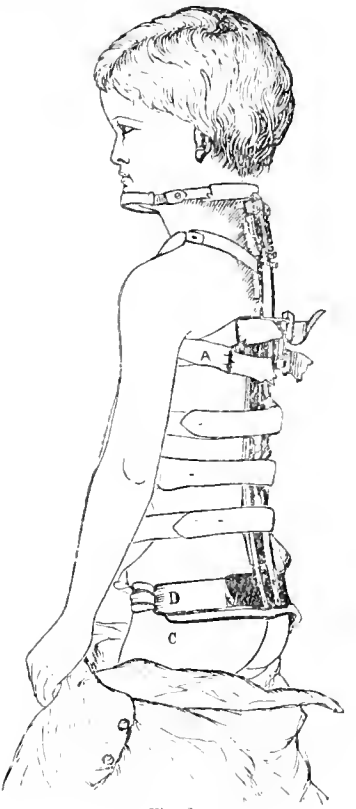

Fig. 2.

are straps (A A) which pass under the arm and are buckled to the uprights, as shown. The instrument is held firmly against the patient's body by the "apron," which is seen with straps fastening around the whole trunk. The upper strap of the apron is fastened to a horizontal bar of steel extending across the patient's back, this not confining the respiratory movements of the chest to such a degree as might be the case if it passed wholly around the body. At the top of the upright is fastened the 'pivot" which holds the "head-piece," and on which the latter rests. This "head-piece" is of steel, opens with a joint, and is fastened together with a clasp (Fig. 3). The chin

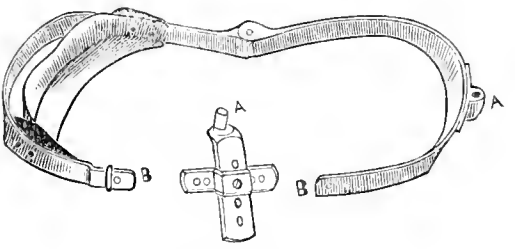

Fig. 3.

rests on a floor of padded leather covered with velvet, but neither the occiput nor the back of the neck necessarily touches the instrument.

The mechanical action is entirely antero-posterior. There is no vertical support. In this respect Dr. Taylor's instrument is a radical innovation on all previous

efforts to support the spinal column by mechanical means.* The antero-posterior action of the instrument—imitating to a certain extent (and to that extent being supplementary to) the spinal column—is accomplished by hinges and adjusting screws, which are shown in Fig. 4. The steel is rendered soft by

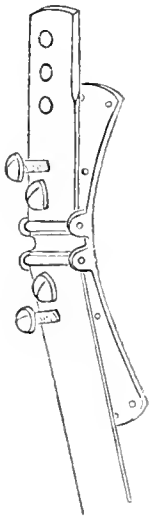

Fig. 4.

annealing, and must be bent by the surgeon's own hands to suit the indications for support. This stage of adjustment is beyond the possible comprehension of the mechanic who may have fashioned the instrument up to this point. For all ordinary cases the instrument as here figured is sufficient. But when there has been extensive destruction of the bodies of the vertebræ, and there are many signs which may lead us to infer the existence of an abscess, there is need of lateral supports to the head in addition to the ordinary antero-posterior one—in such cases small vertical pieces (shown in Fig. 5) are riveted to the "head-piece," and pass up behind and to a point just above the ears, having a band passing around the forehead, and completing an instrument by which the head is firmly held in all directions. This strap about the forehead may be useful also in occasional cases of excessive deformity, in relieving the chin of a part of the pressure against it; for the farther the spinal column has fallen from its natural position the greater must be the force to support it. When support and absolute rest are given to the diseased vertebræ, before caries or interstitial absorption (we omit here tuberculosis) has caused much loss of osseous or intervertebral tissue, we may be confident of saving the affected articulation intact, and of leaving the spinal column flexible, without anchylosis at any point. But when active destruction of the bodies of the vertebræ has commenced—which we can tell by any change in the natural form of that part of the column, even before a sharp projection of a spinous process is perceptible—our labors are increased and the period of reparation prolonged. But we may still expect complete restoration of form and function in a certain number of cases. At a later period, viz., after a sharp angle denotes positively an extensive destruction of vertebral substance, we have not only to wait for the reparative process to obtain in place of the morbid one, but we must continue to protect the affected part till the reparative process is completed in anchylosis. The greatest care should be taken and sufficient time given for obtaining a sound anchylosis, that it may be able to resist the unusual amount of weight and concussion which the position of this point in the middle of a crooked section causes to be transmitted there. A force which in a natural spinal column would be distributed equally throughout the whole or the greater part of the spinal column, in case of distortion is centred, more or less, at the point of greatest deviation, which is also the point of disease.

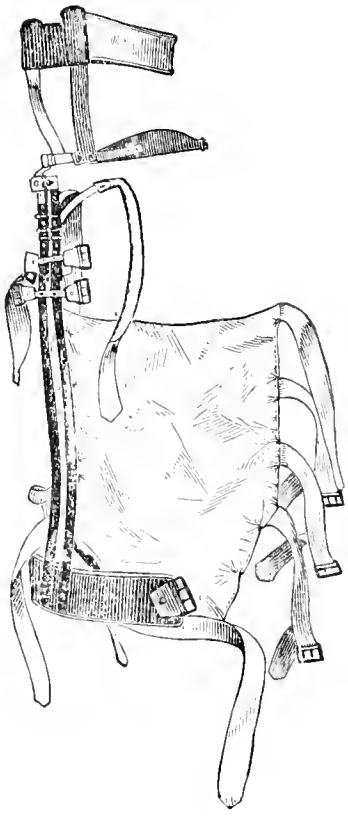

Fig. 5.

In the earlier stages, that is, before destruction of the vertebræ has followed the inflammatory stages, a few months' careful treatment generally suffices to effect a cure, with complete restoration of function. But in the later stages we can never expect the diseased and partially destroyed vertebræ to bear without assistance the pressure of the weight above in less time than from three to five years of careful treatment.

It is a great success which effects a restoration without increase of deformity in that length of time. Our average result in the treatment of disease of the cervical vertebræ is the arrest of further destruction of the vertebræ from the time the treatment commences. In regard to the form of the patient, we can speak more favorably of the disease at the cervical vertebræ than at any other portion of the spinal column; for here, in most cases, we often obtain at any stage a certain amount of diminution of the deformity.

The following cases are a few among many, and are

* See "Mechanical Treatment of Angular Curvature, or Pott's Disease of the Spine," *Transactions of State Medical Society*, 1873.

selected with the view to illustrate a variety of points in regard to their diagnosis as well as treatment.

Case I.—From our private Case-book. R. F., Nov. 8, 1866. This was a little boy from Chicago, three and a half years old, who about one year previously had fallen on the sidewalk. He soon began to complain and carry his head awkwardly; had a disposition to stammer, also paroxysms of difficult respiration, and a dry, short cough. He spent the next

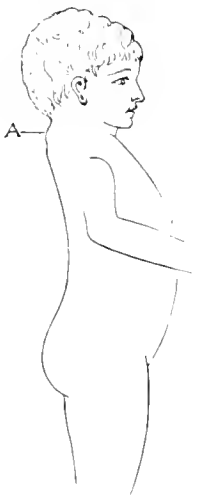

Fig. 6.

winter in New Orleans, and then coming to New York he was treated by an eminent medical gentleman for *asthma*. When examined he was in a most miserable condition. Respiration labored and somewhat prolonged; head thrown back, and there was so much suffering on being moved that he would lie for long periods in one position, generally in his nurse's arms, with his own hands to his chin. There were also pains in the chest and abdomen, and he was much of the time suffused with perspiration. Instrument applied Nov. 8, 1866, and in about a week, by frequent modifications, he began to be well supported. He was at first so doubled, and his muscles were so rigid, that the instrument could not be fitted at once. In a fortnight the "asthma" had left him—it was the characteristic labored respiration of spinal disease, to which allusion has already been made—and he began to walk about. The case has been carefully watched, and has progressed so favorably that he is now apparently as well as any boy of his age. Fig. 6 represents the slight deformity which existed at the time he commenced treatment, and there has been no increase since.

Case II.—From Dispensary Case-book. Carrie P., of Port Jarvis, N. J., aged two and a quarter years, was first seen on the 19th of January, 1869, when she presented a very miserable appearance—a pale, puny, ill-nourished child, with head thrown back and neck almost obliterated, and all the usual symptoms of cervical disease. Her previous history could not be clearly ascertained; but her father had died of Pott's disease. The mother was a poor sewing-woman, and it was some weeks before the child was returned for treatment and the instrument applied; for the Dispensary refuses to receive cases unless some assurance is given by a responsible person that the after-treatment of the patients will be followed out. Her progress, considering all the circumstances of the case, was truly remarkable and rapid. She was obliged to wear the instrument only about fifteen months, since which time she has been entirely well. The deformity, which appeared in a slight projection on the upper cervical region, entirely disappeared, and now presents—what is very common in such cases after successful treatment—a flattened and straightened appearance, instead of the usual slight angle caused by the prominence of the seventh spinous process.

Case III.—From private Case-book. Parmly B., five years and two months old, Woodstock, Vt. Location of disease, sixth and seventh cervical. A healthy and robust child, though weaned at two months of age, at which time he was brought from California, via Panama, to New York. Walked at one year of age; at twenty months he fell from a baby-carriage, and was also sick about the same time with something like diphtheria. After this he began to be weakly, commenced to complain of his neck, particularly when dressed or handled, and to hold his head on one side. At other times he was cheerful and apparently well—variations of condition which usually happen in these cases. He was treated for rheumatism without benefit. Brought to Dr. Taylor, at two and a half years of age, for "wry neck," and received treatment for that affection, as the true nature of the disease was not then discovered. He was only seen two or three times, and then lost sight of until April 13, 1868. He still continued in poor health; did not like to sit up like other children, and when tired would hold up his head by his hands; he still complained of his neck.

April 13, 1868.—Undue prominence of sixth and seventh cervical is evident, but his mother attributed the projection to his being so thin. Disease of the spine is diagnosed from the rational symptoms, as well as from the form, and the spinal assistant applied. He improved at once.

Sept. 22, 1870.—Patient reports in excellent health. Wears spinal assistant occasionally, when exposed to any great fatigue, as a "wise precaution."

February 22, 1873.—Patient has now been entirely without his brace for over two years; is in robust health, riding on horseback, and entering into all the sports of an active boy of his age.

Case IV.—Gertrude B., Northumberland, N.H., eight years old. Disease of the sixth cervical vertebra. Consumption on both sides. History, Oct. 24, 1868:

In Dec., 1867, had scarlet fever badly, which was followed by slow convalescence. In April she began school, apparently well, but in about three weeks she was attacked with a severe illness, the character of which cannot be definitely ascertained, but which was accompanied by fever, cough, restlessness, and pain in the neck and abdomen. She could not be taken up nor handled without the production of intense pain in the neck and back, and "stomach-ache." Towards the last of June she recovered sufficiently to walk alone. Besides the projection of the spinous process of affected vertebræ, the neck is partly flexed and rotated to the right, and all the symptoms point to the existence of Pott's disease. The child is fairly nourished, but has valvular disease of the heart. Oct. 27, 1868, the spinal assistant is applied. In the spring of 1869 she was doing well. She could then rotate the head perfectly. In April, 1870, the patient reported after a year's absence. Rotation of the head was perfect, and health good. A new instrument was applied, as a precaution against sudden shocks or accidental strains; but patient was considered well. She removed this instrument entirely in the course of a

few months, and a year later her father reported her in excellent health.

But it is not always the curable cases which best illustrate the value of a treatment. To prolong a life which seems in jeopardy, to ameliorate severe suffering when you cannot cure, is often a severer test of a method of treatment than the recovery of less severe cases. The two following cases are introduced to show what may often be done in the seemingly most unpromising cases.

Case V.—Mr. C. A. Mallory, forty years old, and married, a native of Connecticut, but for many years resident in Iowa; had been in the army, but by occupation a farmer. He remembers to have received a severe shock while on a reaping-machine, in Aug. 1868, which was followed by "rheumatism" of neck and shoulders. He grew better, and came East on business, and on his return, while standing on the steps of an omnibus in Chicago, with a heavy carpet-bag in his left hand, the horses started, and he was thrown off with such force that, striking on his feet, his left shoulder was dislocated. The dislocation was reduced, with much subsequent pain to patient, and he proceeded on his way; but from that time his neck began to stiffen and he endured much pain in the neck and base of cranium. He was treated again for "rheumatism," and after about six months came East to his friends in Norwalk, Ct. He had gradually grown worse, and at this time he was paralyzed in his upper and lower extremities, and could swallow with difficulty. Soon there was rupture of an abscess situated in the posterior wall of the pharynx, which discharged (January, 1870) through the mouth a large quantity of pus. After this the paralysis was somewhat better, but still existed partially over his whole body below the seat of disease. When Dr. Taylor saw him, in March, 1870, he was lying in a reclining-chair, with his head so strongly flexed and rotated to the right that his chin rested on his chest to the right of the sternum. He could only be fed with a spoon. It was possible, however, by having his head held firmly, to take a few steps when necessity required it, but it was attended with the utmost suffering, and all movement was avoided as far as possible. In addition to undeniable signs of disease at the upper cervical region, there was also a secondary development of the disease at the last dorsal and first lumbar vertebræ. In fact, he had been given up to die by all surgeons who had seen him. Believing there was still a chance for him, he was brought to New York, and an instrument applied March 17, 1870. Improvement began at once, and he was able to go home at the expiration of ten days. After four weeks he returned, being able to walk from the steamboat to the street-cars without difficulty. The aspect of his countenance, which had been extremely haggard, was much improved, and he had begun to feed himself. He continued to visit us with regularity, showing steady improvement in strength, with restoration of the position of his head and diminution of pain, till Aug. 18, when he was obliged to return to Iowa. At that time the face was still a little rotated to the right, but there was some motion, and he could "front face," although with an effort. But he walked and rode about with entire independence, though his paralytic symptoms were not entirely removed. Writes Jan. 26, 1871, that his head is in the natural position, and he can move it forward and backward, and can also rotate it a little. Is able to go without the instrument for a time, and proposes to leave it off entirely in the spring, which is probably a mistaken policy.

Case VI.—Mrs. E. D. Tucker, fifty-four years old, New Haven, Conn. No hereditary disease. Duration of the disease about eight months; cause, traumatic; location, fourth and fifth cervical vertebræ; pain in back of neck and under occiput. History, May 26, 1871: She fell down-stairs last November, and struck the back of her neck, which has been painful and stiff ever since, and is steadily growing more so. She cannot turn her head to either side more than twenty degrees, and says she feels a grating sensation under the occiput when rotation is attempted. When she walks she is obliged to support her head by putting her hand to her forehead, and says that her head feels too heavy for her body. There is slight swelling along the back and side of the neck, which is sensitive. Spinal assistant was applied June 1st. Patient was relieved of pain *at once*, and continued improving steadily. Sept. 23d, 1871. There is no grating sensation on moving her head, and a steady pain, which used to be at the right mastoid process, and "would soon have worn her life out," has disappeared. It returns only when the brace has been off a while. The motion of the head is free, and the patient holds it in a natural position without any effort. She reported to us in January, 1873, in excellent health and with no trace of the disease.

Mortimer Taggert, 15 years of age, applied at the Dispensary for treatment, June 15th, 1871. His gait and attitude were peculiar, and would readily attract attention—(see Fig. 7)—head bent forwards, and chin resting on the sternum. Any attempt to raise the chin, or any jar, occasioned pain referred to the forehead, and to a point over the spinous processes of the fourth and fifth cervical vertebræ, also to each side of that location. There was a slight lateral inclination of the spinal column, which has already been alluded to as one of the physical signs to be regarded in making a diagnosis of cervical disease, and which is easily explained as a compensating curve caused by the effort of the patient to hold his head in a vertical position.

Fig. 7.

In November, 1870, patient's neck became stiff and painful, a few days subsequent to a blow on the neck from the fist of a playmate. About a month afterwards was obliged to go to bed on account of the severity of the pain. He could not be moved or even touched for four months. The pain during this time was "all over," to use the patient's own words, "and a good deal in the stomach." He was treated by blis-

ters and other applications to the neck, without any relief from his suffering. After four months' quiet he began to feel less pain, and for two months previous to his application at the Dispensary had been able to go about. He was beginning, however, to feel that his condition was steadily growing worse, and dreaded a return of the attack of the previous winter.

The spinal assistant, with the chin-piece, was applied on 23d June, 1871, with immediate relief to the patient. The treatment was kept up faithfully, the instrument being worn as usual unremittingly, night as well as day, and in the following August he took off the instrument, without consulting any one, in order to resume his work. Although the treatment was discontinued unadvisedly, it proved not to be with any adverse result. The patient was seen and closely examined in the following January, but no vestige of the disease could be discovered. The movements of the head and neck were perfectly natural. The immediate relief from pain on the application of the spinal assistant, and the subsequent rapid disappearance of all the other signs and symptoms of the disease, proved that it had been arrested before any of the vertebral structure became involved, and shows how important is a diagnosis of the disease before that occurs. The treatment, which was carried out by Dr. N. M. Shaffer, became a matter of a few months instead of years, and there was a perfect restoration of the functions of the spine at the affected point, instead of anchylosis.

This case was again seen a few months after, and the cure as given above confirmed.

IODOFORM IN DISEASES OF THE THROAT AND NARES.

By R. P. LINCOLN, M.D.,

NEW YORK.

Though iodoform is recognized by a few as having some value as a topical remedy, its use seems to be directed almost entirely against venereal manifestations. Even here I do not think its advantages fully appreciated, and the completeness of my conviction impels me to transcribe the subjoined examples from my case-book as proof of its claims to a wider field of usefulness, and as an inducement to others to try a remedy that will realize high expectations.

We are indebted principally to French surgeons for bringing it to the attention of the profession, among others, Morétin, Bouchardat, Lailler, Férćol, and especially Demarquay.* The published accounts of their experience are not calculated to lead one into the error of limiting its applicability to any one class of diseases. In reference to this point, Férćol says: "Et je dirais volontiers, avec M. Besnier, qu'on peut user du procédé toutes les fois qu'une plaie présente une résistance notable à la cicatrisation." † I am prepared to testify to its great usefulness wherever there is an ulcerated or granulated surface whose cicatrization is sought.

It would be beyond my province here to give its chemical, physiological, or therapeutical qualities, yet I desire to refer to the remarkable fact, that, while it contains more than 96 per cent. of iodine in its composition, its application to a highly inflamed and sensitive part is unattended by pain; and while its effect shows it to act as a stimulant, it is at the same time a local anæsthetic.

It was in 1867 that Dr. Sass first called my attention to its wonderful influence on venereal ulcers; since then, when opportunity offered, I have gradually extended its use on ulcerations of the larynx, pharynx, and nares, other than syphilitic.

Did space permit, a large number of cases might be quoted; the following may therefore be considered typical of diseases often met with in treating the upper air-passages, and I believe the experience of others in similar cases will verify my own. As in the cases quoted, the most brilliant results usually attend its use on lesions the result of a venereal taint, and in these iodoform might replace all other remedies for local medication; yet, as in these cases also, the cicatrizing process of ulcerations not venereal is sometimes equally rapid, and almost at all times ultimately complete. The only obstacle to its free use is its peculiar and persistent odor, which to some is very disagreeable, and even intolerable; while, on the contrary, many do not object to it. There is also quite a large class where its use is indicated that have lost the sense of smell, that of course are indifferent to it.

Case I.—Mr. L, a lawyer, about 40 years old, consulted me for persistent epistaxis January last, at the suggestion of Dr. Francis Delafield. Patient stated that in other respects he had always enjoyed robust health, and that there was no hereditary cachexia to which he was subject. He traced back his present trouble to a cold which afflicted him eight years before, since which time he had been subject to frequent and often copious hemorrhages from the right nostril. During the last three or four years they have been of almost daily occurrence, with rarely an intermission of a week, and then usually the temporary effect of treatment. Latterly these attacks have sometimes occurred at night, the patient being awakened by the blood flowing into the throat. The effort of sneezing or coughing would almost always excite bleeding, as would also stooping forward, as in the act of washing the face; even the sudden jar of stepping from a curbstone would bring on an attack. The flow could usually be controlled by compression at the junction of the right ala with the lip, and as a precautionary measure a roll of paper was usually worn under the upper lip, against the reflection of its mucous membrane, which by a tension of the parts kept up slight but constant pressure. During all this time there had been a muco-purulent discharge from this nostril, varying in amount, but never entirely absent, and appearing posteriorly as well as in front. There was in the right ear slight but variable deafness of recent date. The general health was but slightly affected, the only complaint being of a feeling of weakness, experienced only after the loss of an exceptionally large amount of blood. The amount lost each day varied from a drachm to several ounces. The patient first presented himself to me with his handkerchief at his nose, staying the flow of blood, but otherwise appeared to be in perfect physical condition, and his cheek had not entirely lost the ruddy color that was natural to it, though he stated that he was sometimes blanched by the loss of blood.

It was impossible to obtain a satisfactory view of the parts at this visit, because of the free flow of blood which seemed to ooze from every part of the interior of the nostril; and after the failure of ice-water to check this and leave the parts in a condition to be examined, a spray of perchloride of iron was resorted to, which was at once successful. On the following day, after the nostril had been thorough-

* *Bull. Gén. de Thérap.*, Mai 15, 1867.

† Op. cit., Mai 15, 1868, p. 403.

ly cleansed by syringing and the use of pledgets of cotton, an examination revealed an ulcer on the septum, extending from within half an inch of its margin, superficially, as far back as a view could be had; its cartilage was exposed in many places, while at others a granulated surface presented. On the outer side the covering of the turbinated bones was of a mulberry-like appearance, being everywhere apparently covered with fine granulations, which bled on the slightest touch. A view posteriorly afforded an appearance similar to this last on the turbinated portion, while the mucous membrane of the whole posterior nares, particularly that on the right side, was hypertrophied and congested. The patient thought he had tried every known method of treatment, having been "swabbed" with nitrate of silver, and having used in the form of a douche or spray preparations of tannin, iron, alum, and other astringents, besides having taken internally tonic and anti-hemorrhagic remedies.

Treatment.—After carefully freeing the passage of all secretion, I applied powdered iodoform to the diseased surface, and gave the patient an ointment of the same (℥ i. ad adipis ʒ i.) to be applied every night with a camel's-hair pencil, the parts being previously cleansed as well as possible. A light piece of cotton was directed to be worn in this nostril when the patient was out of doors, which served as a respirator. This treatment, without modification, was continued for six weeks, when the membrane appeared healthy and all symptoms of disease had disappeared. There was no epistaxis after the first ten days of treatment, and the catarrhal discharge ceased at the end of the fifth week. At this time, five months since the patient was discharged, there has been but one hemorrhage. This occurred three months ago, during an attack of influenza, and consisted of but a few drops, and stopped spontaneously. Though treatment was resumed for three days, it probably was not necessary.

Case II.—Mr. M., aged 35 years, a resident of Brooklyn, consulted me at the direction of his family physician, Dr. Conklin. He was in the third stage of phthisis pulmonalis, but the suffering from a throat complication was so excessive that it outweighed, in his own mind, the graver trouble below, and the hope of securing an amelioration of the torture depending upon this part of the disease was his reason for coming to me.

He complained of great pain in his throat, and for the past three days of inability to swallow anything; this pain and difficulty of deglutition were much aggravated by the effort as well as by the act of swallowing. In addition to the dread of these symptoms was that of spasmodic coughing, which was now sure to follow any attempt at deglutition. These obstacles had at last become so great that the sufferer could no longer summon the courage to persevere, though it had been but a few weeks that annoyance from this source had been sufficient to modify his habits or facility in eating. The patient presented all the symptoms of advanced phthisis, including aphonia. A laryngoscopic examination revealed a larynx possessed by all the characteristic lesions of laryngeal phthisis—a thickened and gnawed epiglottis, arytenoid tumors, pyramidal in shape and œdematous, the left and larger being superficially ulcerated and covered with a tenacious, glairy mucus, while the other was smaller, and of a dark red, congested appearance. The vocal cords were thickened and fleshy in color.

Treatment.—Incisions were made in each tumor to relieve the congestion and particularly the œdema. A solution of iodide of zinc was applied by the spray-producer to the vocal cords, and powdered iodoform, by means of a tube properly curved for that purpose, to the epiglottis and arytenoid tumors. Applications were made daily, and after the second the patient reported he could swallow comfortably, better than for two months. After the first week iodoform was alone used.

For eight weeks, though the pulmonary disease was exerting its wasting effect upon the general system, there was an evident effort at repair in the larynx, that was partially successful, as shown to an observer by the diminution of the extent of the disease, and evident to the patient by the continued mitigation of the pain and greater ease in deglutition. Finally the patient became so much reduced that he was compelled to discontinue altogether his visits. The effect of the iodoform in preventing the local pain would last one to three days, within which time it was necessary to repeat it, and while this could be done with a moderate degree of regularity he could take nourishment with comparative ease. During the last week of his illness, which occurred ten weeks after his first visit, he sent for me three times to visit him in Brooklyn and "apply that powder," so much comfort did he anticipate from it.

Case III.—Early in my use of iodoform as a local remedy in diseases of the nasal organs, occurred the following case of ordinary nasal catarrh that had resisted other measures. The patient was a young lady, eighteen years of age, from the interior of Pennsylvania, and applied to me in February, 1868. Her health had never been impaired except from nasal catarrh, and from this she had never been free, though usually incommoded less in the warm weather than at other times. She was of a strumous diathesis, evinced by the complexion and enlargement of the glandular tissue in different parts of the body. There was a complete absence of the sense of smell, while the odor of her own breath was offensive to others. The discharge was muco-purulent and purulent, with heavy crusts thrown off both from the nostril anteriorly and sometimes expectorated. There was almost constant frontal pain, and the tear often overflowed from obstruction in the duct. On examining anteriorly, there was found a submucous infiltration and hypertrophy of the tissues nearly sufficient to occlude the passage of the left nostril, while the mucous membrane itself was congested and covered with a muco-purulent secretion. The right nostril was quite free, except where obstructed by crusts, the removal of which disclosed an ulcered and unhealthy surface. So far as could be ascertained there was no exposure or exfoliation of the turbinated bones, but the tissue covering it readily broke down under the manipulation of a probe. On examining from behind the palate, the posterior portion of the turbinated bones appeared similar to what was found in front, though naturally paler, and the other parts were generally hypertrophied, with spots of ulceration scattered over the surface. The hypertrophy of the adenoid tissue of the vault was strongly marked. There was also mucous and submucous thickening of the pharynx. She had undergone much treatment, having tried variously medicated nasal douches, and had had applied "caustics" by means of a sponge and brush; iron had been taken internally; but all these means, as well as a year's residence abroad, were of no avail.

Treatment.—The patient submitted herself to almost daily treatment. The passages having been thoroughly cleansed with a weak solution of compound tincture of iodine by means of a posterior nasal douche, any crusts being removed by instruments when necessary, a fine spray of tannin and glycerine was applied

to the left nostril, and a saturated solution of nitrate of silver to the right nostril, posterior nares, and pharynx. In a few days chromic acid was applied to the tonsils to reduce their slight enlargement. Cod-liver oil, which she had never before taken, was prescribed. At the end of two weeks there had been an improvement in all the symptoms, and an examination of the left nostril warranted a verdict of well, anteriorly; while from the right and from the posterior nares there was still some of the old discharge. Everywhere here the mucous membrane presented a healthier appearance; there was less thickening and a better color, though considerable ulceration remained. The tonsils and pharynx required no further attention. The frontal pain had ceased. The same treatment was continued in the right nostril and posterior nares another fortnight with but little additional benefit, though there was no longer any complaint of the overflow of the tears. The use of the nitrate was then discontinued and an ointment of iodoform substituted, which in turn was abandoned in a short time for powdered iodoform. For ten days this was freely spread over the diseased surface, at the end of which time there was no discharge from the nostril in front, and but little from behind.

An examination at this time showed the mucous membrane to be everywhere healthy, except the adenoid tissue of the vault, which was still rough and thickened. Chromic acid was then thoroughly applied to this part, and when the slough had separated, iodoform effected a restoration of a healthy surface, when all the symptoms of a catarrh had ceased. The patient was discharged ten weeks from the beginning of treatment. The following autumn, and again a year later, she reported herself as remaining well.

Case IV.—Mrs. P., aged 40 years, applied to me at the suggestion of Dr. Roosa, June 30, 1873. She has been twenty years married, is the mother of four children, the eldest eighteen and the youngest three years of age; all of whom are strong and healthy, except the second, a daughter, who is a deaf mute, the effect of scarlet fever. Her own parents as well as her grandparents were healthy, and exceptionally long lived. She has two sisters and one brother living and healthy; one brother, previously healthy, died two years ago of an acute disease.

Her husband stated that he had always been free from any disease.

Our patient was vaccinated in her fourth month with virus from another child. Though a robust infant before, from this time she became sickly and feeble, and remained so for two years, when she had an attack of "erysipelas of the face and head," after which she became strong and well. She remained apparently healthy until 1862, when an eruption appeared on the face and ears. It was not itchy, and terminated in white scales, and disappeared without leaving any discoloration, in three or four weeks, under the administration, according to her physician, of arsenic.

There was no fever at this time, and she was confident there was no analogous condition of the scalp, though she remembers the hair fell out so as to require attention.

She dates the beginning of her present trouble from a cold in the head, caught while on a trip up the Mississippi river in April, 1864. On reaching this city she consulted a skilful and distinguished surgeon, who pronounced her affection "catarrh of the head," whose treatment she followed for some months, taking medicine internally as well as having local treatment, but all "without avail." Homœopathic treatment was then adopted for a couple of years, after which she consulted a specialist, who told her that "by a great deal of cutting and burning" he could help her.

She gave me a list of thirteen different physicians, of various practices, with an apology that it was so incomplete, to whose treatment she had subjected herself, and who with confident assurance pronounced the affection a "purely local disease," others "a scrofulous," and still others "a blood disease."

In 1867 the disease had extended to the throat, where, from that time, some degree of ulceration has almost constantly been present.

In August, 1868, the first splinter of bone came away from the nostril, and during the succeeding four years a dozen or more pieces, at irregular intervals, appeared in the discharge, principally from the mouth.

During this period of more than nine years, except early in the disease a temporary amelioration of a week or two, usually after taking "potash," she has been subject to a muco-purulent discharge from the nose and throat. This symptom has suffered frequent exacerbations on the access of any slight cold, to which she seems to have been exceptionably susceptible. Though the appearance of the diseased parts was so repulsive when she visited me, there was no perceptible taint to her breath. The sense of smell was lost early in the disease, and that of taste impaired. One year and a half ago she became deaf in her left ear, and remains so now. Early last April she suffered an acute attack of "erysipelas of the face and head," since which her old disease has been much worse, and her strength more impaired than ever. For several weeks previous to her visit to me the difficulty of deglutition had constantly increased, and had at last become so great that her husband said, "She is literally starving." Whenever, notwithstanding the pain, she did attempt to swallow, spasmodic coughing would ensue, to be followed by attacks of dyspnœa.

The patient entered my office supported by her husband, and presented the appearance of a person much reduced by protracted illness, exsanguine, but not extremely emaciated; stooping, and breathing through her open mouth with an audible sound. She spoke only in a whisper, and then with evident difficulty after several attempts to clear the throat. The bridge of her nose was depressed nearly to a level with her face. Several of the left cervical glands were each as large as small filberts, and were so before the throat-trouble. There were none enlarged behind the ears or at the elbows.

Pulse 75 and weak. Temperature normal.

The swollen and displaced parts within the nostrils, which were everywhere ulcerated, prevented a satisfactory examination anteriorly. No air could be forced through the nostrils on expiration, but on the most powerful inspiration the least air passed in, though through which it was impossible determine. On inspecting by the mouth, there was found a muco-purulent secretion covering the palate, pharynx, larynx, and posterior nares, which it was necessary to remove before the condition of the concealed surface could be determined. It was then found that the uvula had been entirely destroyed, and the palate cleft in the median line to the extent of nearly half an inch. The free border of the palate was occupied by an ulcer half an inch deep on its inferior aspect, which was continuous, with a similar condition on its posterior and nasal surface, as well as upon its arches, and even in the larynx. The posterior and lateral walls of the pharynx were covered with a fibrous-looking membrane, firmly adherent, and with no appearance of an attempt at granulation. Below, this condition extended beyond the point of contact with the larynx,

and above, in the pharyngo-nasal portion, it gradually gave place to a state of ulceration, unhealthy granulation, and thickening, which obtained throughout this cavity. The epiglottis, and the interior of the larynx, but particularly the glasso-epiglottic folds, were so swollen as to prevent a view of the vocal cords; and this whole surface seemed to be occupied by one ulcer, continuous with that already described. On account of the infiltration and thickening, neither the faucial extremity of the Eustachian tube nor the posterior border of the turbinated bones could be seen with the aid of the rhinoscope.

Treatment.—The discharge having already been removed so far as possible, I applied freely to the whole diseased tract, in the form of a fine spray, a solution of sulphurous acid and glycerine—seven parts of the former to one of the latter—and prescribed a gargle of carbolic acid, water, and glycerine, and internally iron and iodide of potassium; there was also advised an eggnog twice a day, and a clyster of beef-tea morning and night.

June 1.—Patient had been able to take the medicine and a few spoonfuls of nog. The enemas were well retained and gave strength. There was no change in the disease, and the following prescription was substituted for the first, a dessertspoonful of which was ordered to be taken three times a day: R. Hydrarg. iod. rub., gr. ij.; potass. iodidi, ʒ iss.; vin. pepsin. et syr. simp., āā ʒ iij.

June 6.—Complained of tenderness of teeth. Though the full dose of the medicine had not been taken, it was stopped entirely, and chlorate of potash ordered to be used internally and as a gargle.

There was still no satisfactory change in the comfort of the patient or in the appearance of the throat, except a slight diminution of the inflammation bordering the ulceration on the palate, though nitrate of silver and also carbolic acid had been tried in place of the sulphurous acid.

An application of acid nitrate of mercury was then made to the whole pharynx, and extended cautiously to the posterior nares and the most prominent parts of the diseased larynx; this caused excessive pain and necessitated a dose of morphine.

At the expiration of a day and a half the slough made by the application had almost entirely separated, leaving exposed a pale, granulating surface. Powdered iodoform was then daily applied to the whole surface, including the nasal passages.

June 9.—There was a marked improvement throughout the diseased tract, a healthy action being everywhere established. The patient stated she could swallow so much better that she had eaten a piece of beefsteak, the first for several weeks, and had resumed the nog in full doses. The tenderness of the teeth had nearly passed away. Cod-liver oil was prescribed.

So symmetrical, laterally, was the character and extent of the disease, that to the right half I applied a fine spray of nitrate of silver (ʒ i. ad aq. ʒ i.) and continued the iodoform on the left half.

June 14.—The process of cicatrization was so much more rapid on the left side than the right, that I did not feel justified in a longer use of the silver, and therefore extended the iodoform application to the whole surface. The stomach proved too feeble to retain the oil, and as our patient was gaining rapidly in every particular, no further attempt was made with internal remedies; she could now swallow without pain, though it required care and deliberation in deglutition to prevent food passing into the pharyngo-nasal cavity. Air now passed through the nostrils, but not with sufficient freedom for easy respiration; phonation was easy, though hoarse.

She was now instructed in the use of the throat douche and posterior nasal syringe, by means of which was used as a douche the fluid ordered for a gargle.

The only additional modification introduced during the remainder of the treatment was the occasional use of chromic acid to check any exuberant granulations, or to prevent undue contraction that sometimes threatened during the process of cicatrization.

The iodoform was continued almost daily till July 28, when she was discharged, there being no further symptoms of disease.

A NEW TREATMENT FOR THE PREVENTION OF HYDROPHOBIA AFTER INOCULATION.

By PALUEL DE MARMON, M.D.,

KINGSBRIDGE, N. Y.

On the 28th of June, 1871, Ella ——, of New York, was bitten by a dog, which, according to all the evidence, as hereafter described, was rabid. I saw the child one hour after the accident: a piece of the right cheek, about the size of a silver-dollar coin, irregular in shape and depth, had been torn out by the animal. She also bore the marks of the dog's teeth upon the right arm and leg.

I cauterized the wound immediately with a saturated solution of carbolic acid, and had it kept wet constantly with a weaker solution of the same. I ordered, besides, two drops of liquor ammonia fortis to be given every two hours in water.

June 29th.—The little girl slept well, is in good spirits, has good appetite, and no pain. June 30th.—Continues to do well. July 1st.—Increased the dose of ammonia to three drops; wound cauterized upon the edges with nitrate of silver to correct some irregularities in the cicatrix. The same treatment was continued until August the 9th, and was religiously followed; the wound was not allowed, during the whole time, to be dry a single instant, thanks to the unremitting attention of a devoted mother. On the 10th of August the wound was entirely closed, and the cicatrix, healthy and regular, reduced to about one-tenth of its original size, and without a single bridle.

It is now two years since the accident happened, and no symptoms of hydrophobia have made their appearance. I think I am well authorized to suppose the patient out of danger.

The Dog's History, and Post-mortem Examination.—The dog, which was totally unknown in the neighborhood, was lying in the coachman's room, under the bed. When the man entered his apartment the animal looked at him and walked out. It then attempted to pass by the patient's sister, a little girl seven years old, and did not appear to notice her; but when it went by the patient, this little child, probably on account of fear, made a motion with her hand as if to drive away the animal. It was at that time that the dog sprang at her and bit her.

The dog was chased by four men, and finally caught and killed. During the chase he bit a duck, which was killed a short time after. The dog was first struck on the back of its neck with the butt-end of a whip; it did not yell, but only groaned slightly. In the chase given to him he did not seem to get out of the way when any of the men were in front of him in a threatening position—when he was at last struck to the ground

with a hay-fork, without yelling or attempting to defend himself, and was then clubbed and his head broken.

Autopsy was made 15 hours after death, June 29th. Rigor mortis very pronounced, no signs of decomposition, no smell; all the internal organs were healthy, the gall-bladder very full, the lungs slightly congested, the blood extravasated in the splanchnic cavity was dark and liquid.

The stomach was rather small, and contained a quantity of *hair, mud*, two whole *humble-bees*, one large *butterfly* with wings almost intact, one small *white mushroom*, some *straw, grass*, and the piece of the child's cheek nearly all digested but the skin.

The mouth was filled with bloody froth, and on the tongue—that is to say, beneath and on the sides of it—some small pustules, varying from the size of a millet-seed to that of a grain of wheat, irregular in shape, and filled with a light, whitish liquid, could be plainly observed; I counted twenty-three of them. These, in all probability, were what has been described by some authors under the name of *Lyssæ*, and supposed by them to contain the rabid virus.

The above data display undeniably all the features of hydrophobia in the dog as described by authors; and in fact, who ever heard of a dog in a normal condition having such polyphagous propensities? On the contrary, when he is mad "the stomach contains a strange mixture of straw, hair, paper, hay, horse-dung, and earth." (*Clymer's ed. of Aitken's Practice.*) "The dog who is mad swallows, *pêle-mêle*, objects the most foreign to alimentation" (*E. Littré et Robin in Dict. de Nysten, 12th edition*). "It eats the straw of its bed, horse-dung, excrements, pieces of leather, wood . . . . in him there is no feeling; he may be beaten, struck, burned, without uttering a complaint" (*Nouveau Dict. des Sc. médicales et vétérinaires*). "Very frequently we can see him eat his litter, pieces of wood, earth, etc. The knowledge of this fact has a great importance, because, in making the autopsy of the rabid dog, we find in his stomach all the substances which have not been subjected to digestion, and that in this we have a proof of the disease" (*A. Trousseau, Clinique méd. de l'Hôtel Dieu*). "A mad dog does not always refuse to eat, but a fact quite remarkable and characteristic," says M. Bouley, "is the depravation of appetite; the animal may be seen to tear, destroy, or swallow objects not made to eat; and one should always mistrust a dog which tears with obstination carpets, blankets, pillows, or eats wood, earth, litter, etc." (*Girisolle, Pathologie interne.*)

As we may easily see by the above, eminent authors agree upon this point of pathology, and confirm my views of the case I have reported. It is true that cases of hydrophobia have been cured spontaneously; but nevertheless, the treatment by carbolic acid may be tried again in combination with ammonia, and I should be happy to hear of any other case where it may have been successful.

KINGSBRIDGE, NEW YORK.

REMOVAL OF A FRAGMENT OF CATHETER FROM URETHRA BY DIVULSION.

By AMBROSE L. RANNEY, M.D.,

NEW YORK.

CASES of foreign bodies in the urethra or bladder are not of common occurrence in private practice.

Dr. Weir, of this city, reported a case in THE MEDICAL RECORD of 1868, where he removed from a female bladder a hair-pin, covered with urinal incrustations to the amount of twenty-nine grains.

Dr. J. M. Reeves, of Dayton, Ohio, reports a case* where a pregnant woman, troubled with frequent retention of urine, broke off some inches of a male flexible catheter in her bladder, where it remained for a sufficiently long time to be heavily incrustated before removal.

Several cases of pessaries being removed from female bladders are on record.

Dr. Post, of this city, reports a case of perforation of the male bladder,† in jumping over an upright stick, a piece of cloth being carried into the cavity of the bladder, where it acted as a nucleus for a vesical stone, which was afterwards cured by lithotripsy.

Dr. C. M. Allin reports a case in which a fragment of an ivory pen-handle was removed from a male bladder, having been introduced during an attempt at onanism.

Dr. Pancoast, of Philadelphia, also removed a portion of a slate-pencil from a male bladder, passed there through similar indulgence.

Dr. Van Buren, of this city, removed from the bladder of a patient in Bellevue a calculus, of which the nucleus was composed of a head of wheaten straw, passed down the urethra, by an old man, for sexual excitement.

Dr. Jas. R. Wood, of this city, reports a case of removal of a pewter spoon-handle from a male urethra. Also a second case, where a leather string was passed down a male urethra into the bladder, and there rendered incapable of removal by a *knot* having formed.

A case is reported in which a female malingerer would frequently resort to the insertion of pieces of common brick, carefully oiled, into her bladder through her urethra.

Mr. Tyrrell, of London, reports a case of extraction of a piece of a silver catheter from a male bladder, using his rectal touch to retain the foreign body in position till it could be grasped with forceps.

Mr. Lamotte removed a PIN from a female bladder by allowing it to drop into the eye of a catheter, and thus withdrawing it.

In connection with these few cases and many others which have been reported, I take, therefore, the liberty of presenting to the attention of the medical profession the following history:

John R——, 35 years. Patient was sent to me by a neighboring physician, at 7 P.M., April 21, 1873, suffering from retention of urine. He, however, succeeded in fully evacuating his bladder, without assistance, soon after, and therefore postponed his visit to my office till 8 A.M., April 22d, when he gave me the following history: No syphilitic lesion, hereditary or acquired, had ever appeared; family history good; general condition excellent. Some five years previous to date he was attacked with a gonorrhœa of no unusual severity, which lasted about three months. Since then had suffered from numerous similar attacks, but could not give exact data as to period of occurrence or length of duration. Noticed a diminution in size of stream one year previous to date, and had frequently resorted, since then, to the passage of a flexible catheter, corresponding to a No. 5 (English measure), which, with difficulty, he himself passed till urine escaped.

On April 22d, while endeavoring to introduce his

* *Medical Times*, 1870.

† THE MEDICAL RECORD, 1872.

catheter, he failed to pass an apparent obstruction "deep down in his urethra," and on withdrawing the instrument found that it had *broken* above the eye, the fragment remaining either in the urethra or bladder. On calling on a physician, efforts were made to relieve his retention, which were partially successful, and he was then sent to me for treatment. I instructed patient to pass water for my inspection, which he did without much exertion, in a small spiral stream, to the amount of about ℥iv. On examination it revealed the existence of large quantities of phosphates, but no albumen or sugar; was dark sherry in color: neutral in reaction; sp. gravity 1024. On examination of his urethra with flexible *bulbous* instruments, the meatus was found to admit a No. 15, which was immediately arrested in the "fossa navicularis." Subsequent trial of smaller sizes allowed of the passage of a No. 8 through this obstruction for the distance of two and a quarter inches from the meatus, when a second obstruction was met, and the instrument arrested. This allowed of the passage of a No. 6, when a third structure was detected, just anterior to the bulbo-membranous junction, measuring five and three-fourths inches from the meatus, and which failed to admit any bulbous instrument. After carefully injecting the urethra with oil, I succeeded in passing a spiral guide of whalebone into the bladder, without pain or particular inconvenience to patient, during the passage of which, however, I discovered that the orifice of the lower stricture was slightly to the right of the median line, and near the posterior urethral wall. This I did by the old method of so directing the points at the two extremities of the guide, that the FREE extremity should serve as an accurate index to the position of the one entering the mouth of the urethral obstruction.

Realizing the danger which the patient would necessarily run should so admirable a nucleus for a vesical calculus be allowed to remain, even for a short time, in the bladder—especially when the urine was loaded with a phosphatic deposit—and feeling confident that, could *dilatation* be rapidly performed, the broken extremity of the catheter, with its long axis in the direction of the urinal current, would pass through the urethra before any crystallization of urinal salts could occur, I proposed, before withdrawing the guide, to begin dilatation at the first sitting, without submitting the patient to a previous preparation by internal administration of Tinct. Ferri Mur. and Quinine, by which I believe great assistance is often afforded.

Accordingly, Nos. 3, 5, 7, and 8 tunnelled conical sounds were successively passed over the guide, with no appearance of rupture at seat of stricture or great pain to patient.

Solid conical sounds were then substituted and the guide withdrawn. Nos. 7, 8, 9, 10, and 12 were passed, when a slight appearance of blood, scarcely a *drop* at the most, indicated *divulsion*. Nos. 13 and 14 were then passed, and 10 grs. of quinine given to patient, with directions to take a hot bath immediately on returning home, and to be repeated night and morning for the day following.

That night, on the first attempt at micturition, the fragment of the catheter was passed, and the patient brought it to my office on the following day. On measurement it was found to be seven-eighths of an inch in length, and showed no deposit on its surface, though it had been retained in bladder thirty-six hours. Patient has experienced no unpleasant symptoms since divulsion. He has had No. 14 sound passed every other day up to present time, and urinates in a copious stream, without twist or any abnormal direction. A No. 12 bulbous instrument, however, still slightly shows the seat of former obstructions.

69 MADISON AVENUE.

Progress of Medical Science.

ELASTIC BANDS IN THE TREATMENT OF FRACTURES.—Dr. J. W. Southworth (*Buff. Med. and Surg. Jour.*) advocates the use of elastic retention straps in place of the ordinary retention bands or bandages in the treatment of fractures. These elastic straps may be improvised by taking the common rubber bands, one-fourth to one-half an inch wide, as sold by stationers, doubling them and passing strips of muslin through them, making it part of the strap, and thus allowing it to be stretched to the degree deemed advisable to exert a proper amount of constricting force when applied around the splints. In fractures of the fore-arm about four are required, in fractures of the leg and thigh proportionately more, the elastic portion being placed alternately on opposite sides.

This mode of dressing retains an even adaptation of the splints, whatever may be the condition of the limb as regards swelling.

A CHILD DIES BY VOMITING INTO ITS OWN LARYNX.—A little boy, aged one year, was fed in superabundance from a bottle, and put to bed at 6 P.M. At 12 M. it died, under symptoms of the most profound dyspnœa. On section, the two lower lobes of the lungs were found stuffed with a grayish fluid having a strong odor of butter. Altered milk was found in the trachea and bronchi. The milk contained in the stomach must have been vomited, and the child being in a horizontal position it found its way into the respiratory passages. Dr. Parrot narrates the case, considers this accident to be more frequent than is generally believed, on which account he calls to it the attention of fellow-practitioners.—*Rivista Clinica di Bologna*, July 25, 1873.

UTERO-PLACENTAL VACUUM.—Dr. H. G. Landis, in the *Medical Times* of April 12th, reports a case of retained placenta, which he caused to be easily delivered by simply perforating it. He did this from the consideration that the placenta resembled, in one respect, a boy's leather "sucker."

NATURE OF MUMPS.—Dr. Bouchut, in a note communicated to the Academy of Sciences by Claude Bernard, states that parotitis is simply a salivary retention due to catarrhal inflammation of the excreting canal of the parotid.

WRIGHT'S FORMULA FOR HEADACHE FOLLOWING ALCOHOL DEBAUCH.—The *Boston Journal* reprints the following, "for the use of prohibitionists," which originally appeared in the *Rev. de Thérap.* and *Canada Med. Record*: Take of solution of acetate of ammonia, tincture of bitter orange-peel, syrup of bitter orange-peel, each 20 parts, water 500 parts. To be given in repeated teaspoonful doses.

DIAGNOSIS OF UTERINE FIBROMATA.—Dr. Abeiller alludes to the mistakes in diagnoses which are liable to those who do not make their examinations during a menstrual period, since it is only at this time that the efforts of the uterus tend to expel these tumors, and they are therefore brought nearer to the os, causing unusual dilatation of the cervix and affording better opportunities for examination.—*Gaz. Méd. de Paris*, No. 11.

On Continuous Discharges after Delivery.—Dr. A. Wiltshire says that these discharges are most common among patients of the poorer class, who are, by the exigencies of their lives, obliged to rise too soon from the lying-in couch, and who are, moreover, as a rule, sadly under-fed, not only at and during childbirth, but before and after. More rarely are they met with in higher ranks of society, chiefly in constitutionally delicate women, or in persons who have become weakened by too rapid child-bearing, or other debilitating causes. All classes alike are apt to blame their medical attendant for the persistence for some time of sanguineous discharges, in the belief that they are due to negligence or want of skill on his part.

The cause of this condition is due, in the great majority of, if not all, cases, to subinvolution of the uterus.

Involution should progress equally in every part of the womb, so that at the end of the process the normal relative proportions should be maintained; especially does this apply to that portion corresponding to the placental site where the uterine wall is thicker than elsewhere. It is here, however, that the process most often fails, leaving a surface prone to discharge blood and other fluids; and it is here, the author believes, that the persistent "colored shows" and "waters" mostly originate.

These cases are characterized by the persistence, with it may be occasional remissions or intermissions, of a sanguineous (red or greenish) flow, which sometimes weakens the patient to the extent of interfering with lactation. Subinvolution is liable to persons affected with heart disease and chronic diseases which are accompanied with marked congestion of the venous system, as chronic bronchitis with emphysema, congestive liver diseases, etc. Feverishness hinders involution, and Joulin says the process does not actively set in until the pyrexia due to the establishment of lactation has passed away. It is, therefore, important to arrest all pyrexial complications. As regards the constitutionally feeble, in whom all vital processes are slow, absorption and restitution are not likely to progress very rapidly when the debility, which is normal to such persons, is intensified by the exhaustion of parturition, and the usual insufficient or improper diet to which lying-in women are commonly condemned. For such is a liberal diet especially useful.

Bi-manual palpation and measurement show in these cases excessive bulk. Ordinarily this coexists with increased length, but cases have been noticed in which the length of the axis was normal while the uterus was broader. On the relation of flexion and version to this condition Dr. Wiltshire does not lay much stress, remarking that "such accidents do occasionally complicate these cases, and aggravate them considerably."

Under the head of preventive treatment the writer impresses the necessity of prohibiting too early rising, and next regulation of the diet, the quality of which should be inversely proportionate to the quantity taken, due regard being had for the existence of fever, as determined by the thermometer, the habits and inclinations of the patient, and her intention to nurse the child or not.

Under the head of curative treatment he recommends the recumbent position, a firm bandage to the lower belly, and rich diet. Occasionally cases are seen in which there is an excess of nutrition, and subinvolution disappears under a regulated diet, potash or lithia, and aperients, and anti-rheumatic remedies in patients of that diathesis. Ergot is recommended, and digitalis; and strychnia in some cases complicated with heart lesions. Very striking results have followed the use of quinine, as suggested by Monteverdi. Gueneau de Mussy, at the Hôtel Dieu, has of late used it with considerable success in eight-grain doses for atonic menorrhagia.

Some patients, where nutrition appears to have failed seriously, improve wonderfully under arsenic. Anodynes, especially opiates, should be sparingly used. Syrup of iodide of iron is recommended as a tonic, sulphate of magnesia to keep the bowels opened, and local application of iodine to the hypogastrium when there is much pain. Injections, if used, should be copious, and the writer prefers cold to hot ones. Astringents may be introduced into these injections, if necessary, and good may often be derived from hip-baths, the author having a high opinion of sea-water for this purpose, as well as for injections.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month, by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, September 15, 1873.

THE HYGIENE OF PUBLIC SCHOOLS.

THE school system, lying as it does at the foundation of all good government, naturally invests every subject directly or indirectly connected with it with the greatest possible interest. As far as education pure and simple is concerned, great improvements have been made, and every friend of progress has no small reason for congratulation when he compares the present condition of our school system with what it was twenty-five years ago. Money has been expended liberally upon buildings, apparatus of the most costly character has been placed at the disposal of the child of the poorest, and from one point of view everything seems to have been done to keep up with the educational requirements of the age.

It would be well if we, interested as a liberal profession in education generally, could stop here, and with the majority who believe in the necessity of mental culture think that everything was being done to make the system as perfect in every respect as was possible. That the latter is not the case must be admitted by every one who gives the subject of school hygiene any attention whatever. The very efforts which have been made by our educators to cultivate the mind, the very desires they have had to develop the brain, have caused them to lose sight of another element of no less importance—the strictly sanitary requirements of the teachers and scholars. It is true, in view of the present ignorance of sanitary laws, even among men of education, we can hardly be surprised that the question of hygiene receives so little attention; but the fact only goes to prove the great necessity of medical men looking into the matter and raising their voices against the perniciousness of the present plan.

We are led to make some remarks upon the subject at this time on account of the opportunity which is offered us of presenting to the notice of our readers some important facts contained in a paper recently read before the New York Academy of Medicine by Dr. R. J. O'Sullivan, and also to many important points noted in the discussion thereon. The paper in question has the title of "The Hygiene of Primary Schools;" an abstract of which, with the discussion, has been published in a few of the recent numbers of the *New York School Journal*.

It will be recollected that Dr. O'Sullivan has for a year or two past, and up to the time that the Board of Education decided that sanitary supervision of the schools was unnecessary, acted in the capacity of medical inspector, and on this account the facts which he presents in his paper, founded as they are upon personal observation, are of peculiar value.

The most important point in the paper has reference to the earliest age at which a pupil should be admitted into our schools. It is very properly contended that seven years is a minimum age, not because mental exertion would be injurious to healthy intellectual growth, but because school life under its present hygienic surroundings is very unfavorable to the child's physical development. In other words, it is to be understood that although a child is capable of reasonable understanding and a limited amount of intellectual development prior to the seventh year, such education should be given it out of school and without the usual restraint.

In connection with the age of admission, the division of time in schools has a very important relation. There is no questioning the fact that the hours for study are too long in the infant classes. In corroboration of the above the following assertion is made, and although it proves an extreme case it nevertheless shows how much the little ones can be compelled to stand and yet live: "I have found primary schools in which the pupils were allowed no recess between their entry into the school in the morning and the dinner-hour, or between 1 o'clock and the hour of breaking up." In order to give the requisite amount of exercise to the muscles it would doubtless be necessary, in the infant classes at least, to modify much of the arrangement of studies; but we maintain that the end more than justifies the means. The younger the child the more danger there is from long-continued confinement. This is particularly the case before the seventh year, during which period the conditions of the rapid development of particular portions of the body demand an almost absolute freedom from restraint. This fact is well established by the remarks of Prof. Jacobi in discussing the paper.

In view of the large number of children who attend the public schools—estimated at one hundred thousand—and in view of the increase of certain diseases and bodily defects in children generally, it is sometimes interesting to inquire how much the present

school system has to do in explaining the relation between cause and effect. In the matter of the prevalence of near-sightedness in scholars, a very straightforward explanation is given by ophthalmologists. Graefe of Berlin, Cohn of Breslau, Erismann of St. Petersburg, and Agnew of New York, all of whom have had abundant facilities for observation, state that much of the eye diseases in pupils is due to the defects in lighting the rooms, inducing an undue exercise of tension in an effort to see; and Graefe has shown that a persistency in such efforts produces disease in the internal tissues of the eye. Bearing upon this question we quote the following remarks of Dr. C. R. Agnew, likewise made during the discussion of Dr. O'Sullivan's paper: "Every one familiar with our school and college life in New York, and elsewhere in the United States, knows that many of our school-houses are bad in light, bad in ventilation, bad in desks and seats, bad in the cramming to which the students are exposed. That near-sightedness and other forms of eye disease are rapidly increasing, and that the chances are against a lad or girl getting what is called a completed collegiate education without irreparable damage done to health and prospect of future usefulness, is certainly true."

Another great evil connected with our school system, and one which in the aggregate affects the health of the greatest number of scholars, is defective ventilation and insufficiency of heat in cold weather. To show to what extent foul air can be breathed in our school-rooms, we quote from the paper a little fact of experience: "Enter a crowded class-room in any of our school buildings in winter when the windows are shut. The oppressive atmosphere of that room is surcharged with carbonic acid gas, decaying organic matter, and moisture from the respiration and perspiration of the inmates. In some recent experiments made by an expert, the air of a class-room was found to hold, one window being open, carbonic acid to the extent of seventeen and two-tenth parts per ten thousand. That was surely bad enough, showing the presence of this gas in a proportion four times greater than the normal quantity. But warmth is essential as well as ventilation; and as the scholars were becoming chilled by the current of cold air entering through the open window, it had to be closed. After ten minutes a new analysis of the air was made, and the proportion of carbonic acid was now thirty-two and two-tenths per ten thousand. This test showed only the amount of carbonic acid gas; but the other poisonous elements of impure air are at least quite as injurious. I do not of course pretend to say that the air in our schools is generally as foul as this; but no sane man will affirm that in any of them the problem of ventilation has been anything like satisfactorily solved. It is not for the physician to indicate the mechanical contrivances which are requisite for the solution of it. That is a question for the architects, and they will answer it, I am convinced, if school boards will require them to do so. Let such boards only bear in mind that the 'style' of a building is not the question, and that the first and foremost care must be to secure good ventilation."

That the spread of contagious diseases is much promoted by the lack of the most ordinary sanitary regulation, is painfully evident to every physician. The school-room is in fact the very hotbed of propagation for scarlet fever, measles, small-pox, whooping-cough, etc.

If we were to give a cursory notice of the diseases which are liable to be engendered or propagated by the school system as at present tolerated, we could name almost every disease belonging to childhood.

There are many diseases directly chargeable to our faulty school management which may not be prevented, many ailments beyond the power of science to mitigate; but these are exceedingly few, the great majority of evils being such as can be remedied with very little trouble. The remedy which suggests itself to every medical man is the only one which can be looked to with confidence, viz., medical inspection. The unsanitary condition of our school-rooms, coupled with the forcing practice so fashionable in our schools, has been due to the want of the right sort of knowledge on the part of the teachers and others in authority. In spite of this very obvious fact, the Board of Education voted that sanitary inspection of the schools was unnecessary, and abolished the office of Medical Superintendent. Although Dr. O'Sullivan served the Board faithfully in the latter capacity, and would be well qualified to discharge similar duties in future, we do not care to advocate him any more than any other capable medical man. Our object is to speak against the discontinuance of the office as a matter of principle. That such a step on the part of the Board was radically wrong, and in every way injudicious, is more and more evident the more the subject is examined into, the more the facts connected with the whole system, founded as they are on actual observation, are appreciated. If it is not worth while to look after the health of children, which number in the aggregate a full one hundred thousand, as well as the teachers, which exceed two thousand, then we are wrong in our conjectures, and it may be useless to urge the necessity of reform. We confess ourselves unable to say how the Board can possibly dispense with medical inspection. There is, in fact, not a single one of the conditions to which we have referred which cannot be properly met and speedily remedied by the means adverted to.

We have already seen what medical supervision has done towards preventing the spread of small-pox: — of forty thousand pupils vaccinated under the supervision of Dr. O'Sullivan during a recent epidemic, every one escaped contagion. It may be urged that the Board of Health can look after such matters; but in

view of the immense amount of special work to be performed this is absolutely impossible unless special medical officers be appointed for that purpose. But we care not how the inspectors are appointed, so long as competent men are chosen to perform the duties.

As the case now stands, there is not only no medical inspection of our public schools, but, worse than this, medical inspection having been once instituted, is boldly and defiantly abolished. The duty of medical men in this matter is plain enough, and looks in one of the directions of good which they can accomplish as educators of the people and as creators of opinion upon all matters of hygiene. We appeal to the profession, and urge them to take this important subject under consideration, and use every endeavor to educate the people up to the point of appreciating, of demanding the necessary reforms. We are pleased to see so much attention given to the subject, and such efforts made in the direction of the necessary influence to be used, that in the discussion of the paper we can find such gentlemen as Agnew, Jacobi, O'Sullivan, and Peters to speak so earnestly and so much to the point upon the question at issue. Let the profession everywhere follow their lead, and if they act with determination they can create such a sentiment among their respective communities as no school board shall dare, even for political reasons, to disrespect.

The matter is too serious a one to pass by; the facts are abundant to prove the most shameful neglect of the health of the rising generation. We have the necessary data from the schools in this city where great pretensions are made towards perfecting the system of education, and it is fair to presume that the evils exist to a proportionate extent in other localities. In fact, it is reasonable to suppose that elsewhere there are, if possible, greater evils to overcome. Let the various medical societies throughout the country look into the matter; let even individual physicians impress the necessity of reform upon their patients; let every legitimate means individually and collectively be used to this end, and our legislators will soon trim their opinions to suit the demands of the people. A short time since we congratulated the profession that almost every school district in this city had a medical man upon its board; let these gentlemen do their duty as medical men, and, with their brethren throughout the city, not rest satisfied until they are fairly represented in the Central Board of Education. If the present Board of Education had but a single member from our profession, the resolution to abolish sanitary inspection of the schools would not have passed without a timely protest. We trust that the initiative has already been taken. In this connection we express our satisfaction that Dr. O'Sullivan's paper has been published, with the discussion thereon, in a paper that reaches a large class of thinking readers—readers who are ready and willing to appreciate the necessity for the reform advocated.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting June 26, 1873.

DR. E. MASON, President, in the Chair.

AN INTERESTING CASE OF CONGENITAL DEFORMITY.

DR. JACOBI exhibited a living subject, a male, aged nine years, who had a congenital deformity of the face. The deformity was confined principally to the left side of the root of the nose and the internal margin of the brow adjoining. It consisted of an hypertrophy of the skin and subcutaneous tissue, the redundancy being disposed of in vertical folds. Although this was an anomaly in its way, there were other peculiar features connected with the case which gave it interest in a pathological point of view, and threw some light upon the probable origin of the deformity already alluded to, and to the other changes to be noted. Associated with this deformity of the brow there was a marked lack of development of the corresponding side of the skull and face. On examination it was found that the left half of the face was decidedly smaller than the right, due to a lack of development of all its component parts. The left half of the chin was smaller than the right half, not only in its soft but in its bony parts; the same might be said of that side of the nose, the eyebrows, and arches of the frontal bone, the malar bone, and in fact all the bony walls of the left orbit, proportionately decreasing the size of the latter. The ears appeared to have been uniformly developed.

In searching for the cause of this deformity, the idea that the veins had been atrophied as the result of early meningitis had to be abandoned, for the reason that the extremities had not been involved—that the deformity was confined to a very limited portion of the body. This latter fact directed attention to the possibility of the trigeminus nerve being in some manner affected. In connection with this supposition there were other interesting points worthy of notice, viz., the groove of the hard palate of the left side was very deep, while that of the right was normally flat. This condition is one very frequently associated with certain anomalies of the cranium, especially at its base, which anomalies are due, for the most part, to premature ossification of the spheno-occipital synchondrosis. Although normally syndostosis does not occur until before the fifteenth year, bony union may take place as early as birth, or even in intra-uterine life. When the latter condition obtained, the sella turcica were small, also the alæ nasi, the middle portion of the cranium was very little developed, as well as the internal portion of the brain. The vomer was also retracted, the nose more or less sunken and retracted, the root of the nose broader than usual, giving more than the usual distance between the orbits. In connection with the above it may be stated that the general physical development of the child was tardy, and that there was a very low order of intellect.

Dr. Jacobi was inclined to believe that a syndostosis of the spheno-occipital articulation on left side might explain the malformations referred to. If such were the case the trigeminus nerve of that side would be retarded in its development, resulting ultimately in paralysis of its trophic and centric fibres. In proof of the latter, he instanced the fact that the soft palate reacted very slowly on being irritated.

In regard to the condition of the skin at the root of

the nose he believed it to be an angeioma due to mal-development of the trigeminus nerve and constriction of the cranial arteries, which conditions appeared to be due to the premature syndostosis, already alluded to, at the base of the brain. After the question of its pathology was settled, another came up in regard to treatment.

Dr. Sayre remarked that he had seen two or three similar cases, but in none was treatment of any avail.

Dr. Mason thought that the tumor might be an elephantiasis, and if he was right in his supposition he believed it would be best to remove the whole mass at one operation. As it might, however, prove to be an unusual case of angeioma, in which the cellular tissue predominated over the vascular, but in which the vascular element was nevertheless considerable, he thought it prudent to remove the upper portion of the mass first, and see what ultimate effect it might have upon the lower portion.

Dr. Putnam was inclined to the opinion that the malformation was due originally to cerebral hernia, and that this and other changes referred to by Dr. Jacobi could be explained by centric lesions of the brain itself.

MORBUS COXARIUS—CAN OPERATION ARREST WAXY DEGENERATION?

Dr. Sayre exhibited a specimen of morbus coxarius removed by operation from a boy æt. 11 years. The disease had existed for some considerable time, but the diagnosis of waxy kidney and waxy liver having been made out, it was decided not to operate. The patient, however, was so determined to have the bone exsected that he was constantly begging to have it done. Dr. Sayre finally consented to operate, in the belief that by arresting the discharge which produced the waxy degeneration of the internal organs he might not only relieve the patient of much trouble and suffering, but possibly arrest the secondary disease. The head, neck, and trochanters were removed in the usual manner. The patient vomited considerably in consequence of the anæsthetic, but was otherwise doing well.

Dr. Loomis did not think that waxy degeneration of the kidney was necessarily a rapidly fatal disease; on the contrary, he had known patients to live with it a number of years. He believed that the opinions of surgeons in regard to the dangerous influences which kidney diseases exerted over operations would be greatly modified when continued observation and experience should enable us to settle the real significance of the presence of albumen and casts in the urine.

Dr. Jacobi did not see any objection to the operation performed by Dr. Sayre, but, on the contrary, believed it to be perfectly justifiable.

Dr. Putnam remarked that patients did not commence to run down and die with amyloid degeneration until the deposit took place in the muscular coats of the stomach and the intestine; until such time there was always a reasonable hope that operations having for their object the lessening of long-continued discharges would result in benefit.

MULTIPLE FIBROUS STRICTURE OF THE RECTUM, WITH AUTOPSY.

Dr. F. D. Lente, of Cold Spring, presented a specimen, with the following history: Mrs. S., aged 32 years, of rather strumous habit, but in fair flesh, applied to me through her physician, Dr. House, of Haverstraw, for advice regarding a long-standing disease of the rectum. She has never been very strong since she was a girl. Her catamenia have always been regular. Has had children. The first symptoms of her present trouble showed themselves about eight years ago. Consulted a physician at that time, but, as usual in such cases, nothing was done. Has consulted, first and last, nine different physicians and surgeons in New York and Brooklyn—the last was Prof. F. H. Hamilton. He advised her, she says, to continue the treatment which she had been using at times for the past two years, namely, the introduction of bougies. She had never used one larger than a No. 11 urethral bougie. Notwithstanding their small size, their passage was painful, and the distress continued for about fifteen minutes after their withdrawal. About five years ago, noticed a purulent discharge, which increased for three years, and has remained the same ever since. It passes away in gushes, and unconsciously, sometimes falling, in quite a puddle on the floor. She has usually an evacuation daily, which is generally figured, though very small, and always flattened. She has to strain some fifteen minutes. She is in the habit of using an injection of water, or mucilage, or some application which is supposed to have a soothing effect; but they all give more or less pain. The evacuations are accompanied by a discharge of blood and matter. Two recto-vaginal fistulas have been discovered, which cause an increase of the soreness in the rectum, and allow the passage of pus and gas.

Middle of April, 1873.—On examination, I find a stricture at the upper border of the internal sphincter, but so much irritability both of the anus and the stricture as to render an anæsthetic imperative. Under ether I passed the index finger, with some difficulty, through the first stricture, and encountered another about 3½ inches from the anus, admitting the finger to the first joint; there are no irregularities or nodules. On examination, by means of Sims' speculum, the stricture and the surrounding membrane have a vascular, erectile appearance, and there is pretty free arterial oozing. Passed a very small-sized flexible, conical, rectal bougie through these two strictures without much difficulty. Advised injections of a sol. of carbolic acid, commencing with gr. xv. to the pint, about four ounces each time.

May 14.—Saw patient to-day with Dr. House. Better in every respect. Much less discharge since she commenced the injections, the strength of which has been increased to ʒ ss. to the pint. It is remarkable that they always cause a feeling of relief, the reverse of what she has experienced with any other. She has not been able to use the rectal bougie, but uses a No. 15 olive-pointed flexible urethral instrument, which is considerably larger than the instrument she has heretofore employed. It was intended that the sol. of acid should be washed out, after a few minutes, by a larger enema of warm water, but she never passes it, and it has no unpleasant constitutional effect in any way. On examination, find that there is very much less irritability of the rectum, so that I am able to pass the rectal bougie easily through the strictures without ether; but, on approaching the upper part of the rectum, there is more resistance, and pain is complained of; both these symptoms increase as the instrument passes on; but finally, and with no undue force, it passes into the sigmoid flexure. The pain shoots across the hypogastrium, and does not pass off on withdrawing the bougie. The existence of a third stricture is thus rendered very probable, and patient is aware of it herself, and very much discouraged, knowing that it is too high to be reached by the operation (free division) which I had proposed as a last resort for the others.

May 20.—The hypogastric pain continued, Dr.

House informs me, for three days, requiring her to keep her bed; it then subsided, and she has since felt unusually well. Heard nothing of the case, being absent from home, until the 25th, when Dr. House called me to see her, and gave the following history: That on the 22d she felt so much better that she went to the city on some business, returned feeling well; had a good night; and the next morning, on passing her flexible catheter through the strictures, as usual, in order to use the carbolic solution, and on reaching the situation of the upper stricture she felt a sharp pain, which shot across the hypogastrium, and increased rapidly in severity. On visiting her, the doctor found unmistakable evidences of a most dangerous peritonitis. The symptoms increased; the pulse ranging to 160; and the prostration, vomiting, etc., becoming constantly more alarming, notwithstanding the relief of the pain by hypodermic injections of morphia, until the afternoon of Sunday the 25th, when I was summoned. On arriving at Haverstraw, I found that the patient had been dead two hours. In the opinion of Dr. House and myself, there was no doubt of the cause of death, namely, a perforation of the bowel; and I ventured to diagnose the exact spot, namely, in the substance of the upper stricture, from the fact that, after the alarming symptoms had continued for some hours, she had a more solid and satisfactory evacuation than she had had for years.

Assisted by Dr. House, I made an autopsy three hours after death. On exposing the contents of the abdominal cavity, evidences of an intense peritoneal inflammation were at once apparent—dilated capillaries, and the viscera glued together everywhere by layers of lymph; a moderate amount of turbid serum occupying the pelvis. The upper part of the rectum was adherent to the right of the promontory of the sacrum, and on gently detaching it, the perforation, in the midst of the blackened tissue of the bowels, was found. The rectum was now dissected out and removed. On laying it open, it was found that the perforation had occurred, as had been predicted, just in the upper stricture. This and the other strictures were found to be composed of dense fibrous deposit, from half an inch to three-quarters in thickness. The whole rectum, from a point three-quarters of an inch above the upper stricture, was entirely denuded of its mucous lining, and exhibited the ashy surface seen after death from chronic dysentery. The other coats of the intestine were not at all thinned or weakened, even in the immediate vicinity of the perforation.

The particular interest in this case centres in two points: the perforation, and the unusual destruction of the mucous lining of the rectum. It is not easy to explain why this ulcer should have formed, and especially at such a point where the gut was reinforced by so thick a deposit of dense fibrous tissue, and where there had evidently been no preliminary softening of the tissues, even in the immediate vicinity of the circumscribed slough which gave rise to the perforation, unless the dilatation by the larger bougie on the 14th, eleven days before death, had set up an inflammatory action, which, in a tissue but imperfectly organized, might readily end in sloughing. The bougie passed in without force, having been only moderately grasped by the stricture, and requiring for its passage through it only a steady, equable pressure. It is impossible, in such a tissue as was found to have constituted these strictures, that any *tearing* could have taken place with such an instrument, which is merely an enlarged edition of the ordinary olive-pointed French flexible urethral bougie, is hollow and soft, and, in my opinion, the only kind of bougie which can, with any degree of safety, be used in dilating these strictures, more especially when distant from the anus. This was the only specimen recently sent as a sample by the French manufacturers to Tiemann & Co., of New York, and it is to be hoped that this enterprising firm will soon supply the market with them, and with similar ones for the œsophagus. Almost all strictures of the rectum are very sensitive, and it is quite common for severe pain to be experienced during their dilatation, and for severe symptoms to follow—often more severe than those which this patient experienced during the three days following the application. The improvement which ensued after these first unpleasant symptoms passed off, showed also that no laceration had occurred. Whether the ulcer existed previous to the dilatation or whether it occurred solely as a consequence of the slight bruising of an imperfectly organized tissue, the *fact* remains as another of the numerous warnings recorded by almost every writer on the subject, against the old method of treating all strictures of the rectum by bougies, which, though *apparently* simple and harmless, is probably the most dangerous. In this case, there was, unhappily, no alternative, this stricture being out of the reach of any other treatment, and it would have been useless to have attacked the others by any radical method as long as this remained unrelieved.

As regards the destruction of the lining membrane, I had already given the opinion that very extensive ulcerations existed, since the long continuance and the unusual amount of the purulent discharge could be accounted for in no other manner; but the extent of the ulceration actually revealed by the autopsy was entirely unexpected, especially in connection with simple fibrous stricture, and such as could admit of somewhat solid passages. The possibility of the existence of such a condition still further strengthens the position which I have elsewhere taken,* that the sooner a stricture of the rectum, even if not very close, is completely divided, and thus relieved at one operation, the less the danger which the patient will incur.

New Instruments.

A NEW VAGINAL SPECULUM.

By J. H. CHURCHILL, M.D.,

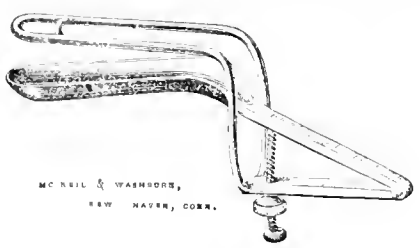
CROSS RIVER, N. Y.

It is perhaps easier to state the requirements of a good speculum than it is to fulfil the indications. New instruments are being constantly devised which are acceptable to a portion of the profession, but none satisfactory to the whole. There is, however, one broad principle of construction pretty generally received, viz., that it should be bivalvular in form.

As to the requirements of a vaginal speculum I make the following postulates: It should be, 1st, easy of introduction; 2d, self-retaining in situ; 3d, fully exposing the parts to be examined; 4th, giving as much room as possible for instruments; 5th, giving as little inconvenience to the patient as is compatible with the ends to be attained; 6th, of simple mechanical construction.

* *Am. Jour. of Med. Sci.* for July, 1873.

The accompanying engraving of my speculum sufficiently explains itself; I therefore give no description



of it. The idea occurred to me in the Fall of 1871, at which time I made a small model. In May, 1872, I had a full-sized instrument made, substantially as here represented, which has given me good satisfaction ever since.

In regard to some possible objections, I will say that the tissues do not drop through the wire blade to obstruct the view; and were the blade solid, or partially filled with two wires in the centre, one design of the instrument would be defeated, viz., complete exposure of vagina as well as uterus, and plenty of room for operative measures.

The patient may be examined à la vache or on the back.

The instrument is manufactured by McNeil and Washburne, New Haven, Conn.

CROSS RIVER, N. Y.

Obituary.

HENRY STEWART HEWIT, M.D., NEW YORK.

DR. HENRY STEWART HEWIT, who died in this city on the 19th ultimo, was the son of the Rev. Nathaniel Hewit, of Bridgeport, Conn., formerly of Fairfield, where Henry S. was born on the 26th of December, 1825. He was also grandson of the Hon. James Hillhouse, of New Haven. When seventeen years old he entered Yale College, but leaving before the completion of the course, commenced the study of medicine with Dr. Valentine Mott, of New York, and took his degree of Doctor in Medicine from the Medical Department of the University of New York in 1847. For about six months he served as *interne* in Bellevue Hospital, and in the following year (1848) entered the United States Army as Assistant Surgeon, and was ordered to Vera Cruz, remaining in that capacity there, and in California, until the termination of the war with Mexico, and for three years thereafter. In 1852 he settled in San Francisco, Cal., where he practised his profession until 1855, when he returned to this city.

At the outbreak of the war, in 1861, Dr. Hewit again entered the United States service as Brigade Surgeon, and from 1862 to 1864 was attached to the Staff of General Grant as Medical Director of the Department of West Tennessee and Mississippi. In 1863 he was taken prisoner, and was for one week in captivity in the Libby prison at Richmond, when he was exchanged and sent North in charge of sick and wounded prisoners, without parole.

In 1864 he took charge of No. 5 General Hospital, at Frederick, Md., where he remained until 1865. With the termination of the war he resigned his position and resumed practice in New York City. During the latter part of his service he was raised by *brevet* to the rank of Colonel.

When the Charity Hospital was reorganized in 1866, Dr. Hewit was among the newly appointed visiting physicians, and continued in the discharge of his duties until the occasion of his last visit, two days before his death.

In 1866 he resumed his charge as Visiting Physician to the House of the Good Shepherd, to which he had been appointed in 1856, and in 1867 he became Visiting Physician to the Home connected with St. Stephen's Roman Catholic Church. In 1872 he was appointed one of the Clinical Professors of Surgery in the Medical Department of the University of the City of New York, and at the time of his death was Vice-President of the Alumni Association of that school, Member of the Pathological Society, of the Academy of Medicine, of the Medical Library and Journal Association, and of the Physicians' Mutual Aid Association. He was also Consulting Surgeon to the Central Dispensary.

His death occurred very unexpectedly. At six o'clock P.M. of the 19th he was at the University. Returning home, he complained of feeling unwell, and immediately after dinner retired to his room and went to bed. Not long afterwards his stertorous breathing attracted the attention of the family, and without recovering consciousness he died at half-past eleven o'clock the same evening, of apoplexy.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from Aug. 19, 1873, *to Sept.* 4, 1873.

MAGRUDER, D. L., Surgeon, leave of absence extended 30 days. S. O. 171, A. G. O., Aug. 23, 1873.

WRIGHT, J. P., Surgeon, granted leave of absence for 30 days. S. O. 178, Dept. of Dakota, Aug. 13, 1873.

KNICKERBOCKER, B., Asst. Surgeon, leave of absence further extended 30 days. S. O. 173, A. G. O., Aug. 27, 1873.

NOTSON, WM. M., Asst. Surgeon, assigned to duty at Fort Gratiot, Mich. S. O. 106, Dept. of the Lakes, Aug. 26, 1873.

BROWN, HARVEY E., Asst. Surgeon, to proceed to Key West, Fla., and report to the Commanding Officer Dept. of the Gulf for assignment to duty. S. O. 170, A. G. O., Aug. 22, 1873.

KINSMAN, J. H., Asst. Surgeon, granted leave of absence for 60 days. S. O. 67, Mil. Division of the Missouri, Aug. 11, 1873.

CARVALLO, CARLOS, Asst. Surgeon, assigned to duty at Fort Mackinac, Mich. S. O. 106, C. S., Dept. of the Lakes.

KING, WM. H., Asst. Surgeon, assigned to duty at Newberry, S. C. S. O. 151, Dept. of the South, Aug. 25, 1873.

Medical Items and News.

A LIBERAL DONATION.—Mrs. Quincy Shaw, daughter of Professor Agassiz, has contributed one hundred thousand dollars to the Museum of Comparative Zoölogy, in which her father is so deeply interested.

ORDRONAUX.—John Ordronaux, M.D., LL.D., Professor of Medical Jurisprudence in the Law School of Columbia College, Boston University, etc., has been appointed Commissioner in Lunacy for the State of New York, in accordance with the provision of a recent law.

PROF. J. PANCOAST.—The Trustees of Jefferson Medical College having requested Prof. J. Pancoast to withdraw his resignation of the chair of anatomy in that institution, he has complied with the request, and will discharge the duties of the chair during the ensuing session.

THE ALUMNI ASSOCIATION of the Bellevue Hospital Medical College are to have their first dinner on the 30th of October next, at Delmonico's.

A TRIUMPH OF MORALITY.—Among the buildings destroyed by the fire in Boston of May last was "*Dr. Jourdain's Anatomical Museum*," one of the detestable exhibitions of casts and models which add their quota to the immorality of nearly all of our large cities. In view of the possibility of its renewal, the *Boston Society for Medical Observation* petitioned the Mayor that a license to exhibit another collection of the same sort be denied. A few days later a letter was received from the Mayor, which showed a most cordial approval of the action of the Society, and contained the assurance that such an application would be met by a prompt refusal. *The Clinic*, of Cincinnati, recommends that the medical societies of other cities should take similar action with regard to the like nuisances.

SURGEON GEN. JAMES C. PALMER, U.S.N., has been retired from active service, and Medical Director Joseph Beale, U.S.N., appointed in his stead.

DR. D. B. ST. JOHN ROOSA, of New York, has been elected President of the American Otological Society.

THE MEDICAL REGISTER FOR NEW YORK AND VICINITY, 1873–74, Dr. A. E. M. Purdy Editor, comes to us with the usual annual welcome. We have looked it over with care, and are enabled to say that it sustains its reputation for accuracy and usefulness. In addition to the material of former years, it contains a list of the medical, pharmaceutical, and dental institutions of the United States; also a list of the registered pharmacists and dentists. The obituaries are, as usual, carefully and discriminately written. A very commendable feature is the introduction of steel portraits of Drs. W. J. MacNevin and James L. Brown, to whose memory the work is tastefully and appropriately dedicated. The amount of practical information in this work renders it invaluable to any physician who wishes a medical guide-book of New York and vicinity.

RULES FOR FEEDING BABIES.—The following excellent rules, on the feeding of babies in general, are extracted from an essay recently read by Prof. A. Jacobi, M.D., of this city, before the Public Health Association. The rules in question were prepared especially as a guide to the public, and coming from such a source, are more than ordinarily valuable. We wish they could be placed in the hands of every mother and every nurse in the land. Embodying as they do the results of the experience of one of our highest authorities on the subject, they are also of particular value to the general medical practitioner. They are as follows:—

I. *Nursing Babies.*—Overfeeding does more harm than anything else. Nurse a baby of a month or two every two or three hours. Nurse a baby of six months and over, five times in twenty-four hours, and no more. When a baby gets thirsty in the meantime, give it a drink of water, or barley-water. *No sugar.* In hot weather—but in the hottest days only—mix a few drops of whiskey with either water or food, the whiskey not to exceed a teaspoonful in twenty-four hours.

II. *Feeding Babies.*—Boil a teaspoonful of powdered barley (grind it in a coffee grinder) and a gill of water, with a little salt, for fifteen minutes; strain it and mix it with half as much boiled milk, and a lump of white sugar. Give it lukewarm, through a nursing bottle. Keep bottle and mouth-piece in a bowl of water when not in use. Babies of five and six months, half barley-water and half boiled milk, with salt and white sugar. Older babies more milk in proportion. When babies are very costive, use oatmeal instead of barley. Cook and strain. When your breast-milk is half enough, change off between breast-milk and food. In hot summer weather try the food with a small strip of blue litmus-paper. If the blue paper turns red, either make a fresh mess or add a small pinch of baking soda to the food. Infants of six months may have beef-tea or beef-soup once a day, by itself, or mixed with other food. Babies of ten or twelve months may have a crust of bread and a piece of rare beef to suck. No child under two years ought to eat at your table. Give no candies, in fact nothing that is not contained in these rules, without a doctor's order.

III. *Summer Complaint.*—It comes from over feeding and hot and foul air; never from teething. Keep doors and windows open; wash your children with cold water at least twice a day, and oftener in the very hot season. When babies vomit and purge, give nothing to eat or drink for four or six hours, but all the fresh air you can. After that time you give a few drops of whiskey in a teaspoonful of ice-water every ten minutes, but not more until the doctor comes. When there is vomiting and purging, give no milk. Give no laudanum, no paregoric, no soothing syrup, no teas.

A TRAINING SCHOOL FOR NURSES is to be opened after November 1st, in connection with the Massachusetts General Hospital, and the future superintendent is visiting Bellevue Hospital in order to become familiar with the course of instruction already inaugurated in the latter institution. Thus far the school at Bellevue has fully answered all expectations.

THE MIDDLETOWN (N. Y.) PHYSICIANS have organized themselves into an association for the purpose of protection against "imposition by a class of people who never pay their physicians' bills, and without any other reason than to evade such payment, change from one physician to another and thereby escape." The secretary of the association is to keep each member informed of all persons who habitually refuse or neglect to pay their bills, and these will have to get along "without benefit of" doctor, or else pay "cash strictly in advance" for attendance.

THE SOCIAL EVIL IN ST. LOUIS.—A St. Louis judge has decided that the law "regulating" the social evil, and which virtually licenses houses of ill-fame, is unconstitutional, first, because it is a special statute, applicable to the City of St. Louis alone, while the State Constitution forbids special laws in cases where provision can be made by general laws; and second, because it is a special law in its application to but one sex, instead of to both sexes, which is contrary to the spirit of the Bill of Rights. The Judge certainly seems to give good reasons for his decision, considered from the standpoint of law alone.

DISRAELI has at last been installed as Rector of the University of Glasgow.

CALL FOR A MEETING OF THE SURGEONS OF THE CONFEDERATE ARMY DURING THE LATE WAR.—A circular addressed to the field and hospital surgeons of the late Confederate States, for a meeting to be held at Atlanta, Ga., on the 20th of May, 1874, has been published in Southern and Western journals, and signed by Dr. S. P. Moore, late Surgeon-General, and Drs. Lorrd, McGuire, Rice, Logan, Darby, and twenty other well-known Confederate surgeons; being based not alone upon the action of the Georgia Medical Association, but upon the earnest solicitations of many Confederate surgeons throughout the South. The object of the meeting is "for the advancement of science—to rescue from oblivion all the important medical and surgical facts developed within the armies of the Confederate States during the late war."

THE HAMPSHIRE MEDICAL COLLEGE has lately been able to complete its new and elegant hall, in great part through the liberality of a Mr. Stoughton of this city.

THE CHOLERA IN NASHVILLE.—Dr. W. K. Bowling, in a very able article in the *Nashville Jour. of Med. and Surg.*, remonstrates against the truth of the statements made by Dr. John C. Peters to the Board of Health of this city, regarding the outbreak of cholera in Nashville during July last, and shows as plainly as can be done by an analysis of individual cases, that, 1st, The disease was not contagious. 2d, That there is not the slightest evidence that it was introduced through any "initial case," and that Dr. Peters's statement that he had "positive information that cases were brought to Nashville, and died there," is a sheer fabrication. 3d, That as regards preferred spots and places, instead of being, as Dr. Peters stated, "almost exclusively confined to the outer limits and low portions of the city," and that it "carried off hundreds of those living near the small streams, or so-called branches, licks, and runs of water, especially Lick Branch, upon one side, and Wilson's Spring Branch upon the other," the disease was most prevalent in localities where the drainage was perfect and malarial influences absolutely *nil*. Dr. Bowling says: "We have shown that the terrific mortality in the hamlet of New Bethel, which carried off nearly half its inhabitants, occurred in a high and dry region, thoroughly drained, and no branch or run in a mile of it. Also on Rolling-Mill Hill, with no branch or run near it, except the Cumberland River, and that separated from the village by a bluff of rock two hundred feet high. . . . On these branches, and all the low grounds they and their tributaries drain, there were but sixty out of eight hundred deaths, seven hundred and forty being on high land." He further stigmatizes Dr. Peters's report as "a tissue of misrepresentations from beginning to end, which will figure in sanitary science hereafter and serve a purpose for ring-makers and job-hunters." The only "localizing causes" which Dr. Bowling deems of value are destitution and the use of vegetables, fruits, and such animal products as butter, cheese, milk, eggs, or honey.

THE *Clinic*, of Cincinnati, also says, regarding the cholera in that city: "The report with which Dr. Peters hastily rushed into the New York daily papers, has done him no credit. It is superficial and untruthful, and his predictions have all proven equally false."

PHILADELPHIA MEDICAL DIPLOMAS.—During the past four weeks five medical diplomas, issued by the American Institute of Philadelphia, have been taken to the Spanish Consul by Cubans for indorsement. The last one was issued September 1, to a Cuban who left Havana February 28, for Spain, and who arrived at New York June 9. It is alleged that they are bogus diplomas, having been purchased, the holders not having gone through a course of lectures. The Spanish Consul laid the matter before Mayor Stokley, and he will take action. All diplomas received by Spaniards or Cubans in this country must be indorsed by a resident Spanish Consul.

A STRIKE AMONG THE DOCTORS.—A melancholy illustration of the social status of physicians has occurred in Aargu, Switzerland, where a regular strike has been entered into by a formal resolution to the effect that the physicians will suspend all visits to the sick poor of the city until a decent remuneration is furnished by the civil authorities. The same rules exist in this regard as prevailed in 1804. While everything else has changed so many times, the fee for visits to the sick poor has remained the same. The scale is arranged so that a physician who visits a patient three-quarters of an hour distant receives from the city authorities the miserable pittance of 70 centimes (35 cts.). A common message carrier receives for the same labor, one franc, *i.e.*, 30 centimes more.—*Allg. Wien. Med. Zeit.*, July 29, 1873.

UNIVERSITY OF PENNSYLVANIA.—Until the new college building and hospital on the west side of the Schuylkill are ready for occupancy, the Medical Department of the University of Pennsylvania have secured possession of the old Pennsylvania College building, where lectures will be given next winter.

DR. EDWARD WARREN, late professor in the Baltimore College of Physicians and Surgeons, has recently been appointed by the Khédive of Egypt to the position of staff-surgeon in his army, with the rank of colonel, and with the privilege of practising medicine and surgery in the city of Cairo. Dr. Warren is the author of the famous repartee to the Attorney-General, in the Wharton case, that "lawyers' mistakes sometimes hang six feet in the air."

DR. LYMAN CONGDON, of Syracuse, formerly superintendent of the Willard Asylum, has been appointed superintendent of the Inebriate Asylum at Binghamton, vice Dr. Dodge, resigned.

THE MAINE MEDICAL SCHOOL.—The Overseers and Trustees of Bowdoin College have made the following elections for the Medical School of Maine: Dr. E. W. Jenks, Professor of Diseases of Women; Dr. Alfred Mitchell, Professor of Obstetrics and Diseases of Children; Dr. Robert Amory, Professor of Physiology; Dr. T. H. Gerrish, Professor of Materia Medica.

A REAL LOVER OF HIS RACE, in view of the approaching era of political speech-making, advertises for some secret and expeditious method of communicating lockjaw.

THE NEW HOSPITAL BUILDING IN NEW HAVEN, erected during the past year, is situated on the grounds of the General Hospital Society, and connected by a corridor with the old hospital building. It is considered a model hospital building, and consists of a centre building, with two wings, all three stories above the basement, with a frontage of 263 feet. The centre building is 50 by 64 feet, the west wing 29 by 87 feet, the east wing 29 by 112 feet, with a capacity for 114 beds, besides several large rooms for the accommodation of special patients. Unusual attention has been given to both heating and ventilation, also to all other matters of detail, such as bath-tubs, wash-basins, water-closets, gas, medicine, and linen-closets. The entire cost, when completed, will be about $84,000, which has been defrayed by the subscriptions of benevolent persons.

Medical Department of Life Insurance.

THE LAWS OF TRANSMISSION OF RESEMBLANCE FROM PARENTS TO THEIR CHILDREN.

By JOHN STOCKTON-HOUGH, M.D.,

OF PHILADELPHIA.

PART II.

WHY CHILDREN RESEMBLE THEIR MOTHERS MORE THAN THEIR FATHERS.

BUFFON says: "The molecules furnished by the father ought to procure his resemblance, if they are more abundant than those of the mother, and when the father furnishes less it leaves the infant more of the resemblance of the mother, which latter occurs very frequently."

Darwin has progressed but little further, where he suggests that the resemblance of offspring to one parent in one part, and the other in another part, is not difficult to understand on the admission that the gemmules in the fertilized germ are superabundant in number, and that those derived from one parent have some advantage in number, affinity, or vigor over those derived from the other parent."*

These explanations are scarcely more definite, and little different from the ancient opinions on the same subject, a sample of which we give from Lactantius: † Similitudines autem in corporibus filiorum sic fieri putant. [Varro scilicet et Aristoteles] cum semina inter se permixta coalescunt, si virile superaverit, patri similem provenire, seu marem seu fœminam. Si muliebre prævaluerit, progeniem respondere maternam. ‡

"Even in hybrid plants, Kœlreuter says he has produced or diminished paternal resemblance by increasing the quantity of impregnating dust," while Mr. Knight says: "Except in cases where superfœtation took place, I have invariably found the effect of a very large or a very small quantity of pollen to be invariably the same in its influence on the offspring." §

It is well enough to observe here that the discrepancy between these observers may very possibly be due to the time or *degree of maturation of the ovules*, when the pollen was applied.

It is quite possible that great inequality in the ages of the parents may have some effect in determining the resemblance to either parent, as some authors attribute defects in children to this cause, and Hoffacker and Saddler have shown that the proportion of sexes born to such parents differs very considerably from that among couples of nearly the same ages.

Helvetius, Weikard, and others, thought that the resemblance of children to their parents depended less upon hereditary transmission than upon education, imitation, and other analogous exterior circumstances. Burdach* very properly remarks, that "with the excellent intention of raising a man, which is free to all who desire to make use of that liberty, it is too far from the truth to hazard that hypothesis; for hereditary qualities have really more control over our constitution and our character than all the influences from without, physical and moral. As the children of a marriage often differ altogether the one from the others, in regard to constitution, inclinations, and propensities, although having all been raised under circumstances equally good," etc.

Congenital conditions are not the only ones which are subject to hereditary transmission; the same thing happens equally to those which are accidentally acquired or have been subject to the will. It is not rare to see mastiffs,† dogs, and cats, born with a short tail resembling the acquired malformation in their parents.‡

It seems, therefore, from all the authorities cited, to be pretty generally believed that mothers impress their children, of both sexes, with their physical and moral peculiarities, their constitutional tendencies and hereditary diseases and defects; in short, a general resemblance more marked than that derived from their fathers; and it is not at all surprising that this should be so, for the child is for a considerable period, amounting to at least two years, under the exclusive control and influence of the mother and her varying physical condition during this time.

In the first place, it may be well to inquire, when and where either parent begins to impress the product with a resemblance to themselves. For convenience, we may divide the time and place of impression into four parts, viz.: 1. Impression on either element before fecundation. 2. Impression from the instant of fecundation until the product leaves the Graafian follicle. 3. During gestation. 4. During lactation. At each one of these periods the ovum or product of conception usually receives impressions, but most in the second, or indeed principally there, as some authors have it, for they say that both resemblance and hereditary disease are communicated during this period. Constitutional diseases and peculiarities are probably communicated during this time, though the period of gestation must be reckoned to have great influence on the tastes, inclinations, and *qualités* of the physical and mental faculties.

It is quite probable that the ova of the female have an initial existence, as primordial cells or germs, at a very early period in the life of the child, and are in some degree capable of receiving and retaining impressions which may influence the products derived from them.

On the other hand, the spermatozoa are probably not in a condition, (if indeed they have an existence,) much before puberty to receive or retain the result of impressions made upon the man. So then, before impregnation, the female element has, in all probability, been subjected to the varying physical conditions of the woman for a much greater length of time than the male element has been to the varying physical states of the man; and the former is, moreover, much more susceptible to such impressions than the latter. Some may think that the ova are not susceptible of being influenced by such methods as I have suggested; to

‡ Dr. Allen, of Lowell, Massachusetts, very properly calls attention to the great want of rules whereby we may judge of resemblance and constitutional predisposition. He says: It is true that the general fact of resemblance of children to parents has long been admitted; but then we have no guide or rules whereby every feature and shade of this likeness can be traced out between the offspring and the parent, or dissimilarity accounted for. While in books and journals there are many admissions that there is, and must be, much truth in this law of resemblance, you may search medical and other libraries through and through without finding a single treatise or scarcely an essay that discusses this topic in an intelligible manner. But it is an encouraging fact that the most progressive men in the medical profession, both in Great Britain and in our own country, are waking up to the truth and importance of this subject, especially as it is manifested in the transmission of disease. A careful inquiry into the diseases of a person's parents and ancestors enables one to understand more distinctly what are his predispositions to particular diseases, and what are constitutional and what are not.—Nathan Allen, M.D., LL.D., "Hereditary Influence in the Improvement of Stock," &c. 1872, pp 30, p. 10.

‡ Burdach, Physiol., v. ii., p. 251.

these I can only point to the great difference in appearance, constitution, viability, tastes and inclinations of children by the same parents, while twins are proverbially alike in some one if not all these particulars.

Dr. Martin Barry, in his observations on the "*direction*" of development as influencing the "*individual* peculiarities of structure," says: "Strictly speaking, therefore, no two individuals of different births can have the same parentage; for though the *individuality* of the parent, or of each parent, does not change, yet as *individuals*, the parents are continually changing.

"The more nearly *contemporaneous* separation of their elements, and the contemporaneous derivation of nourishment from the maternal fluids, during fœtal life—but especially the former—are perhaps the causes why twins are sometimes so much alike in individual structure; and *super*-fœtation may be, in part at least, the cause why this is not always the case.

"There is, however, another cause why individuals, even of the same birth, should differ, viz.: the different periods, at which the maternal portion of the germs may have been first secreted in the ovary; for, though continually renewed, they must have in consequence a more or less peculiar state of being."* This point is well illustrated in the frequency of differences in color, constitution, etc., in the young of the same birth in multiparous animals.

We conclude, therefore, that there are few, if any, physical, moral or mental acts of a woman's life that are not without some influence, however inappreciable, on every child which she may subsequently bear. And every *succeeding* child is influenced by the impressions left on the maternal organism by each and every *preceding* child, though they may all have been of the same father, and this influence is increased with the number of fathers. This brings us to the subject of resemblance of a child by a second husband to the first, which is not within the limits of the subject under discussion.

After or at the time of impregnation, the father begins to exert a combined influence with the mother, though this influence is much less considerable than that of the female, for in addition to the influence exerted before impregnation, she has begun a new process which only ceases at the completion of the term of gestation. During lactation, the child is impressed in some degree, however slight, by the varying conditions of the mother. Through this source it may imbibe each vices, diseases, tastes, and inclinations. Indeed, some writers have made this an argument against the use of the milk of the lower animals, lest the child should be brutalized by such food. Tupper† contends that children are even educated in their mother's milk. Every child a woman bears inoculates, so to speak, her constitution with some of the peculiarities of the father of the product, and, other things being equal, it is probable that the greater the number of children the greater will be the impression made upon her system by the husband, until she will finally come to resemble‡ him in some degree at least. This influence is probably greater in the cases of gestations with daughters than with sons, for three reasons, viz.: 1. The father's influence begins earlier in the case of female conceptions, as the ovum is fecundated at an earlier period of development. 2. Female fœtuses sap the vitality of the mother more than males. 3. Daughters resemble the father more than sons. From these reasons, then, it is only fair to infer that a woman who had borne a certain number of daughters ought to resemble their father more than after bearing the same number of sons. The husband will therefore lose a part of his individuality, or rather his wife will have acquired a share of it. If this be true, the younger children ought to resemble the father more than the elder, and, if the mother's system can be inoculated with his defects and diseases, even though they be constitutional, as is certainly the case in syphilis, it is only fair to infer that the younger children would be more likely to inherit a predisposition to these affections than the elder,* and consequently have relatively a lower viability.

This fact of a woman acquiring a resemblance to her husband might be used as an argument against the propriety of a widow marrying her deceased husband's brother, though it would not materially affect the propriety of a widower marrying his deceased wife's sister

It is well known also that women sometimes become masculine, and females of the lower animals take on secondary sexual characters of the male, though the reverse seldom, if ever, happens.

I am told that Mr. Tylor† has ingeniously explained some apparent anomalies in the prohibition of consanguineous marriages not extending equally to the relatives on both the male and female sides. Though I have not seen this work, I imagine it refers to the matter just mentioned.

Mr. Clark, a breeder of fighting cocks, "found, after repeated trials, that there was a greater reduction of weight in the young from a father paired with his daughter, than from a mother with her son."‡ From this it would appear that there is a greater resemblance between the father and daughter than between the mother and son.

Gaertner§ repeatedly found that when a hybrid was used as the father, and either one of the pure parent-species or a third species was used as the mother, the offspring were more variable than when the same hybrid was used as the mother and either pure parent or the same third species as the father.

Sedgwick, after referring to the transmission of hypospadias by females, is of the opinion that "it cannot at present be satisfactorily decided whether such interruptions in the transmission of peculiarities thus necessarily limited to the male sex are equally liable to occur in those peculiar to females by transmission through males. It is well known that the power of giving a copious supply of milk may be transmitted by the bull as well as by the cow; but my observations on this subject lead me to infer that, in all cases of interrupted descent in hereditary disease, the transmission by females is more common than by males, and that as regards the class now under consideration, it may be asserted, in general terms, that whilst there is little difficulty on the part of females to transmit diseases and defects of exclusively male organs, there are very few, or rather scarcely any, corresponding cases in which the reverse occurs."‖

ATAVISM.

Atavism, from *atavus*, an ancestor, is a term applied to the resemblance of a child to the grandparents or more remote ancestors, rather than to its own parents. Rückschlag in German, Pas-en-arrière in French, and Reversion in English, are synonymous terms.

Atavism is a word, like Idiosyncrasy or Catalysis, with a conventional meaning, expressive of a condition, without embodying in any degree an explanation of the cause. Indeed, no explanation of the proximate cause has ever been given, to my knowledge, though evolutionists have been satisfied in ascribing atavism to "*reversion*," which, though new, is scarcely an improvement on the ancient term, as it only means a turning back to an original condition, which would seem to indicate a deterioration or inferior degree of development, an inference manifestly incorrect.

The true cause of atavism is a *dynamic* one, just as I shall show, in a succeeding article, that "the cause of the rotation of, and nearly equal number of, sexes in births" is a dynamic one, the fœtus *in utero* impressing the mother in a *greater* and *lesser degree alternately*,—one sapping the vitality of the mother in a greater degree, and the next succeeding one in a lesser degree. I cannot stop now to discuss this theory further, but must refer the reader to the article above mentioned.

Atavism, however, is usually subject to *sexual differentiation*, which fully confirms the view I have given of the proximate cause. This will be explained further on.

Atavism, then, is due to the dynamic force in one generation exhausting itself in the next, then regaining, then losing, in a series of alternations. This dynamic difference in the resultant, so to speak, of the elements uniting to form a new being, finds an explanation in the different states or conditions of development, or degrees of maturity of the ovum at the time of fecundation (the variations in the law are explained by differences in nutrition before and after fecundation).

Darwin * says: "When one parent alone displays some newly acquired and generally inheritable character, and the offspring do not inherit it, the cause may lie in the other parent having the power of prepotent transmission. But when both parents are similarly characterized, and the child does not, whatever the cause may be, inherit the character in question, but resembles its grandparents, we have one of the simplest cases of reversion. We continually see another and even more simple case of atavism, though not generally included under this head, namely, when the son more closely resembles his maternal than his paternal grandsire in some male attribute, as in peculiarity in the beard of man, the horns of the bull, the hackles or comb of the cock, or as in certain diseases necessarily confined to the male sex; for the mother cannot possess or exhibit such male attributes, yet the child has inherited them, through her blood, from his maternal grandsire."

"Atavism, or the principle of latent inheritance, is a normal phenomenon in certain forms of disease, as in color-blindness and the hemorrhagic diathesis, in which it is associated with sexual limitation, and pursues for the most part a very regular course. It is well known that in these two forms of disease the order observed, both in their development and transmission, is usually complete, so that whilst the disease in each case shows itself only in the males of the first, third, and fifth generations, its transmission is effected only by the females of the second and fourth generations; and as this occurred also in my case of ichthyosis and in other diseases already noticed, the question naturally presents itself whether in those cases in which two or more members of the same family are affected, without any evidence of the occurrence of the same disease in preceding generations, it may, notwithstanding, have occurred without being recorded."*

Sedgwick states, in opposition somewhat to M. Girou's † opinion on this subject, "that although the principle of atavism is intimately associated with that of sexual limitation, both in natural as well as in morbid development, yet it is far more common in the latter than in the former state." ‡

"M. Girou endeavored to show that children naturally resembled their grandparents of the same sex, and that the transmission of this family likeness was effected through parents of the opposite sex. It is, however, quite evident that although such atavic resemblances may often be noticed, yet contrary facts can be so readily adduced as to disprove the general application of the above principle in the normal development of the human race." . . In connection also with this subject, it may be observed that in the offspring of dissimilar parents there is never, as a rule, complete fusion of the two parents, but a distribution of the characters peculiar to each; and although this is less strongly marked in the offspring of the human race than it is in that of the lower animals—as, for example, in the case of some hermaphrodite insects, in which family quarterings may result from specific distinctions of sex being associated without fusion in the same specimen—yet, as regards the inheritance of disease, it will be found that the morbid characteristics of one or the other parent are either completely repeated or completely absent, but not fused together in the offspring. This is what is meant in inheritance by the doctrine of 'election,' which is based on the observation that certain attributes of organization peculiar to one parent are repeated in the offspring; and it offers a reasonable explanation of the fact that children often inherit the defects of one parent, whilst in many other respects they resemble the other; and the inheritance in these cases, both natural and morbid, may sometimes be conveyed to them by atavic descent." (Sedgwick.)

Mr. Westwood observed in a specimen of the scare egger moth at Berlin, that the front part of the body and front wings were half male and half female, and the hind part and hind wings half female and half male; the characters of the male and female insect being exhibited on opposite quarters of this specimen.

Indeed the exhibition of secondary sexual characters or peculiarities belonging to the opposite sex to that of their possessor, in animals naturally dioecious, is not without example even in the human race. We see women with beard, and men without; so also there are masculine women, possessing other peculiarities of the male, and effeminate men possessing characteristics of the female. Even where there is no apparent mixture of physical characters of one sex in an individual of the opposite sex, the mind of some men is effeminate, while that of some women is masculine.

Hence the following epigram of Martial:

> But while thy limbs we rough and bristly find,
> Effeminate and wanton is thy mind.
> —Lib. ii., Epigr. 36.

Also:

> Dum dubitat natura gravis puerum faceretne puellam,
> Factus es O pulcher pene puella puer.
> Ausonius,—Epigram 107.

* Animals and Plants under Domestication, vol. ii., p. 29.

* Sedgwick, op. cit., July, 1863, p. 186.
† De la Génération, Paris, 1828.
‡ Op. cit., July, 1863, p. 190.

Cases are not wanting in which one half of the body resembled one parent and the other half the other parent. Sibley relates the case of a young girl in Somersetshire, with hair on her head of two remarkably distinct colors; the right side from an exact parallel line which divided the skull into two equal parts was almost black; but the left side, from the same line, was of a reddish yellow. As she grew up the dark hair became jet black, exactly like that of her father; while the other side became of a strong carroty red, precisely like that of her mother. The hair on all other parts of her body was diversified in the same manner. She lived to be 28 years of age, and was resorted to as a great curiosity.

Another case is recorded by the same author where the son of a white father and a negro-mother had the whole of the right side white like the father, and that of the left black like the mother. Half the hair on the head was long and brown like the father, and the other half black and woolly like the mother.

A third case is given, where a negro-man married a white woman. By her he had two sons and three daughters, who were mulattos, except the eldest son, who was the first-born. From the head to the navel, all around his body he was remarkably fair, had a fine skin, handsome round features, light-brown hair, and sanguine complexion, like his mother; but below this he was completely black, with short woolly hair, exactly like the father.*

Buffon declares that the offspring of a black man and a white woman are often pied or spotted. I remember having seen a black woman having large white patches on different parts of the body. Though I have several times seen the offspring of a white woman and colored man, and less frequently the reverse, they presented nothing unusual.

Prof. Asa Gray † described an apple half russet and half Spitzenberg, the line of demarcation being quite distinct. Apples have also been found with one half sweet and the other half sour. This is the more remarkable from the fact that apples have five carpels, from which we would expect the divisions to be in fifths rather than halves.

Sedgwick says: It appears to be the rule in reproduction, that the lower the position of the organized beings the more constant is the occurrence of the principle of atavic or uninterrupted inheritance, this associated principle of sexual limitation being gradually merged into that of alternation of form. So that whilst in the higher invertebratæ there are alternations between the sexual and the virgin forms of reproduction, and in many of the lower invertebratæ between the hermaphrodite and the gemmiparous, in the corresponding alternations which occur in some of the lowest conditions of animal life, the sexual element, if not altogether lost, exists in too rudimentary a form for us to recognize its presence.

"It may also be remarked, that although the occurrence of atavism in disease is usually effected through the female, yet it occurs also, though less frequently, through the male sex. Illustrations of this are given in many cases of disease already cited, and among the lower animals it may often be noticed as a natural phenomenon. It is well known, for example, that the supply of milk by cows is hereditarily influenced by the bulls rather than by the cows from which they are directly descended, and that the character of the secretion, as regards both the quantity and the quality of the milk, is chiefly derived from the paternal grandmother by atavic descent,* and as we descend still lower in the scale, we find, for example, in the case of insects, evidence more or less decisive in favor of the transmission by either sex of the distinctive peculiarities of the other."

From all that has been brought forward concerning atavism or interrupted descent, it would appear as if it were quite as important, in getting the family history of an individual with a view of predicting his longevity, to inquire into the history of his grandparents, as well as that of his parents. Indeed, according to the showing of some authors cited, the facts concerning the grandparents would be much more important than those concerning the parents; yet in my experience I have not known such facts to be required by life companies, though I have often given them.

(To be continued.)

MEDICAL EXAMINATIONS.†

THE subject of Medical Examinations for Life Insurance has given rise to such frequent and voluminous discussion in the insurance publications, by their editors, by the General Agents and Solicitors, and occasionally by the Doctors themselves, that the topic has well-nigh become a threadbare one; yet it may be fairly doubted if any of the numerous writers, who have felt competent to deal with the question, have had anything more than confused impressions as to its importance, and a striking lack of practical knowledge of the matter in its relations to the business of life insurance as at present conducted by the companies—nor does the writer of the present article claim any special fitness for the task, further than may naturally have fallen to him in the course of some years' acquaintance with insurance companies and their agents and medical examiners, and an earnest desire to further in his feeble way the correction of abuses which he conceives to exist—abuses which are fraught with evil for the companies, the agents, and the doctors. . . . . The mistakes in the selection of medical examiners, commence, it is fair to assume, with the companies themselves, in a too loose administration of their medical affairs at the head offices, and in too great latitude of judgment given their general agents. That many of the companies manage loosely and carelessly their medical affairs, may be seen by reference to the official reports for the last few years. A striking difference in the ratios of mortality will not fail to strike even a casual observer. That this inequality is due in great measure, if not altogether, to different degrees of care and competence in the choice of risks, is an inference to be correctly drawn; and the conclusion is inevitable that all companies are not equally judicious and skilful, though they all equally claim to be. Some special facts bearing upon this point, within the personal knowledge of the writer, it would not, under the circumstances, be proper to state; it is otherwise, however, with regard to the second proposition—that too great extent of judgment is allowed to general agents upon matters purely medical, about which they comprehend little or nothing.

* Burdach, Traité de Physiologie, tom. ii. p. 117, and Giron, De la Génération, p. 127. Out of Sedgwick, op. cit., p. 191-2; also Thierry.

† The original article, of which this is a pretty full extract, will be found in the May and June numbers of the *Coast Review*, a vigorous journal published monthly in San Francisco, California. The writer is evidently well acquainted with the evils of which he speaks, and does not hesitate to lay the blame upon those who deserve it. His statements concerning the proportion of unfit medical examiners are, we think, altogether too strong, at least so far as the Eastern and Middle States are concerned. We have no knowledge of the fitness or unfitness of medical examiners in California, but presume that the proportion of good physicians is as large there as elsewhere.—EDITOR.

A general agent of one of the largest Eastern companies was asked by the resident medical officer of another Eastern company for certain information as to the qualifications and standing of a gentleman who had been employed as physician by the former—and, in substance, this is the answer received: "Well, he's a pretty good kind of a fellow—I've known him a long time—I do not really think he is much of a doctor, but I reckon he is *good enough to make medical examinations. I* accept his work *myself*." And this is a fair example of the ignorance and self-sufficiency pervading the mind of the average general agent upon this important subject. A man may not be a very good doctor, yet he is capable of making a sufficiently thorough and intelligent examination for life insurance! So far is this from the truth, that it should be one of the first things impressed upon those who make choice of the medical officers for a company, that *it requires a physician of greater skill, of better judgment, of higher integrity, to make a thorough, honest, and efficient examination of a man who declares himself to be in perfect health*—as is the case with all applicants for insurance—*than to diagnosticate disease in one who states himself to be sick, or prescribe remedies for his ailment.*

Another general agent of a pre-eminently "conservative" company is at great pains and expense of words in *instructing* his examiners in the rules and regulations of his employers bearing upon certain hereditary diseases—*as interpreted by himself*—and this same general agent, in filling out an application, proposes to suppress a statement, made by the applicant, of the existence of consumption in a collateral branch of his family, as being entirely irrelevant to the case in hand, and calculated to produce an "unnecessary prejudice" at the home office.

Taking solicitors for insurance as a class, there can be no manner of doubt that the medical man is selected by them solely on account of his "social qualities," of the assistance expected to be obtained from him, of his extensive acquaintance and generally "accommodating" disposition, and not because of his down-right ability to serve the company employing him. Indeed, were the desire ever so strong to employ physicians for their capability and integrity alone, the average solicitor is not a man able to make the discrimination.

In what has been written here we are aware that strong language has been made use of. We have not hesitated to call a spade a spade, when we have felt assured we were right. The truth of this matter of the abuses to which the customary mode of choosing medical examiners is subject, has been long enough hid in a well, and the evils inevitably growing out of it have been too industriously kept out of sight. We do not expect any one of the general agents to believe what we have said, and we are sorry for it.

> "No rogue e'er felt the halter draw,
> With good opinion of the law."

Something further remains to be said of the medical examiners themselves—something to be said plainly—it is to be hoped not unpleasantly.

We deem it well to apologize in advance to those of our medical examiners (and there are many of them), who sincerely feel the responsibility of their position, and endeavor to discharge their duties with scrupulous fairness to the companies. These gentlemen we hold in the highest respect.

There is a class of men, though, who write themselves doctors, through having, like Molière's *Malade Imaginaire*, fitted themselves out with a melancholy cap and robe, and committed to memory a few set phrases of macaronic Latin, in whose hands a large share of medical examinations is habitually placed—Dulcamaras, Sangrados, Slops, hangers-on of insurance offices—whom, without knowing exactly why, we cannot help regarding with a curious mixture of sorrow and contempt.

There is another, and yet a larger, class of medical examiners whose chief fault lies in their extreme carelessness. To the first of these three classes we are not now addressing ourselves. To the other two, whatever criticism of medical examiners follows here is intended to apply.

It was assumed before that the prevailing mode of choosing medical examiners, in placing too much power in the hands of agents, is the cause of much of the increased mortality of the companies—that a large share of this mortality might have been avoided, had greater care and more intelligent methods obtained in the selection of risks,—and we have not thought any elaborate discourse necessary in support of our assumption.* The thing is too obvious, and the facts too easy of access. We shall astonish some of our friends when we say that we do not believe that one medical examiner out of four appreciates the responsibility of his position; that not one out of four but enters upon his examination with a tacit prejudice in favor of the agent and the applicant, and that not two out of the four will be able to entirely overcome this prejudice when the certificate comes to be filled up. This is a sweeping statement, but we believe it is within the truth. Look now, for a moment, at the position of the medical examiner, as we conceive him to exist. *Item:* he is appointed by the agent. *Item:* appointed by the agent in the interest of the agent. *Item:* he is, probably, the friend or acquaintance of the party to be examined. *Item:* the party to be examined may require, at some future time, the services of a physician. *Item:* therefore not to be offended. *Item:* this agent will doubtless have other applicants to be examined. *Item:* therefore on no account to be offended. *Item:* the company is large and prosperous. If this man die, the loss, being distributed among so many policyholders, will be inappreciable. *Item:* he is poor, and if he die uninsured, his family will be left unprovided for. *Item:* if we err at all, let it be on the side of charity. And, after the examination is over, let us add, finally, *Item:* this is a first-class risk . . . . . Do you say that such reasoning as this is mere nonsense, that, in a few exceptional cases, such considerations as we have supposed may have some weight with the medical man, but they are of only very unfrequent application?

Tell us, then, how you will account for occurrences like the following: A medical man who stands at the very head of his profession in the region in which he lives, a graduate of one of the first medical schools in the country, and who is employed by the most careful companies—a man fond of boasting of his skill and sagacity—examines, and accepts unqualifiedly, for a $10,000 policy, an applicant well-known to him, and with whom he is in daily intercourse, who bears the reputation of being a confirmed drunkard.

In conclusion, we wish to offer only this suggestion of obvious import: that the *entire control* of a company's medical affairs be left with medical men of known integrity, who shall be made to feel themselves, in their standing at the home office, wholly independent of agency influences—as the first and most essential step in any amelioration of existing evils.

* The mortality of the fifty-five companies doing business in the State of New York shows an increase for 1872 over 1871, of almost twenty per cent.—a rate altogether out of proportion to the rise of mortality naturally due to advanced age of the risks.

ON THE QUESTION OF SENDING MEDICAL EXAMINERS' REPORTS DIRECTLY TO THE HOME OFFICE.

BY A MEDICAL DIRECTOR.

Among all the life companies, excepting one, it is customary for the medical examiner to make out his report on the back of the application, and then to entrust it to the agent for transmission to the home office. This practice, it appears, meets with universal condemnation on the part of all medical examiners outside of the larger cities.

In a previous article, without having given much thought to the subject, we expressed the belief that the proposed plan of sending the physician's report directly to the home office, separate from the application, would not obviate the difficulties and temptations complained of. After reading, however, the communications published in the last two numbers of the insurance department of this journal, we do not hesitate to say that we now entertain a different view in regard to this question, and are disposed, with the writers referred to, to advocate the plan of separate medical reports. These examiners understand thoroughly the working of the present method by actual experience, and their views are therefore entitled to greater weight than those of any person who simply considers the question in the abstract. They urge the change on the following grounds:

First, because it enables the examiner to give the company an unbiased estimate of the risk, without subjecting himself to the ill-will of the applicant.

Where the examiner entertains doubts whether or not he should recommend the applicant, who is perhaps at the same time his patient or a personal friend, it will undoubtedly strengthen his hesitating loyalty to the company to have this opportunity of making a confidential report. The presence of the applicant, and often also of the agent, not unfrequently obscures the judgment of the examiner, who, if left to himself for a moment and allowed to decide by confidential letter to the home office, would give the company the full benefit of any doubts that might beset his mind.

The second reason urged in its favor is that it renders it impossible for the agent or any other interested person to tamper with the physician's report.

We can readily conceive that agents might be found who would do such a thing, and yet we have never heard of a single instance where the physician's *no* was changed to a *yes*. A slight change like this, however, is all that is needed in those instances where the physician simply declines to recommend the risk without stating, in his preceding answers, anything sufficiently grave to contradict the final approving *yes*. In the ordinary course of things, the physician never sees his certificate again after it has once passed out of his hands, and yet he is the only person capable of detecting a fraud of this nature.

It is apparent, therefore, that the companies incur a very great danger in continuing the present practice of allowing the agents to receive and transmit the examiner's report to the home office.

The next most important question is, What are the objections to the carrying out of the plan advocated? The increased expense can hardly be brought forward as a serious objection, for it surely would not exceed $100 per thousand applications—a trifling sum to pay for the greater protection against fraud.

Another objection to the plan would be the vexatious delays caused in the issue of the policy, owing to the tardiness of the doctors in sending on their reports to the home office. We admit that in all matters of correspondence country physicians, as a class, are *apparently* dilatory. Ample excuse, however, may be found for this in the nature of a country practice, which leaves no time for letter-writing. But the case here is different, for the examination once made and the applicant out of the way, the physician has simply to add his recommendation or rejection of the risk, and place the report in an envelope ready for mailing. This is a much simpler matter than writing a letter, and differs from the method now followed only in the fact that the examiner must himself place the report in the mail, and not deliver it unsealed to the agent for that purpose. We do not believe, however, that, in the carrying out of the plan, this objection would prove a serious obstacle in the way. The chief trouble to be anticipated would come from the agents, who would be quick to see in this method the death-blow to one of their favorite practices. We refer to the custom of taking a rejected applicant from one physician to another, until he finally passes a favorable examination. The applicant at the same time is told that the refusal of one physician to recommend the risk is not to be considered as a rejection, unless the company has formally refused to write a policy upon his life. By this stretch of conscience the applicant is enabled to write out a clean application, and the agent in this way secures his prize. The proposed change would in a great measure put an end to this unscrupulous practice, and hence the opposition to be expected from those who depend upon it for at least a part of their fees.

A few companies have had the independence to take the appointment of medical examiners entirely out of the hands of their agents. In doing so they met with decided opposition on the part of many of these men, but we believe that we state the truth in saying that not one of these companies would now return to the old method, so confident are they of the greater safety of the new. For these companies a change like the one here advocated would be a comparatively easy matter, and would probably meet with but little opposition. The other companies, however, being still to a great extent at the mercy of their agents, would find that the change involved serious difficulties.

A FEW REMARKS ON THE APPOINTMENT OF MEDICAL OFFICERS TO LIFE-INSURANCE COMPANIES.

BY A CANADIAN EXAMINER.

The devotion of a certain space in the Record to the discussion of subjects relating to the Medical Department of Life Insurance will certainly prove a valuable and much needed addition to periodical medical literature, and it is to be hoped that examiners throughout the country will avail themselves of this means for the exchange of opinion and the free discussion of questions bearing on their special duties and responsibilities. Medical officers are, it is supposed, the confidential advisers of the companies whose fees they receive; they are expected, in the words of a recent communication by a secretary, to "resolutely stand like an alert and faithful sentinel between the company on the one hand, and the unsafe and undesirable risk seeking admission thereto on the other." * We are told that "upon his skill and fidelity and independence depend largely the prosperity and even safety

* Quoted by Secretary from Prof. J. Adams Allen's work on "Medical Examinations for Life Insurance."—Editor.

of the company for which he acts." Admitting that these quotations describe correctly the relation which ought to exist between the company and its physician, does the company use the most reliable means at its command to secure in its examiner skill, diligence, truthfulness, and independence?

In ordinary business transactions it is the almost invariable rule that persons entrusted with extremely important duties, involving large sums of money, are required to furnish bonds that their contract shall be fairly carried out, and although this rule cannot be applied in the case under consideration, it points to the necessity of exercising great vigilance and caution. The examiner should be selected by the representatives of the company at its head office, on the recommendation of a competent and duly authorized medical man or Board, and not, as is too frequently the case, either directly or indirectly by outside agents. Agents acquire their incomes from premiums actually paid, and every applicant rejected by the medical examiner deprives them of a certain sum of money. It is natural to suppose—at any rate experience has taught us, especially where the cause of rejection is not satisfactory to the agent—that the greater number of agents resent this; that they feel aggrieved; and although it may not be in their power formally to remove the examiner, they often manage gradually to displace him by one more pliant or ignorant, or with more sympathy for his employer than for the company. Companies generally, in disputes between the agent and examiner, quietly sustain the former in preference. Competition runs high, and good canvassers seem to be of more value than reliable examiners. It must be a source of satisfaction to the profession to know that there are comparatively few of its members open to the charge of wilfully and for a consideration falsifying their reports or concealing information which would undoubtedly reject the applicant; still, to be weak is human, and it can be readily understood that where a slight doubt existed, a man fundamentally honest might give the benefit of it to the agent, if personally interested, instead of, as in duty bound, to the company. Other arguments might be adduced, if necessary, to show conclusively the ill effects to the company of giving agents any voice in the selection of examiners; they will, however, readily suggest themselves to any one who even casually considers the matter. I am aware that nominally all medical appointments are made at the home office, but practically there are very many exceptions to this rule.

The writer before quoted, who, I presume, is not a medical man, lays great stress on the advantage possessed by the examiner in the personal knowledge of the general health, habits, and local reputation of applicants. Except in very small places this knowledge rarely obtains. For the most part the persons to be examined are totally unknown, and in many instances are desirous of concealing any weak point in their history or present health. The canvasser also is frequently equally anxious to cover any suspicious circumstance in his client's history, and endeavors to hurry him through. When it is remembered how difficult it often is in private practice, with all the willing assistance the patient can give, to form an exact opinion as to the nature of a disease, or even in some instances as to the existence of a disease at all other than in imagination, it is not to be wondered at that persons suffering from obscure diseases, or addicted to vicious habits, with every motive for concealment, should manage to pass the most vigilant and honorable physician.

The duties of the medical examiner are to the conscientious man difficult and onerous, and their proper performance does not depend so much on the "business-like view" consideration of the "financial bearing," and other matters of that sort, as upon the possession of skill, thoroughness, honesty, and independence. The last may in a great measure be secured to him by the company for which he acts.

ON THE DIFFICULTY OF CORRECTLY ESTIMATING RISKS AT A DISTANCE.

BY A MEDICAL DIRECTOR.

If any one of our subscribers is tired of reading the dry and tedious details of the manner in which the examiner's report should be filled out, or how he should pay special attention to this, that, or the other part of the examination, let him attempt to pass judgment upon a hundred or more applications from distant towns. He will then doubtless appreciate the difficulties of the task, and sympathize with us in our efforts to lighten them.

If errors creep into the application in regard to matters of a professional nature, the physician at the home office is not surprised to find them, nor does he anticipate that these errors will seriously interfere with his reaching a tolerably correct estimate of the applicant's past history, present condition of health, and inherited predisposition to disease. A merchant, for instance, who had never studied medicine, would be very likely to give incorrect names to the sicknesses he had had, and the agent, who assists him in filling out his application, would of course not be able to render these statements any more accurate. If the physician at the home office possessed no other facts than these upon which to base his decision, the office of medical director might very properly be abolished. This deficiency, however, is meant to be supplied by the certificate of the examining physician. If the person to be insured says in his application that he has had "rheumatism," but leaves out the very important collateral facts as to duration, severity, and frequency of the attacks, the medical examiner is expected to bring out all these details in his report. If it was a moderately severe attack, it will be sufficient to simply state: "Acute articular rheumatism in 1862. Sick three weeks. No heart complication. No return since;" or, if insignificant in its nature—"Simply rheumatic pains. No fever. Not confined to bed." Many examiners think that if they simply answer *no* to the various questions in the form which they are required to fill out, the physician at the home office should be satisfied with this information. Experience has shown, however, that this is not a safe thing to do. Every medical director can recall instances where the examining physician has entirely overlooked serious sicknesses in the applicant's past history, notwithstanding the fact that the applicant himself had hinted to them in his application. The importance of this matter is brought out still more prominently by a study of the losses of any of our life-insurance companies. A comparison of the original application and medical examiner's report, with the certificate of the physician in attendance upon the applicant during his last illness, not infrequently reveals the fact that the seeds of the fatal disease were already sprouting at the time the company accepted the risk.

If medical examiners throughout the country are disposed to find fault with the home authorities for being too particular about apparently trifling matters, let them remember that in most instances they are en-

tire strangers to the medical director, and that in the next place the action complained of is necessitated by the experience of the past. They should make it a rule, furthermore, to explain satisfactorily, if possible, every pathological statement that may appear in the application. Much, if not all, of the present correspondence about imperfect medical reports would then be unnecessary.

CORRESPONDENCE.

To the Editor of the Medical Record.

I indorse entirely the article signed "Medical Examiner" in your issue of June 16, and would make one or two further suggestions.

It is hard for an agent who has spent days and weeks to secure an *apparently* good risk, to have his prospective commission knocked from his grasp by one or two words of a medical examiner. Many of them will not stand it, and if they have any doubt of the application's passing at the home office, they will fill out a new blank and try some other physician. To illustrate: Some six years ago, I examined a man for one of our largest companies and found a defect in one of his lungs. I do not remember now what it was. I afterwards learned that the agent made out a new application, took the applicant to another town, had him examined by a physician who he said was "not too conscientious," and he passed. I recently learned that the gentleman insured complains of weak lungs. Now I would suggest that the companies require the medical examinations to be made privately, without the presence of the soliciting agent, and that, when made, the application should be sent directly to the home office, by the examiner, not subject to inspection and review by the agent.

This plan would not be so lucrative for the agents, and would probably be opposed by them, but it would undoubtedly be better for the companies.

I think discussions of these subjects in your journal will tend in time to correct many absurd theories and practices in regard to the examinations, in different companies. S. Q. Lapius.

To the Editor of the Medical Record.

Sir: From an experience of several years as medical examiner for various companies, I feel sure that the most important change which can be made in the present mode of conducting examinations for life insurance is to have the medical examination made on a blank, entirely separate from the application, which should be forwarded to the company by the examiner, and not seen by either the agent or applicant. This reform was well advocated by J. C. R., in your journal for July 15, but my experience may perhaps be offered in support of his.

Let the questions concerning family history and the past and present health of the applicant appear on both the application and the medical examination blank, and then the separate statements can be used in corroboration of each other. Often an applicant, upon being questioned by me in regard to a certain point, would reply, "Let me see what I said about that to the agent;" but I say, "That has nothing to do with the matter; please answer *my* question."

On any disputed or doubtful points the agent will always give the applicant the benefit of the doubt, whereas the company should have the benefit of the doubt, or the case should at least be stated in full and not slurred over, as is done by nine agents out of ten. In saying this I do not mean to impugn the honesty of life-insurance agents, for the popular impression that they are all sharpers is of course entirely erroneous; but where one's self-interest is so much involved, any man, no matter how honest, will, unconsciously perhaps, favor his own interests.

Again, especially in country places and smaller cities, the physician, applicant, and agent are all perhaps fellow-townsmen and friends, and statements made in confidence to the medical examiner should be communicated only to the home office, and not passed through the hands of agents and clerks, who at some time or other may use facts thus obtained to the annoyance of an applicant. Many a man has facts in his family history and own personal history which he would tell without hesitation to the examiner, as the confidential adviser of the company, and one who is in the habit of daily hearing such confidences and keeping them to himself. Many an applicant, for this reason, leaves questions in the application unanswered, or evasively answered, until the medical examiner draws out the full statement.

Furthermore, the agent takes the application in the man's place of business, in a car or public conveyance, and in the presence of third parties, whereas the medical examination is made at leisure in the private office of the examiner.

Again, the medical examiner, no matter how competent or honest, if not a man of entire independence and decision (and we are not all such, unfortunately), often finds it difficult in doubtful cases not to be influenced by the solicitations of the agent, and to always say *no* decidedly, but will be led to state facts more mildly and more favorably to the applicant than he would if he knew the examination were only to be seen at the home office.

In smaller towns and cities a physician by rejecting an applicant will often lose patients and make enemies; whereas this trouble could be entirely avoided, and the responsibility thrown on the home office, if a separate blank were used. The companies should furnish the examiners with the necessary blanks, which, in addition to the medical questions, might be headed with the amount and kind of policy the applicant wishes.

Having had no experience at a home office, I am unable to say whether there are any good and sufficient reasons for not having separate blanks for medical examinations; but if this reform could be carried out, I feel sure that the examinations of the average examiner would be far more valuable and reliable than they now are. In large cities, where companies can pick their examiners from a number of competent physicians, and thus secure first-class men, on whom they can thoroughly depend, and with whom they can become personally acquainted, this reform may not be so important; but the large majority of examiners do not sustain these personal relations to the companies, and the more safeguards thrown about examinations the better for examiners and examinees. H. T.

Boston, Sept. 2.

EDITOR'S NOTE.

Anonymous Articles.—Writers of anonymous articles for the insurance department must not be disappointed if their contributions do not appear in the Record. If the contributor wishes to write under an assumed name, or anonymously, he has only to inform the editor by letter that such is his wish, and it will be complied with; but the real name and address of the writer must always be designated in the letter.

Original Lectures.

PAIN AS A SYMPTOM OF DISEASE.

A CLINICAL LECTURE.

By ALFRED L. LOOMIS, M.D.,

PROFESSOR OF PRACTICAL MEDICINE, MEDICAL DEPARTMENT UNIVERSITY OF THE CITY OF NEW YORK.

(Reported phonographically for THE MEDICAL RECORD.)

To-day, gentlemen, I purpose to take up the subject of pain as a symptom of disease. Before the examination of patients who have pain as a prominent symptom, I will make a few general remarks upon the subject.

Ordinarily when the physician is called to see a patient, he is called for the purpose of giving relief to some prominent symptom. Sometimes this prominent symptom is dyspnœa, sometimes fever, but more frequently rather than for the relief of any other symptom the physician is called because the patient is suffering pain. When you are called to a case in which pain is a leading feature, you should regard it only as a symptom, although it may be a prominent one, and immediately set about finding an answer to the question, What is the cause of the pain? All pain indicates a morbid condition of the nerves or nerve-centres, and this morbid condition may be either in the peripheral extremities of the nerve or in its continuity, and it may be the result of a structural lesion, or simply a disturbance of nutrition in the nerve or nerve-centre. No patient has pain unless there is something wrong about the nerves, and usually the wrong is at the seat of the pain. Take, for instance, a case of pleurisy, and there is pain because the peripheral nerves are involved in the structural changes which take place during the progress of the inflammation. In inflammation we have redness, swelling, and pain; and pain as a symptom of inflammation is developed after the swelling has taken place, for with the swelling there is pressure on the peripheral nerves.

A common term for pain is neuralgia. This term is employed by different medical writers and physicians in very different ways, and with many different meanings. There are those who restrict the term neuralgia to functional pain, depending upon functional disturbances of the nerves or nerve-centres. There are those who restrict the term to disease of the nerve-fibre itself, induced by pressure or some form of disease of the nerve-tissue. If you look into the dictionary you will find that the word simply means pain in the nerve, consequently the term may be used by different persons in different senses, and with perfect propriety, for the expression of different conditions. I would restrict the term neuralgia to a condition of the nerve in which there is disturbance of nutrition. There are not necessarily structural changes in the nerve-tissue, but there is a disturbance of its nutrition.

We consequently have a very great variety of neuralgias. We have the malarial neuralgias; we have the neuralgias which occur in advancing life, first beginning when the patient is somewhat advanced in years. Its explanation in these later cases lies in the fact that the blood-vessels are becoming diseased, and the circulation is consequently more or less interfered with, and from this the nutrition is disturbed in all the tissues of the body, and in this general disturbance the nerves are involved.

There is another form of neuralgia which depends upon certain poisons which may be introduced into the system through the lungs, skin, or stomach. Syphilis I do not embrace under this head, but have special reference to the neuralgias which sometimes follow the constitutional effects of mercury, phosphorus, lead, etc. In these cases the patients have pain along the course and at the extremities of the nerve, which is undoubtedly due to an interference with their nutrition.

There is no question about the truthfulness of the statement that the nerve affected is not in a state of hyperæsthesia. As a rule, the tissues where it occurs are not in a state of hyperæsthesia; on the contrary, there is sometimes slight loss of sensibility in the part which is the seat of the neuralgia, and in some conditions, with the loss of nutrition we have disturbances of the function of the nerve, so far as it has to do with the nutrition of the part supplied by the nerve affected.

When I speak of pain in a nerve, or neuralgia, I mean that the nutrition of the nerve is interfered with, but not necessarily at the point where the pain exists. For instance, from disturbances of the cardiac plexus, by reflex irritation we have disturbances of the brachial nerves producing pain in the arm, in the top of the shoulder and base of the neck; or we may have the pain located in one particular point, in connection with irritation at a point very distant from the seat of pain.

Thus the introduction of ice into the stomach may cause a certain kind of pain in the head, which is reflex in character; but we cannot tell why the pain is produced by the introduction of the cold. Whenever a neuralgic cause is continued for a sufficient length of time, there will be interference with the nutrition of the affected nerves, and we may have as a result a chronic neuralgia. It is very common to have neuralgia in malarious districts, but it is necessary that there should be a certain amount of disturbance of the general system by the malarial poison before the constituents of the blood can interfere with the nutrition of the tissues; but when this point is reached we have fully developed malarial neuralgias. The list of neuralgias from blood-poisoning is a long one, and I shall not detain you with the enumeration. Why certain nerves are selected in malarial neuralgia, I cannot tell, and the same may be said of many other causes; it is simply a clinical fact. What I wish particularly to have you grasp is, that pain is not produced simply by a disturbance of the function of the nerve. Nor is it necessary that there should be any change in the constituents of the nerve which can strictly be classified under the head of pathological lesions.

After the exciting causes of pain have existed a certain length of time, atrophy of the nerve ensues; but when the atrophy comes, we have such changes taking place in the nerve that the pain usually subsides, and a paralysis takes the place of the neuralgia. This is especially the case where neuralgia depends on pressure along the course of a nerve, for wherever the pressure is continued sufficiently long, atrophy of the nerve takes place.

With these general remarks I invite your attention, first, to Miss H——, æt. 23, who gives pain as the prominent symptom in her disease. She tells us that the shortness of her breath and pain about her heart were the two things which led her to believe that she was sick. Dyspnœa and pain in her case, therefore, are the two prominent symptoms. She has suffered from the pain about one year, and she farther describes it as a sharp pain, which at times was so severe that she thought she was going to die. With this pain was associated a difficulty of breathing, which gave

her the sense of suffocation. As soon as the pain comes, for it comes and goes, she grows pale, the extremities become cold, and while the paroxysm lasts the symptoms are very urgent. This pain is in the præcordial region, extends upwards upon the side of the neck and head, through the left shoulder and sometimes down the left arm, but she never feels it in the right side, or down the right arm. We come now to ask the question, What may cause pain situated in this locality? Neuralgia is suggested by one of the gentlemen, and by that term he would take in all the conditions which indicate nutritional disturbance in the nerves. We would not speak of the pain of pleurisy in this sense, because we have there a pressure on the peripheral nerves as the direct cause of the pain. This pain in this patient I suppose may be called cardiac neuralgia. The cardiac plexus of nerves is involved, and the pain in the shoulder and down the arm is a reflex pain. This question involves a history of angina pectoris, for this form of cardiac pain may be regarded as one form of angina. The next question to consider is, What does such a cardiac pain continuing for a year indicate?

Probably it will be connected with some difficulty about the heart itself; and while the gentlemen are listening to this heart, I will say a few words about pain in connection with cardiac disease. Pain is not present in every case of cardiac disease, nor even in a majority of cases; but, on the contrary, in a majority of cases of cardiac diseases there is no pain. The class of patients in whom you would expect to have pain as a prominent symptom in connection with cardiac disease, pain in the shoulder, and pain running down the arm, are first, not *simply* valvular lesions of the heart, for in a majority of simple valvular lesions pain is not present; but the exact condition of the heart in those cases in which pain is present as a prominent symptom, is one of dilatation. As long as we have a valvular lesion which is compensated by a hypertrophy of the wall sufficient to cause the circulation to go on well, nothing special perhaps occurs; but when there is dilatation, the compensatory hypertrophy no longer being able to maintain an equality in the circulation, it becomes difficult for the heart to do its work, it staggers and pauses in its efforts, and we have pain.

We do not have angina or pain as prominent symptoms in cardiac disease, except in those cases in which there is a weakening of the walls of the heart, either from dilatation or degeneration of the walls themselves. Improper nutrition of the heart caused by disease of the coronary arteries may produce degeneration of the walls of the heart, and some of the books state that almost all cases of angina are due to a plugging up of the coronary arteries; but I am of the opinion that such statements are erroneous. The dilatation of the cavities of the heart which occurs in connection with valvular disease is the result of over-distention, and this distention is brought about by sudden calls upon the heart for increased action. For example, the walls of a heart are just able to do their work, when, from a valvular lesion, there is a certain amount of obstruction to be overcome. While everything is quiet, the heart performs its work very comfortably; but if the patient awakes suddenly in the night from fright, frightful dreams, or has the nightmare, and increased action is called for immediately, the left ventricle becomes distended and cannot empty itself; then the left auricle becomes distended, and from this the distention extends to the lungs, and the patient cannot breathe, except with a sense of suffocation; immediately the right side of the heart becomes distended, and by this simple distention of the heart the return of the blood is interfered with, and the man may die suddenly from the over-distention of the heart and interference with the coronary circulation. Angina therefore occurs in connection with organic lesions of the heart, either valvular or lesions connected with the coronary artery, which cause interference with the nutrition of the muscle of the heart itself. I do not believe that it ever occurs as the result of simple spasm of the heart. Patients may, perhaps, die with cardiac neuralgia, but the neuralgia is not the cause of death. Physical examination of the patient before you shows that there is some cardiac dilatation, the apex beating about two inches to the left of its normal position: that there is mitral obstruction, indicated by a presystolic murmur at the apex, accompanied by a purring thrill which almost certainly denotes mitral stenosis, and that there is mitral regurgitation indicated by the systolic murmur at the apex and communicated to the left. Let me impress upon you that pain as a prominent symptom in cardiac disease indicates disease of a serious nature, and when it exists as a constant symptom you are very apt to have a cardiac disease which you will not be obliged to watch for a very long time. In this patient, just as soon as the heart is overtaxed in the least, either from physical exercise or mental excitement, it gives rise to pain, and sometimes very distressing pain. The second case which I present to you, in which pain is present as a prominent symptom, is this man, 33 years of age, who gives no venereal history, but has had articular rheumatism three times. The last attack was in March, 1872; but he first felt pain in his chest in the following September. The pain in his case is located just at the right of the sternum—at about the junction of the third rib with the sternum—comes and goes, extends down the *right* arm, and is sometimes felt as low down as the elbow; it is a sharp throbbing pain, and can be produced at any time by excitement or exercise, but is relieved by making pressure over the point where the pain is located. In this case, as in the other, we will ask the question, What might be present to produce pain in this particular locality? Before answering that question, we may exclude diseases of the heart, now assuming pain as the chief criterion in making up the diagnosis, because there is no pain in the left side, shoulder, or arm.

One of the gentlemen suggests that the pain in this case may be produced by an aneurism. Mediastinal tumor pressing upwards is mentioned, and another gentleman suggests that it may be due to periostitis, or an exostosis as the result of periostitis. With regard to the mediastinal tumor and disease of the bones, it would hardly be expected that the pain would be increased upon exercise or excitement, as it is in this case, although there is a possibility that it might be somewhat increased. In addition, the pains of periostitis are localized, do not run down the arm, and are worse at night. These features are absent in this case; besides, the patient does not give any history of syphilis. It is not probably intercostal neuralgia, because it does not run along the course of the nerves, is throbbing in character, which is not the character of the pain in this form of neuralgia. Intercostal neuralgic pains sometimes come on after fatigue and exercise, but usually exercise does not produce them; besides, they are generally associated with other forms of neuralgia, and we do not have a localized pain, as in this case, at the point where the disease is. Physical examination of this man shows us a tumor situated in the same locality with the pain; it is immovable, has an impulse, and the impulse is obtained by placing the hand over the exact place where the pain is located.

This tumor extends about three inches in either direction, and there is also an impulse in the carotids upon both sides. At the seat of the pain we find all the symptoms of an aneurism—an aneurism of the ascending portion of the aorta, increasing upwards and laterally.

This third patient which I present complains chiefly of pain in the chest, and locates his pain in the same region as did the second—at the junction of the third rib with the right side of the sternum. He has had this pain nearly two years. He gives a complete syphilitic history. The character of the pain is burning, and he describes it as a "burning pain and heat." There was no tenderness upon pressure at first; but about six months after it first commenced, pressure began to give pain, and now pressure aggravates his pain very much. The pain is more in the evening. Exercise does not cause or increase it, unless he exercises with the arms. It is also worse at every change of the weather. In this case the pain is localized; there is no pain running down the arms or present in the shoulders. Sometimes the pain extends from the front through to the angle of the scapula behind, and this is its chief variation. Physical examination of this case reveals a prominence more marked than in the case which we have just examined, and extending from the upper portion of the clavicular to the lower border of the infra-clavicular space. As the hand is laid upon the tumor a distinct impulse is felt, a heaving impulse, which feels very much like the impulse of the heart. The apex of the heart beats in about its normal position; there are no cardiac murmurs, and there is no murmur present over the tumor. In the other man there were cardiac murmurs, cardiac hypertrophy, and dulness over the space occupied by the tumor. In this case there is great tenderness upon pressure, and dulness over the region of the tumor, but no cardiac murmurs or hypertrophy.

Again recurring to the question, What may give rise to pain in this locality, as well as the presence of such a tumor as is presented here? and the first answer which is made is *aneurism*. And at the same time the question is asked, Which are most painful, thoracic or abdominal aneurisms? The pain which accompanies both varieties is in the direction of the enlargement of the aneurismal tumor.

As a rule, patients do not suffer as severe pain from thoracic as with abdominal aneurisms. In aneurism of the thoracic aorta those patients suffer most who have aneurism of the descending portion of the arch pressing backwards upon the spinal column.

In connection with thoracic aneurisms we always expect to find cardiac hypertrophy. There is no cardiac hypertrophy present in this man, and there has been at no time an aneurismal *bruit*. The impulse is heaving in character, the man has had syphilis, and it seems to me altogether probable that he is suffering from an exostosis. Aneurisms in this locality do not get better; but this man is constantly improving in health, and the tumor is diminishing in size. The pain is probably due to changes in the bony wall of the chest at that point. As our hour, gentlemen, is up, I will continue this subject at our next clinic.

ONLY FOUR CENTENARIANS IN GREAT BRITAIN.—Mr. Thoms, in his treatise on "Human Longevity," asserts that of the regiment of centenarians claimed by Great Britain, only four seem to be incontestably worthy of such distinction, the statements of a large number being absolutely false, and of others more than doubtful.

Original Communications.

DRAINAGE THROUGH THE CUL-DE-SAC OF DOUGLASS, AFTER OVARIOTOMY:

WITH THE HISTORY OF A CASE.

BY ALEX. J. C. SKENE, M.D.,

PROFESSOR OF GYNÆCOLOGY IN THE LONG ISLAND COLLEGE HOSPITAL, BROOKLYN, N. Y.

WHEN any proposed mode of treatment is under discussion, new facts for or against are valuable in helping to determine the final verdict. This is my reason for offering some observations on drainage after ovariotomy, and relating the history of a recent case. The paper on ovariotomy recently published in the *New York Medical Journal*, by Dr. J. Marion Sims, is particularly interesting, owing to the positiveness with which it advocates drainage through the cul-de-sac of Douglass. Indeed, far more is claimed in that paper than is well proved, though possibly the whole may be true. One might well hesitate to accept the views expressed regarding the pathology of fatal cases after ovariotomy, because the ground taken is not well sustained by the arguments given.

The same might to a certain extent be said regarding the method of drainage recommended. Drainage through the sac of Douglass has not been practised long enough to establish its merits. There are, however, good reasons given in the paper of Dr. Sims why this mode of drainage should have a fair trial by ovariotomists. All appear to agree to the necessity for drainage after ovariotomy, at least in many cases, and that the surgeon should in all cases be prepared to drain or wash out the abdominal cavity at any time, should necessity call for it; but there are, perhaps, not sufficient data derived from practical observations to determine the relative merits of drainage through the lower angle of the abdominal wound and through the cul-de-sac of Douglass. The favorable results obtained in the five cases of Dr. Spencer Wells, by puncturing the sac of Douglass to evacuate accumulations there, and the history of Dr. J. M. Sims's cases treated by this mode of drainage, are quite sufficient to justify any one in giving this mode of practice a fair trial.

Some of the arguments against this method are: That fluids will accumulate among the intestines in the abdominal cavity, and will not settle down into the pelvic cavity. To this it may be said, that the same objection may be raised against washing out the cavity through the abdominal wound.

Again, it is claimed that opening the sac of Douglass, and keeping it open by a drainage-tube, will allow the admittance of air and favor the decomposition of any fluids that may be present, and thereby induce septicæmia. This argument is not valid, in all cases at least, as the history given here will show.

A careful study of Dr. Sims's paper persuaded me that the mode of drainage recommended deserved to be tried more extensively than it had been, and I resolved to practise it the first time an opportunity offered. I found, however, the truth of Dr. Sims's statement when he said, "I am not satisfied with any method as yet adopted for drainage." To carry out the principles of drainage under consideration, the following indications must be fulfilled: a tube is required which can be introduced with perfect facility, retained in place with certainty, and be easily removed.

None of the instruments devised by Dr. Sims entire-

ly fulfil these requirements. With a view to improvement I had the following instrument devised: A trocar 8 inches long, and curved at the pointed end to correspond to the axis of the pelvic cavity. A canula 2¾ inches long is made to fit the curved end of the trocar.

Fig. 1. shows the general outline of this instrument.

About one inch from the upper end of the canula two pieces of silver-wire are attached, one on each of the straight sides. The canula, from these wires upwards, is perforated all round with small holes.

Fig. 2 shows this.

The canula has a screw-thread cut inside of its lower end, so that another tube can be attached to it. A small piece of tube, about half an inch long, has a thread cut on its outside, which fits into the thread in the lower end of the canula; at the other end of this tube there is a

Fig. 1.

Fig. 2.

Fig. 3.

small flange, made suitable for the attachment of a piece of rubber tubing.

This short piece of tube, with the rubber tube attached, is screwed into the lower end of the canula, after it is introduced, through the sac of Douglass, into the vagina.

Fig. 3 shows the short tube, with the rubber tube connected, the dotted line marking the latter.

The mode of introducing the tube is as follows: The operator stands on the left side of the patient. The trocar and canula are held between the first and second fingers of the right hand (the trocar being withdrawn a short distance to protect its sharp point). In this way the instrument is carried down to the most dependent portion of the sac of Douglass. A little pressure is then made on the handle of the trocar, sufficient to engage the point in the tissues. The handle is then seized in the right hand, and the first and second fingers of the left hand carried up into the vagina until the point of the trocar can be felt. While counterpressure is made with the fingers of the left hand, the trocar and canula are thrust through from the sac of Douglass into the vagina. The canula is seized between the fingers of the left hand, and held in place while the trocar is withdrawn. The left hand is then removed from the vagina, and the upper end of the canula held in place with the two fingers of the right hand, care being taken to see that the two wings of silver-wire projecting on each side of the canula are made to rest on the floor of the sac of Douglass. An assistant then introduces a bivalve speculum and exposes the lower end of the canula, and having the other tube ready, he screws it into the canula. The speculum is removed, and the rubber tube cut off at the requisite length, and the operation is completed.

What remains to be said regarding this method of drainage can be best given in the history of the following case:—

Mrs. C., æt. 30 years, mother of three children, the last six months old. Eighteen months ago she was seen, and a cyst of the left ovary diagnosticated. The tumor progressed in growth rather rapidly. In a few months from the discovery of her trouble she became pregnant. No great difficulty was experienced until the beginning of the ninth month of utero-gestation, when she had an attack of circumscribed peritonitis. She got well of that, and her child was born at full time. Her labor was normal, and she made a good recovery. In December she had another attack of peritonitis, which was quite severe. She recovered her health only partially after that. Her general condition being as good as we could hope to get, the operation was performed on the 15th of March, 1873. There were present Profs. Armor and Greene, Drs. Corey, Mason, Pilcher, Bunker, and Mr. Cushing.

On making the incision, I found the abdominal walls very much attenuated, and the sac was closely adherent. While trying to separate the two, the sac was opened. A trocar was passed into the sac through this opening, but the contents would not flow out. Two or three pins were passed through the edges of the opening of the sac, and a ligature carried around under them. This closed the wound in the sac. The incision was enlarged sufficiently, when adhesions were found all over the abdominal walls anteriorly and laterally. The omentum was also firmly adherent to the tumor. The adhesions were broken down with considerable trouble. Rather free hemorrhage followed, which required the use of persulphate of iron to arrest. The pedicle (a small one) was transfixed with silver-wire, ligated in two halves, and dropped back into the pelvic cavity. The drainage-tube was then introduced in the manner already described. This part of the operation was accomplished in less than four minutes. Cleansing the abdominal cavity was then undertaken, and some slight oozing from small blood-vessels arrested by the application of the persulphate of iron. At this stage of the operation the patient began to show signs of prostration, which necessitated our hastening the completion of what remained to be done. Consequently the most scrupulous care could not be exercised in cleansing the peritoneal cavity. The abdominal wound was completely closed in the usual manner. About one hour was occupied in the entire operation. She gradually rallied from the slight shock, and with the exception of an attack of vomiting, which continued off and on for about five hours, she made a most desirable recovery. At the end of 24 days after the operation, she was able to be around looking after her household cares.

I desire to call especial attention to the behavior of the drainage-tube, as that is the feature in the history of the case which is of interest. When the tube was introduced the rubber portion was cut off at the ostium vaginæ, so that the labia majora closed over the end of it. While the abdominal wound was being closed, bloody serum began to flow from the tube in small quantity. This discharge from the tube continued during the afternoon and night of the 15th. From about four o'clock until eight on the morning of the 16th no discharge occurred. Fearing that the tube might have become closed by a blood-clot or other obstruction, I injected about one ounce of

artificial serum. The discharge soon after that returned, and continued perceptibly through the day and into the night. On the morning of the 17th the flow was quite profuse for about an hour, during which time three large napkins were saturated with a dark, reddish-brown fluid. When this free flow subsided, a small red spot of fresh blood was observed on the napkin. Several more stains of the same kind were noticed through the day. This led me to suppose that she had begun to menstruate, but it was proved that such was not the case by first washing out the vagina and finding that clear water returned, and then washing out the tube, which brought away some fresh streaks of blood.

On the 18th the discharge of the same fluid was quite free; on the 19th and 20th it was scanty; there was no fluid at all on the 21st; during the 22d day there was a scanty flow of light-colored serum; on the 29th day, and the fourteenth day after the operation, the tube was removed. The patient was placed on the left side and Sims's speculum introduced; the lower end of the silver-tube was seized by the forceps, and while traction was made the vaginal wall was pushed backwards by the first and second fingers placed one on each side of the tube. This pressure upwards of the vagina with the fingers caused the flexible little wings of silver-wire (which retained the tube in place) to be folded up along the side of the tube, so that they offered no great resistance to the removal of the tube. While the tube was being removed the patient complained of pain, but it was only momentary, and subsided immediately on the tube being withdrawn. The opening made by the tube healed up very promptly.

I desire briefly to recall some of the advantages claimed for this method of drainage, and also the strongest objections raised against it. The facts in this case will show to some extent the truth of either or both. First, it is claimed that the abdominal and pelvic cavities are most conveniently drained through the sac of Douglass; indeed, it is the only way by which they can be drained. This case shows that drainage in this way can be accomplished very satisfactorily. As already stated, the abdominal and pelvic cavities could not be thoroughly cleansed during the operation; the abdominal wound was closed, while possibly there remained some blood in those cavities, and there was likely to be some more accumulated from oozing. Still, this was drained off, as was proved by the free discharge from the tube, and also by the fact that no trouble followed, which likely would have been the case if no drainage had been made. As already stated, objections have been raised to this mode of drainage on the ground that, while the pelvic cavity might be emptied in this way, accumulations would remain in the abdominal cavity. This is true, but only to a very limited extent. Fluid may remain among the intestines for any length of time in the dead subject; but if the trunk is made to incline from the head downwards, fluids will naturally gravitate to the pelvis. This settling down of the fluids is materially aided by the peristaltic action of the bowels.

Evidently many ovariotomists recognize this fact, and give directions to have the head of the bed elevated so that any fluids may settle down into the pelvis. Granting, however, that a tube in the sac of Douglass is not certain to keep the abdominal and pelvic cavities free from fluids, it is also evident that the two cavities cannot be emptied with any more certainty through an opening in the lower angle of the abdominal wound. Again, it is stated that Prof. Wm. Warren Greene (who was among the first, or the first, to establish drainage in this way) has abandoned it, because he believes that inflammation of the areolar tissue and its consequent results were induced by the presence of the foreign bodies in the roof of the pelvis. It must be remembered, however, that Prof. Greene's method of drainage was very imperfect. He simply brought the ends of the ligatures of the pedicle out of the sac of Douglass into the vagina. This could not insure a reliable opening for drainage, and the presence of organic ligatures would be much more likely to cause irritation and inflammation than the metallic tube.

Strong objections have been raised to this mode of drainage, on the ground that by making an opening in the sac of Douglass air would be admitted and expelled by inspiration and expiration. This would favor the decomposition of fluids, and increase the danger, which we wished to avoid. I am perfectly satisfied that this did not occur in the case here related. The patient being firmly bandaged and lying quietly in bed, her breathing was wholly thoracic, so that the pelvic organs were not disturbed at all by the action of her lungs. The labia majora closed over the end of the tube, acting as a valve and preventing air from entering. While the fluid could and did flow away, there was not the slightest disposition to the entrance of air. This can be very readily understood when we remember that no air can enter the pelvic cavity unless a vacuum is formed, and during respiration, when the body is inclined towards the feet, no such vacuity occurs. Air cannot enter the peritoneal cavity through such a drainage-tube any more than it would enter the uterus during menstruation.

If time and experience prove that this mode of drainage can be practised generally with the same safety as in this and other cases treated so, then there will be no doubt as to the superiority of this plan of treatment.

If fluid can be safely removed in this way from the peritoneal cavity as soon as it forms, the decomposition and septicæmia from that source will be prevented, which is certainly much better than any mode of treating blood-poisoning after it occurs.

It is much to be regretted that Dr. Sims leaves his views on pathology so widely open to criticism. His failure to establish the views he holds, regarding the nature of septicæmia and its causes, will lead many to doubt the treatment which he recommends, though it may be most valuable. Sound pathology generally leads to correct therapeutics; but it must be remembered that we occasionally employ treatment, which is known to be most satisfactory, in cases where our views on pathology are obscure and uncertain.

TREATMENT OF ULCERS BY ELECTRICITY.

By ALEXANDER MURRAY, M.D.,

NEW YORK.

Having alluded incidentally to the local treatment of ulcers by electricity,* it may not be out of place to say a few words generally in regard to the mode in which it should be employed.

The method I usually adopt is first to apply a disk of platinum, silver, or zinc, connected with the positive pole of the battery, directly to the base and sides of the ulcer, and then to close the circuit by an electrode, previously covered with clean linen and well moist-

* Part of a paper on the Construction, Use, and Mode of Application of the Galvanic Nipple-shield.

ened with warm water, applied to the edges and around the ulcer for five or six minutes. After this I use for a minute or two longer both poles labile around the sore to the extent of an inch or more, in order to modify malnutrition and stimulate the enfeebled capillary circulation, as well as to electrolyze the callous and infiltrated tissues surrounding the ulcer, and to promote absorption of the exudations.

Should a case of noma pudendi, cancroid, sloughing ulcer, etc., present itself, I use occasionally, as an auxiliary with electricity, a saturated solution of chlorate of potassium, dilute nitric, sulphuric, or hydrochloric acid. I prefer, however, to use the dilute mineral acids, on account of their astringent and chemical properties. I cover the bottom of the ulcer with a little lint, raw cotton, or granulated sponge, and then wet the sponge with whatever agent the nature of the case may seem to require, and apply the metal disk directly to the saturated material; and while I keep one electrode stationary for a few moments in the ulcer, I work the second conductor slowly around the diseased part. I maintain this mode of treatment daily for a few applications, or until the recuperative process is manifest in the ulcer.

It is unnecessary for me to give here a detailed account of the electro-chemical changes which take place at each pole when applied to ulcers, especially when using the various remedial agents mentioned. It will be sufficient for my purpose to remark, that if I wish to use a powerful diffusive agent in a nascent state, such as the chloride of zinc, chlorine, oxygen, etc., I have the immediate means at command. By this method of treatment, and in some special cases also, the advantages of both electricity and topical medication are combined, and are in direct application to the diseased part, and thus we are furnished with reasons to expect more decided and beneficial results than could be hoped for by a single remedy.

I avoid, generally, after local galvanization, all greasy applications to ulcers, and employ as a dressing a little lint, dry, or wet with the solution of chlorinated soda, pure or diluted with water. Occasionally, if the ulcer is small and well-filled with good, even, healthy granulations, I allow nature to take her course in forming a sound cicatrix. This is done by exposing the ulcer to the oxidizing influence of the air for a short time.

When treating ulcers by the electrolytical method, speedy and better results can be obtained by applying the galvanic current as strong as can be comfortably borne, keeping the poles close to each other for five or six minutes in and around the ulcerated part, and by having a séance once or twice a day until there is decided manifestation of a healing process visible, when every third or fourth day will be sufficient for a sitting.

Should an exuberant growth of granulations spring up in the ulcer, an electrode of silver or platinum, connected with the negative pole, should be applied directly to the spongy mass, and the circuit closed on the adjacent parts, and then a strong battery-current should be employed, but not too powerful to cause pain, until the granulations present a smooth, shrunken, and seared appearance, as if they had been slightly cauterized with a hot iron. After this effect is produced the poles should be reversed, and the séance finished with the positive pole in the ulcer for two or three minutes longer.

I have noticed when treating ulcers, particularly open buboes, with the negative pole, by means of a metallic conductor in the sore, that the effect of the action of the pole is somewhat similar to that produced by the local use of the peroxide of hydrogen.

Fistula in ano, when free from any complications, can be successfully treated by introducing an electrode of platinum (a silver probe or a piece of platinum wire No. 14 will answer) into the fistulous canal, and into the rectum a scoop made of wood or hard rubber. The circuit should be closed by the application of a well-moistened chamois-covered disk on the neighboring parts, and moved slowly around and over the fistulous canal in a labile manner.

The object of using the scoop, when the fistula is complete, is to allow the free end of the metal electrode, when inserted in the sinus, to rest against it. By this means we can avoid causing unnecessary irritation or pain in the rectum during the application. The rectal scoop is not required when the fistula is incomplete, with the opening external.

The advantages of this simple and bloodless method of operating are, that it does not need any preparatory treatment, or cause inflammation, hemorrhage, or absence from business. The fistula neither requires dressing, nor is constipation of the bowels necessary after the operation.

One application of galvanism is generally sufficient to close the abnormal opening, which usually occurs in five or six days. The séance should not be longer than from eight to ten minutes. When insensibility is rendered by ether, etc., a strong battery-current should be applied, using the negative pole in the sinus for five or six minutes; then the poles should be reversed, and the positive employed in the fistula during the remainder of the sitting; or we use an application as strong as can be comfortably borne for twenty minutes' duration, without the use of an anæsthetic.

Plated electrodes should not be used on moist or ulcerated surfaces when attached to the positive pole, unless we specially wish to form an oxide, etc., of the metal employed. With a negative connection, however, there is no objection whatever to their use.

As a rule, I would recommend generally the use of platinum or gold, *and especially when we desire ozonization*. When the positive pole is formed of any oxidizing metal, *ozone is not formed*, and the electrode is quickly oxidized.

Dr. Althaus has ascertained, when experimenting on the different animal tissues and fluids of the body by electrolysis, that oxygen, acids, and albumen are accumulated at the positive pole, and hydrogen and alkalies at the negative pole. These agents give the key for further scientific research.

Ozone is supposed to be an intensified, or an allotropic modification of oxygen, and is one of the most powerful oxidizing agents we possess. It has a strong, peculiar odor, which somewhat resembles weak chlorine.

Antozone is also an active condition of oxygen; it unites with water, and is a strongly oxidizing in its action.

Oxygen is a colorless, odorless, and tasteless gas.

Chlorine is a yellowish-green gas of a peculiar suffocating odor.

When treating a large indolent ulcer, situated on the lower extremity, by galvanism, with the positive pole in the sore, I could easily detect the odor of ozone as evolved. This fact induced me to subject to galvanization a piece of lean raw beef, with both poles placed about half an inch from each other. I employed plates of platinum, as this metal forms the best electrode for electrolytic purposes.

At the anode (positive pole) the ozone odor emitted was manifest in a marked degree to the sense of smell, while at the cathode a fleshy odor only was perceptible.

I did not wish to trust altogether to the sense of smell, but was anxious to ascertain its presence beyond a doubt by chemical reagents. The following are the methods I employed when experimenting for ozone: I selected a portion of perfectly fresh beef, free from fat, for each test. Meat that had been kept on ice, or the least tainted, should not be used; for though we may succeed with every reagent employed to-day, we could not, perhaps, with the same meat obtain a satisfactory result on the following day. I submitted a portion of a healthy placenta to galvanization. In a few moments the odor of ozone was perceptible in every part of my office, and at the same time I noticed that there was also a large quantity of hydrogen evolved at the negative pole, with occasional mimic explosions beneath the disk, scattering a bloody froth in all directions. The free elimination of hydrogen and ozone in this instance was to me remarkable, and was in quantity about five or six times as much as I could obtain from a piece of beef of the same size. When ozone is specially prepared, and in its purity, we meet with no difficulties when testing. But with the methods I have adopted a few extraneous agents are developed at the same time with ozone by the electrolytic action of the positive pole. These substances would necessarily interfere more or less with the character of the tests employed, while the small quantity of ozone evolved would not be sufficient to characterize satisfactorily a few of the tests, as, for instance, with indigo a very weak solution should be employed.

The instrument I used when experimenting was a zinc-carbon battery of thirty-two cells, manufactured by the Galvano-Faradic Co.

METHOD I.

After electrolyzation of the beef, and the removal of the conductors, I laid a piece of white bibulous paper, previously impregnated with a solution of iodide of potassium, and then pressed the paper gently with porcelain buttons against the electrolyzed portions of the meat for a few moments, when a brown stain was produced on the paper, oxidizing the potassium and setting the iodine free. By this method of testing I found a few agents satisfactory, while others gave only a faint indication of ozone.

METHOD II.

Upon a glass plate I placed a piece of bibulous paper, saturated with a reagent, and over the paper a thin slice or shaving of raw beef, lastly the platinum plates. I then employed a strong galvanic current for a few minutes. I expected by this method that as soon as the ozone was evolved, and from its diffusive character, a sufficient portion would at least penetrate the meat, and come in contact with the prepared test-paper. Most of the tests employed by this mode of experimenting gave satisfactory results.

METHOD III.

On a piece of raw beef I applied a strip of thick blotting-paper (about one-third the width of the conductor), over it the metal disks. I had my tests, etc., at hand, and as soon as the ozone odor was developed I removed the conductors, and immediately brushed the surface of the paper which had been allowed to remain on the meat with a test solution. By this proceeding the blotting-paper was impregnated with ozone sufficient to characterize satisfactorily whatever tests I choose to employ.

In treating ulcers I have also applied the above method of testing.

METHOD IV.

I placed a piece of beef on the bottom of a small glass jar, and over it the metal conductors, and securely covering the vessel, allowed only the wires of the disks to be exposed, to form the connections with the battery. The test papers were suspended from the inside of the cover, directly over the electrodes. This method gave very unsatisfactory results.

"Necessity is the mother of invention." I may not have employed the most scientific method of ascertaining the presence of this odoriferous agent; however, such as it is, I am convinced of one fact, that I have discovered that ozone is developed by the electrolytic action of the positive pole when applied directly to ulcers. I feel assured in saying of this discovery, that it will have a practical and very important bearing, and aid us also to arrive at a more definite and scientific basis as to which pole we should employ directly in the treatment of diseases by electrolysis.

I find no reference whatever regarding its use or mode of application in any work on electro-therapeutics which I have consulted. I am aware that ozone is derived by the action of the ordinary electrical machine, and evolved when we strike together the metal conductors of a galvanic battery in operation, by chemical action, etc.

OZONE.

TESTS.	Positive Pole.	Negative Pole.
Odor	Sensibly manifest to the sense of smell.	Fleshy odor.
Iodide of potassium	Brown color.	No change.
Iodide of potassium and starch	A purplish shade of deep blue.	"
Tincture of guaiacum	A beautiful shade of light-greenish blue.	Orange-yellow.
Silver leaf	Oxidized.	No change.
Indigo	Decolorized.	"
Reddened litmus paper	Bright red.	Blue.
Blue litmus paper	Reddened.	No change.

Galvanism, when employed in the treatment of ulcers, possesses many important and decided advantages which are wanting in the usual local remedies daily in use. It is easily applied, and its action is various, that is to say, it is electrolytic, catalytic, and thermal. *The elements evolved by the decomposing power of the positive pole*, especially where the conductor is formed of an unoxidizable metal, and applied directly to *the ulcer, possess the following properties: stimulant, antiseptic, disinfectant, deodorizing, oxidizing, besides possessing the power of coagulating blood and albumen, as well as promoting absorption of the abnormal secretions.*

It matters little in the surgical treatment of ulcers what the nature of the agent or agents may be, their action when developed by electrolysis, or whether its beneficial effect are due more to the primary or secondary chemical results which occur in the ulcer during the application. It is sufficient for our purpose when we have the practical fact, that ulcers heal rapidly after its application, generally in about one-sixth the time ordinarily consumed by the usual methods of treatment.

The flabby livid-colored granulations, which are usually found in indolent ulcers, after one or two applications of galvanism are soon changed to a healthy flesh or rose color.

To this method of treatment I would give the name *galvano-ozonization*, a term which fully characterizes its nature.

I am sanguine enough to believe that we have no single remedy or mode of treatment with which I am acquainted during the thirty years I have been engaged in practice, which can be compared to the *galvano-ozonic* method when properly applied to ulcers. The latter usually heal in one, two, or three weeks, when by other methods they frequently take as many months or more to accomplish. This form of application does not interfere with any other kind of treatment, local or constitutional; but on the contrary, allows us to use whatever means the case may require.

Of the electrolytical treatment of malignant ulcers I cannot say as much as regards galvanization alone. My experience of this class of diseases is too limited to give a decided opinion. Of one fact, however, I am certain, it will have a soothing effect, so as to relieve acute pain, and aid considerably whatever local or constitutional treatment may be employed. But this is effected through the direct application of the positive pole. The negative pole in some special cases will occasionally cause the ulcerated surface to slough or spread. Nevertheless we may use both poles in the ulcer at the same time, or the negative first and the positive pole the last.

The thermal effect of galvanism can be easily ascertained by submitting a piece of cooked fresh beef for a few minutes to a strong galvanic current, and after the removal of the metal conductors, the portions of the meat which had been electrolyzed will be found heated to such a degree as to be almost impossible to hold it in the hand even for a few moments. The heat developed on raw beef is not so manifest, owing to the large quantity of moisture in the tissues.

Localized faradization, when employed in the treatment of ulcers, affords very unsatisfactory results. This is no doubt due to the feeble electrolytic action of the induced current.

239 East 10th Street.

Progress of Medical Science.

On the Employment of Perchloride of Iron to Arrest Post-Partum Hemorrhage.—On the 5th of February Dr. Heywood Smith presented to the Obstetrical Society, of London, the following case, illustrating the treatment of post-partum hemorrhage by the intra-uterine injection of perchloride of iron. The patient was delivered of a male infant on the 26th of January. The placenta came away easily in twenty-five minutes. On the third day, the patient complained of severe pain in the hypogastrium. On the tenth day hemorrhage occurred. On the eleventh day, hemorrhage continuing, a solution of one part of strong liq. ferri perchloridi to eight of water was injected. On the sixteenth day, bleeding continuing, the injection was repeated. On the eighteenth day the uterus was again injected with iron, one in four, and again on the twentieth day with equal parts of the solution of iron and water. On the twenty-first day a strong solution of iron was injected into the uterus with a uterine syringe holding about two drachms. This produced severe pain, but completely stopped the hemorrhage, which never amounted to flooding, but oozed continually, and was of a bright-red color. On the twenty-third day the patient was delirious, and the discharge brown and offensive. On the twenty-fifth day she had occasionally great dyspnœa, and picked at the bedclothes, and on the twenty-eighth day she died. The uterus was nearly five inches long and four inches broad, and its walls three-fourths of an inch thick. Its anterior and posterior surfaces were marked with black streaks. The tissue was soft, but otherwise apparently healthy. Its inner surface was covered with a dark reddish-black fluid; and at the junction of the upper third with the lower two-thirds was a depression stained black. Near the centre of it an artery hung out more than an eighth of an inch. Close to the depression, and fitting into it, was a rounded mass of placenta about the size of a small filbert. A small portion of the end of an artery showed the free extremity slightly puckered, its margin rounded, and the canal unobstructed. Dr. Smith believed the case taught—

1. That post-partum hemorrhage, happening after complete contraction of the uterus, and, therefore, after the uterine sinuses have been emptied of blood, is evidently arterial.

2. That when a solution of the perchloride of iron is injected into the uterus, the sinuses take it up and carry it into the veins, the tissues also immediately surrounding the sinuses becoming stained.

3. That the perchloride of iron does not produce contraction, nor, by coagulation of the blood, blocking of the orifices of the uterine arteries.

4. That the perchloride of iron is a styptic, the use of which in the cavity of the puerperal uterus is not innocuous.

In the discussion that followed, Dr. Routh spoke of a case in which the patient was treated with a weak solution of tincture of iron and water for post-partum hemorrhage, and died of puerperal fever, which set in on the third or fourth day, and which, he thought, might be due to the mode of treatment. Dr. Graily Hewitt related a similar case, in which a solution of one to four had been employed, and the patient subsequently died of peritonitis. Dr. Murray had used this mode of treatment with success in ten cases, and thought there was more danger in delay than in its employment. Dr. Braxton Hicks thought Dr. Smith had employed too strong a solution, and remarked that it would have been well if the cervix had been dilated and the interior of the uterus examined. He believed pyæmia might result from depression after severe hemorrhage, where no injection of perchloride of iron had been used. Dr. Sell said that no unfavorable results had attended the use, in Vienna, of a drachm of sesquichloride of iron to one pint of water, when the administration of ergot and the injection of cold water failed to arrest hemorrhage. Dr. Playfair had employed this mode of treatment in several cases, and only once without success. Dr. Smith's case was one of secondary hemorrhage, due to retention of a piece of placenta. He also called attention to the use of too strong a solution of the perchloride.

On the fifth of March the discussion was renewed by Dr. Snow Beck, who stated that he had met with several cases where death had followed the injection of perchloride of iron into the gravoid uterus, to arrest post-partum hemorrhage, all the women presenting symptoms quite analogous to those known under the name of puerperal fever. It was now ascertained that hemorrhage only occurred when the uterus was relaxed. This relaxation allowed the canals of both the arteries and the veins to remain open, when blood was poured out from the arteries, and any styptic injected was too often taken up by the veins, conveyed into the general system, and

caused the certain death of the individual. This had always been verified on the post-mortem examinations he had made. He recommended, however, sponging or swabbing the inner surface of the uterus with an astringent, when the local use of cold, and the introduction of the hand were not sufficient to cause uterine contraction, and this might require to be repeated. Dr. Wynn Williams recommended swabbing with a sponge saturated with equal parts of tincture of perchloride of iron and water—a string being attached to the sponge, which is to remain *in situ* if not expelled by contraction of the uterus. Dr. Protheroe Smith recommended the undiluted tincture of matico instead of the iron tincture, as calculated to avoid some of the dangers attending the use of the latter. Dr. Holman thought the use of the iron solution had, in his hands, saved several lives which would otherwise have been lost. Many patients, especially in the upper classes of society, were in such a debilitated condition as to be quite prostrated by the mere act of parturition; and after it the uterus seemed to have had no power of contraction. In these cases he believed the injection of iron to be of great value. Dr. Edis had seen a case of hemorrhage, occurring ten days after delivery, in which the injection of an ounce of the pure tincture arrested hemorrhage when an injection of equal parts of the tincture and water had failed to do so. In this case no pain or inconvenience followed the treatment. He had used the pure tincture in several other cases with marked success. Dr. Rogers had injected the pure tincture in seven cases with immediate good results, and in only one had serious consequences followed, and this case recovered. He recommended it only as a *dernier ressort*.

Dr. Barnes believed this question was to be decided not by *à priori* anatomical closet speculations, but by experience at the bedside, and said that Dr. Beck, admitting he had never used the remedy, or seen it used, labored by ingenious anatomical argument to prove that perchloride of iron *could not* cause the uterus to contract or close the arteries. The simple answer was that it *did both*, and did it effectually. He had often had his hand in the flaccid, bleeding uterus to clear out placenta and clots, and felt the inner surface of the uterus contracting, corrugating, crinkling under the contact of the iron as it flowed, stopping the bleeding and expelling the hand. Dr. Beck had asserted that ergot, cold, galvanism, and pressure were sufficient to arrest hemorrhage, but he (Dr. Barnes) had seen many women bleed to death after all these means had been used unsuccessfully by skilful men. Referring to the case mentioned by Dr. Bantock, Dr. Barnes said certainly the pain must be attributed to the injection, but it did not follow that it was the cause of death. Dr. Routh's case was one of septicæmia, for which he certainly could not blame the perchloride. Septicæmia sometimes occurred when no styptic had been used. Dr. Barnes added that it had struck him as a remarkable fact that in these discussions those who condemned most warmly the practice of injecting iron solutions to arrest hemorrhage were men who had at most seen it used once, whilst it had been emphatically approved by men whose experience was greatest, and who had used the remedy frequently. Nothing could be truer than Dr. Holman's statement of the risk run by delicate, pampered women, who become exhausted by the mere effort of bringing forth a child. In these cases, where the uterus could not be made to contract, where he could not rely upon reflex excitation, when grasping the uterus must at length be abandoned, then it was that perchloride of iron came in as a new power to save life in the last extremity.

In No. 2 of the *Obstetrical Journal*, Dr. W. S. Playfair gives the history of a case which occurred to him soon after these discussions, in which the use of the perchloride had twice saved the life of a patient when other means had entirely failed. On the second occasion the case progressed favorably for two days, when the pulse and temperature rose. The symptoms assumed a grave character, but at the end of a few days improved coincidently with the discharge from the uterus and vagina of decomposing clots of blood and iron, and from this time the patient recovered rapidly.

In No. 3 of the same journal, Dr. A. B. Steele reports three additional cases which tend to confirm the statements of Dr. Barnes. Dr. Steele believes that the action of the iron injection is not so much that of a direct styptic or hæmostatic as that it is an exciter of reflex contractions of the uterus.

One class of cases to which this mode of treatment appears specially adapted is, he thinks, those not uncommon and most troublesome forms of flooding which might be called recurring hemorrhage, where the uterus alternately contracts and relaxes, and where it is difficult to determine when the patient can be pronounced free from risk of further bleeding.

In a case of abortion at the fourth month, where hemorrhage was not arrested by dilating the cervix and swabbing the cavity of the uterus with undiluted liq. ferri perchloridi, the removal of a minute portion of placenta from the fundus at once put an end to the bleeding.

A Case of Precocious Menstruation.—R. K. Clark, M.D. (*Boston Med. and Surg. Jour.*, writes that a girl, aged 6 years, has menstruated regularly once in twenty-eight days since September last. She is not precocious in any other respect, not large of her age; but the usual change in form suited to a young lady 15 or 16 years of age has taken place, so that she looks like a little woman. An aunt of the child became regularly menstrual at six years of age and continued till she was thirty-eight.

Excision of the Hip-Joint.—G. Troup Maxwell, M.D. (*Phila. Med. Times*), records a successful case of excision of the hip-joint. The patient, male, aged 35, had labored under coxalgia, or tuberculosis of his right hip-joint, eighteen years. He has now a comparatively useful limb, shortened slightly, but with a little motion in the joint, and fitting him for employment in many vocations.

Liquor Ferri Subsulphatis.—V. J. Fourgeaud, M.D. (*The Western Lancet*), has for years relied principally on the liquor ferri subsulphatis, both for local application and internal administration, considering it the most valuable remedy for that class of diseases characterized by exudations, vegetations, false membranes and abnormal formations and growths of a humid and superficial nature on the mucous membranes. He applies the undiluted solution to the affected parts by means of a camel's-hair brush or, better, of a piece of sponge, smaller than is generally used for throat probangs, attached to a suitable holder. In applying the medicated sponge, it should be gently rubbed on the affected parts. The peculiar action of the solution on the exudations or false membranes will cause them to break up more or less completely, according to their different degrees of adhesiveness to the mucous membranes, as shown by the pieces adhering to the sponge, and, also, by their presence in the immediate expectoration. With the local treatment, he prescribes the following for internal adminis-

tration: ℞ Potassæ chloratis, ʒij.; Glycerinæ, ʒi.; Quiniæ sulphatis, ʒi.; Liquoris ferri subsulphatis, gtt. xx.; Aquæ, ʒij. M. Half a teaspoonful to a tablespoonful, according to age, every four hours.

Case of Rupture of the Iris.—Dr. Geo. H. Powers (*Western Lancet*) relates a case of rupture or coloboma of the iris, in a female patient, aged 15, caused by the shock of a blow upon the lid, unaccompanied by any wound or abrasion of the external tunics of the eye, or by internal hemorrhage, or by permanent luxation of the lens, or thus far by cataract. The iris is so far restored in its contractility, that the pupil is very little, if any, larger than that of the other eye, but its displacement downwards causes double images to some extent. Vision is still improving in clearness, and the patient can read large letters. Dr. Powers has never seen a similar case and does not remember one where the injuries were not much greater than in this instance.

Progressive Myopia and its Operative Cure.—Richard H. Derby, M.D., of New York (*N. Y. Med. Journal*) reports several cases of this affection and shows evidence in favor of tenotomy in this class of cases. He calls the attention of the profession to the importance of muscular insufficiency as a cause of progressive myopia, a fact first established by Von Graefe, and rightly regarded as one of his most brilliant contributions to ophthalmic literature.

As a rule, tenotomy is to be performed on that eye which first deviates outward on approaching the fixation object, or it is to be performed on the eye with the strongest facultative divergence, or on the one with the worst acuteness of vision. Immediately after the operation, the effect must be controlled by means of the equilibrium test, made in what is called the "position of election."

The operated eye is to be bandaged, in order that as far as possible no movement of the eye shall modify the immediate effect. If it has been used, the patient must be seen within six or eight hours after the operation, and the equilibrium test made in the position of election.

Poisoning from Chlorate of Potassa.—A. M. Ferris, M.D. (*Pacific Med. & Surg. Jour.*, June, 1873), notes a case of fatal poisoning from chlorate of potash. The patient, male, a native of Ireland, æt. 26, had taken a large spoonful of the article by mistake for Epsom salts. The post-mortem showed that the lungs were healthy, without blood stasis and signs of previous disease. The heart was normal, the walls being of average thickness and valves free from disease. The auricles were distended to their utmost capacity by dark coagula, homogeneous, and of sufficient tenacity to support their own weight and sustain the coat of the cavities from which they were drawn. The large vessels communicating with these cavities were also full of coagula of the same appearance. On removal of the heart, there was but little blood flowed from any of the severed vessels.

Solution of Camphor in Erysipelas.—In the *Gazeta Medica da Bahia* it is said that a few drops of a solution of equal parts of gum camphor and ether, applied from time to time to an erysipelatous surface will, in the majority of cases, effect a cure.

Amenorrhœa.—Wm. H. Baker, M.D., Senior Assistant House Surgeon, N. Y. State Woman's Hospital (*N. Y. Med. Journal*) records three cases of amenorrhœa resulting from undeveloped uteri, in which galvanism or electro-magnetism, applied as a direct stimulant to the uterus, afforded marked benefit.

Pelvic Hæmatocele.—T. G. Wylie, M.D., House Surgeon to N. Y. State Woman's Hospital (*N. Y. Med. Journal*) publishes an interesting case of pelvic hæmatocele, with recovery. The patient, aged 28, when first seen had miscarried six years previously, and for the last two months had uterine hemorrhage. A tumor was discovered in the rectovaginal wall, filling up the *cul-de-sac*, displacing the uterus forward and upward above the pubic bone. A small trocar of an aspirator was introduced twice in the lower part of the tumor from the vagina, and bright red blood was withdrawn, which afforded relief.

Contribution to the Study of Puerperal Septicæmia.—Dr. A. d'Espine has, in the *Archives Gen. de Medecine*, an article under this title, in which he attempts to study the different forms of puerperal poisoning, from the mildest to the most serious, and to show by an uninterrupted series of observations that all these forms belong to the same family. According to M. d'Espine puerperal septicæmia is not a disease by itself, but a series of local and general accidents, more or less grave in character, determined by the absorption of septic material at the surface of a solution of continuity of the utero-vaginal canal, the difference between the divers typical forms depending upon the variable amount of septic material absorbed, and to the mode of introduction—whether by the venous or lymphatic system. These accidents are not peculiar to the puerperal state, and resemble those which produce septicæmia in wounded men and animals.

The point of departure is always in the uterus or vagina; all causes which interfere with cicatrization of the uterine wound, and favor the development of septic material on its surface, are the efficient causes of puerperal septicæmia.

The lymphatics are the usual routes through which the poison is absorbed, and lymphangitis is the ordinary, but not necessary evidence of its passage.

Peritonitis is a *lésion de voisinage* due to the transportation of the septic material by the uterine lymphatics, and comparable to the local inflammations which are developed in the neighborhood of infected wounds.

The effect of the absorption of septic matter upon the organism is to produce congestions and inflammations in all the organs, particularly in the lungs, kidneys, and intestines; subserous ecchymoses or interstitial apoplexies; inflammations, which tend to become localized, especially in the serous membranes, as shown during life by fever, diarrhœa, pulmonary congestion, and epistaxis, followed by transient cutaneous eruptions.

The absorption of purulent matter and of septic material are clinically confounded with each other.

Milk fever does not exist. The fever of the first week is almost always a mild septicæmia due to absorption of the lochia by little wounds in the utero-vaginal canal. It can be prolonged for several weeks when uterine reaction does not take place, and when the lochiæ is fetid, in which cases it is almost always possible to find ulcerations of the cervix or vagina, which are the sites of the absorption.

These mild infections are frequently, but not always, accompanied by uterine angioleucitis and signs of light perimatritis. Whenever the infection is prolonged, death may occur from septic phthisis.

Puerperal pyæmia is a complication of septicæmia,

and coincides almost always with phlebitis of the uterine veins. It is a complication relatively rare, and due, according to all probability, to septic emboli.

Metastatic abscesses of the viscera and their tributaries, as well as nearly all inflammations of the cellular tissue of the articulations, are due to lymphatic infection, and are not embolic.—*Gaz. Méd. de Paris*, June 21.

THE DEAD PRESERVED LIKE WAX.—The Brunetti method for the preservation of the dead consists of the following processes: The circulatory system is cleared thoroughly out by washing with cold water till it issues quite clear from the body. This may occupy from two to five hours. Alcohol is injected so as to abstract as much water as possible. This occupies about a quarter of an hour. Ether is then injected to abstract the fatty matters. This occupies two to ten hours. A strong solution of tannin is then injected. This occupies for imbibition from two to ten hours. The body is then dried in a current of warm air over heated chloride of calcium. This may occupy from two to five hours. The body is then perfectly preserved and resists decay. The Italians are said to exhibit specimens which are as hard as stone and retain the shape perfectly and are equal to the best WAX models.

A more simple form of preparation for injection, well suited for anatomical purposes, consists of glycerine, 14 parts; soft sugar, 2 parts; nitrate of potash, 1 part. It is found that, after saturation for some days in this solution, the parts become comparatively indestructible, and change neither in size nor figure.

TENOTOMY OF THE TENSOR-TYMPANI.—Dr. Chas. S. Turnbull, of Philadelphia, gives an excellent translation of Prof. Joseph Gruber's paper on "Tenotomy of the Tensor Tympani," delivered at the meeting of the Society of Physicians in Vienna, Feb. 16th, 1873. In closing, he says that tenotomy can be successfully made upon the living without danger, when we consider the experience gained by the recital of his case, and it can assist in allaying subjective symptoms in disease.

As this operation is only undertaken in such cases where we are unable to do anything else, we must certainly regard it as an addition to operative otology, and must do our best toward its further development. —*Med. & Surg. Reporter.*

HEREDITARY SYPHILIS AMONG THE ABORIGINES.—Dr. S. P. Cutler, of Memphis, Tenn. (*Nashville Journal Med. & Surgery*), states that, in the Museum of the Med. Department of the University of Louisiana, Professor Joseph Jones has a collection of skeletons, implements of warfare, etc., from the mounds of Middle Tennessee. These are the remains of the mound-builders, whose history is entirely lost. There are about a dozen skulls, and most of the other bones belonging to them.

In that collection of bones, he noticed evident signs of constitutional syphilis, either hereditary, or induced —most likely the former. There were nine tibia, and five fibula, showing unmistakable evidence of the disease; spines of the tibia were quite extensively corroded, mostly the entire length. There were no evidences of the disease about the skull; the teeth, in particular, were perfectly natural and sound—no furrowing or pitting of enamel, which is sometimes noticed in hereditary disease, or even induced, during infancy. These facts, he thinks, show conclusively that syphilis is not altogether a creature of civilization.

PASSAGE OF MANY PINS, ETC., PER ANUM.—James L. Fite, of Lebanon, Tenn. (*Nashville Jour. Med. & Surg.*, June, 1873), reports the case of a child, three months old, who passed per anum without difficulty, within two days, twenty-eight pins, two needles, and an agate button. So far as he could discover the baby had never a pain from the effects of the pins, etc. It was thought that they were given to the baby by a little servant girl on the morning of the day the first pins came away.

VARIX OF THE DORSAL VEIN OF THE PENIS.—In the April number of the *Italian Journal of Venereal and Skin Diseases*, Dr. Francisco Parona narrates a case of a young man of thirty in whom, in consequence of a varicose condition of the vein on the *dorsum penis*, by facilitating the too rapid return of blood from the glands, erection of the penis was prevented. Equal parts of chloral and water were injected into the vein with a Pravaz's syringe, strong compression being made on the proximal side, a cold compress was applied, and a perfect cure resulted.

ABNORMAL OPENING IN THE OCCIPITAL BONE.—Dr. W. H. Lathrop, of Detroit, editor of the *Western Medical Advance*, publishes in his journal an interesting case of a child, which, at the time of its birth, in March last, had attached to the back of the head a tumor fifteen inches in circumference, connected by a pedicle about two inches in circumference. This tumor was caused by a protrusion through an abnormal opening in the occipital bone, the meninges of the brain entering into the walls of the tumor, as in spina bifida. In this case the brain itself passed into the opening to the extent of about an inch. The child died in convulsions 36 hours after delivery. The delivery was effected without instrumental interference; the woman (a primipara, aged 20) was so large and the child's head so small, that, although the face presented, the labor was allowed to take its natural course. The back of the head was pulled strongly backward by the tumor, which thus necessarily caused the face to present. After the head had passed through the external orifice, the tumor was delivered with the shoulders. Some difficulty was experienced in this portion of the delivery, but as traction was easily made upon the axilla, no exertion was required for the purpose by the mother. Spontaneous delivery in such a case would doubtless have been impossible but for the lengthening out of the pedicle, which permitted the delivery of the head by itself. The longest diameter of the unnatural opening was three-eighths of an inch.

Upon examination it was observed that the opening occurred at the "centre of development" of the occipital bone, as described by Gray.

CRANIOTOMY AND EVISCERATION.—Dr. M. M. Shearer, Assistant Surgeon, U. S. A., at Fort Wallace, Colorado Territory, reports to us an interesting case of the above nature. Being called by telegraph to the aid of a physician at Kit Carson, sixty-eight miles from his post, he found on arriving that it was to give assistance in the case of a primipara, twenty-three years old, of stout build and plethoric, who had been in labor seventy-two hours. She was greatly exhausted, had a weak "jerking" pulse, features pallid and pinched, cold perspiration, and she was vomiting a "coffee grounds" fluid. Ammonia and brandy were at once given, and an examination made. To use his own words:—"The membranous cyst had long since given way, and I ascertained the head, with an irregular presentation, solidly impacted in the brim of a pelvis below the ordinary volume. The face was directed to the promontory of the sacrum, the vertex, by pressure, extending below the brim—a most rare irregularity.

In this unfortunate position the cranium was immovably wedged.

"Adopting Ramsbotham's method of ascertaining the capacity of the pelvic brim, I obtained, as a result, conjugate 3¾ inches, lateral 4¾ inches, not the standard, but amply sufficient for the passage of a maturely developed child of ordinary size. The pubic arch, however, was exceedingly faulty, being narrow, deep, and angular. The rami were long, and close together; the symphysis deep. If the brim had been passed, delivery could not have taken place beneath this arch without the aid of forceps. In view of this latter fact—the utter impracticability of turning by hand—the absence of all instruments—and, above all, the exhaustion of the patient, I determined to practise craniotomy. Carrying two fingers of the right hand up the vagina, until they came in contact with the vertex, I made them sheath the cutting edge of an ordinary bistoury, which I introduced with the left hand. The point of the instrument entered the posterior fontanelle. I then incised two and a half inches forwards, through the sagittal suture, withdrew bistoury, and broke up the cranial contents with the handle of a common tablespoon. The broken-up mass came away with the succeeding pain the parietal tables lapped, and the head passed down, turning in its passage to the first position. Making a vectis of my forefinger I extracted below. Placenta came away forty-five minutes subsequently. Patient made a rapid recovery. Weight of child, 10½ lbs., well developed; sex, female."

Physiological Action of Phosphorus.—Wegner has performed a number of experiments on different animals to discover the effects produced upon the system at large when it is brought under the action of small and non-poisonous amounts of phosphorus. He failed to excite a malignant periostitis in animals whose limbs had been fractured and otherwise injured, and in which we might expect results analogous to the well-known affections of persons who are in the habit of inhaling the fumes of phosphorus. He found, however, that these small doses, given over a period of many weeks or months, had quite a different effect from large and poisonous doses. This was especially noticed (1.) in some of the digestive organs. In the stomach, for instance, the mucous membrane was the seat of hyperæmic infarctions and superficial ulcers, whose borders and surfaces were of a dirty brown color. Later on, this membrane became hypertrophied, hard, and assumed a smoke-brown color, which the microscope showed to be due to blood pigment. The glands were also lengthened, and the interstitial connective tissue increased. In the liver there was also an interstitial hepatitis, with an active proliferation of cells about the portal vessels. At the periphery of the liver-acini there was fatty degeneration of the liver cells, which were sometimes stained yellow from the escape of bile under the pressure of the contracting tissue. In fact there was found the interstitial hepatitis, which may lead to smooth induration simply, to acute atrophy or to granular atrophy (cirrhosis). Associated with these appearances were always icterus, venous hyperæmia of the stomach and intestines, and enlargement of the spleen.

(2.) Rabbits that were confined in an atmosphere impregnated with the fumes of phosphorus had necrosis of the jaw, which was essentially the same affection as the lucifer-match-maker's disease.

(3.) When phosphorus was given in infinitesimal doses the changes in the structure of the bone itself were remarkable. At those points in the extremities of the shafts where the cartilage forms the spongy tissue directly, the structure was found solid and compact like the ordinary dense tissue. If the animals continued to be fed with very small doses, the medullary canal was found to be encroached upon, but never occluded entirely; at least this was the case in dogs and rabbits, but in chickens that took phosphorus in their food, without lime, the canal was found to be sometimes completely obliterated.

The practical result of this latter experiment would seem to show that in such diseases as osteomalacia, rickets, etc., we should expect benefit from the long-continued use of phosphorus in very minute doses. At any rate, they were not found to do harm, and always developed remarkable energy in osteoplastic processes. The author also believes that it is phosphorus, and not its products by oxidation, to which this action is due. Perhaps its presence merely in the blood may act upon the bone-making tissues as a specific irritant. —*Virchow's Archiv, Schmidt's Jahrb.*, 4, 1873.

The best Form for Administering the Phosphates.—The great value of the phosphates as therapeutic agents in certain kinds of diseases has led Coirre to inquire into the best way of employing them, and especially one of the most valuable, the phosphate of lime. In order that this remedy may be readily taken up by the system, he recommends that it be given in doses of 10 grs. dissolved in ʒ ss. of water, to which a few drops of hydrochloric acid has been added. This latter represents the free acid of the gastric juice. It aids in the absorption of the phosphate, and is of itself useful, as in small doses it promotes digestion. Its use is indicated in diseases which cause disturbance of the digestive and nervous systems, such as chronic purulent discharges, chlorosis, tuberculosis (where calcification of tubercles may be desirable), and similar affections, in the osteomalacia of pregnant and nursing women, where the phosphate of lime is collected in the blood of the mother for the benefit of the child, but to her own serious detriment.—*Presse Med., Schmidt's Jahrb.*, 4, 1873.

Typhoid Fever from Infected Milk.—A recent outbreak of typhoid fever has occurred in London, in the parishes of Marylebone and St. George's, Hanover Square, very remarkable in its history and limitation. The number of cases is not exactly known, but amounts to several hundred. The families attacked belong, with hardly an exception, to the wealthier classes, and among them are those of well-known physicians and surgeons. The outbreak occurred in the third week of July, and the family of Dr. Murchison was among the earliest attacked. The doctor first directed his attention to the milk supply, and after an extensive examination it was discovered that the source of the poison was in one of the eight farms which supplied the milk consumed by the stricken families. Here not only were cases of typhoid fever in existence, but the water used for dairy purposes was contaminated with excremental and other matters.—*The Practitioner*, Sept.

Poisonous Effects of Tetramethyl of Ammonium.—At a late sitting of the *Society of Biology*, of Paris, M. Rabeauteau made some valuable remarks on the poisonous effects of the above salts, as illustrated by his experiments on animals. For instance, one-sixth of a grain kills a frog in less than five minutes. It is a muscular poison; the muscles of the heart are no longer excitable by electricity ten minutes after death. The iodide of tetramethyl is also a muscular poison of the same sort, less soluble but quite as dangerous.—*The Lancet.*

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month, by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, October 1, 1873.

THE STUDY OF OUR CASES.

The young physician has always plenty of time to study up his cases. His patients are so few and so far between that he has abundance of opportunity for weighing the significance of the symptoms, and for learning the views of the authorities upon them. It would be well if the same opportunity could be enjoyed, and the same disposition could be fostered throughout the whole of his professional life. How different, however, are the circumstances which surround him when his practice increases, and he enjoys the confidence of the community to which he ministers. There is no calling which gives more uncertainty to time than that of a physician in active practice; no profession which in the conscientious discharge of its duties so openly defies any attempt at thorough and systematic study. Every one must acknowledge this as a fact, and be prepared to admit certain conclusions derivable therefrom. Accepting the situation, however—making every allowance for urgent calls, when the meal has to be left unfinished, when the much-needed repose has to be sacrificed, when, in fact, what would be considered the ordinary comforts of existence have to be laid aside to meet an emergency,—we have no right to make ourselves believe that we must not strain a point, must not snatch some time to consult our charts on our journeys. Our duties to our patients, to ourselves, and to our science demand that we do not give ourselves entirely to abstract business. We have no right to assume that, because so many draughts are made upon our time by our professional engagements, we can conscientiously excuse ourselves from a given amount of study.

We should have to imagine a very extreme case if we were ready to admit that any practitioner can be so driven that all the time he had to spare should be spent in eating and sleeping. *Per contra*, the very men who have done the largest practice are those who have been our best students. Not only have these gentlemen found time to study their cases, but have taken the chances in "the midst of the harassing and onerous duties that devolve upon a hospital surgeon, a teacher of surgery, and a private practitioner" (we quote from the preface of one of the best works on surgery written in our language)—have in the face of these drawbacks actually added to our stock of knowledge by writing volumes of their experience.

In this connection we call to mind the work performed by one of the greatest oculists the world has ever produced. We refer to this example at this time, not because it is unparalleled in its way, but for the reason that it is fresh in our mind from recent reading. In the current number of *Harper's Magazine* is an account of Albrecht von Graefe, by the talented "blind preacher," the Rev. William H. Milburn. It will be recollected that the reverend gentleman, before the death of the great oculist, went to Berlin to consult him concerning an operation; that an operation was performed, but without the success that was hoped. The story of blindness is told by one who for forty years has felt it, and carries with it all the interest which naturally attaches to a pathetic narrative from a gifted word-painter; but what interested us particularly, and pointed the healthy moral, was the following account of the life-work of the subject of the sketch:

"He was usually up by seven, passed an hour or two in study, then read and answered his letters while taking his coffee. Nine was the hour for his lecture at the klinik. . . . . The hour's lecture over, during which he held the great throng spellbound and even breathless by his eloquence, the death-like stillness broken now and then by irrepressible applause, he proceeded on his daily visit through the wards of his hospital. . . . . Some days there were as many as sixty to be operated upon. . . . . The operations were usually ended at 5 P.M., at which hour he professed to dine; but his swift horses rarely brought him to his house much before six. At dinner his buoyant spirits would break forth in charming talk, and all kinds of frolic and fun. Long before seven o'clock his anterooms were crowded by patients from all quarters of the earth, waiting for their preliminary examination. These were admitted one by one, each in his turn, to the cabinet, where the master patiently and carefully explored each diseased organ, and kindly, yet honestly, told the sufferer what he had to hope or fear. Thus was he occupied until ten or eleven at night, when the carriage was in waiting to bear him once more swiftly to the klinik, where he made a minute examination of every patient operated on that day and the day before. In my lonely vigils I used to hear his carriage bearing him away at between one and two in the morning. In addition to this daily round, how he found time for his private

studies, and the composition of his voluminous works, is more than I can tell; but time he did find to accomplish, as student and author, what would have made immortality for any other man, and at the same time to achieve such practical feats of skill, energy, and success as would be the full measure for a prodigy. Such was his life at Berlin for ten months a year, from 1850 to 1870, save when interfered with by sickness."

If we were to look around us we could find similar habits in many of our own great men, men who by just such work have made for themselves world-wide reputations not only as students but as authors.

But we cannot expect such work from every practitioner. We may allow, for the sake of the argument, that the degree of labor performed by these gentlemen is an exception to the rule which should be in general force, but some approach can be made to it by every medical man. He may not expect to advance our knowledge, but he can certainly make an effort to keep up with it. More than this, it is his duty so to do. Even if he cannot find time or opportunity to go into the alluring by-paths of investigation, into the fascinations of extended research, he can at least make a note of what is daily passing before him, and work up the material which by the very circumstances of his practice is placed directly before him. The ordinary study of one's cases is the simplest manner to perform such a duty. As far as any system is concerned, each one should create one for himself, governed entirely by the requirements of the case.

A great deal can be learned by experience, but this can be made more than doubly valuable by a reasonable amount of study and reading. A want of a due appreciation of this fact begets shiftlessness in thought, uncertainty in diagnosis, and degenerates practice into a humdrum business in which mere dollars and cents is the only consideration for so many visits.

The practice of medicine followed as a mere business, is the meanest of all vocations; but cultivated as a science, is a fascination. The medical man who never studies his cases, who cares only to recover his patients and collect his bills, who bothers himself but little as to a correct and thorough diagnosis, who does not seek to explain the significance of an anomalous symptom, moves in an atmosphere of distrust created by himself, and denies himself of all that invigorating satisfaction which is always the reward for solving a difficult problem. We maintain that there is nothing which gives a real relish for the drudgery of our profession akin to that which one acquires by a thorough study of individual cases. Once develop a real interest in a case, and we lose sight of the abstract work.

We once heard a celebrated teacher say that the pleasantest hours he spent were those in which he could arrange his cases in memory and talk them over with the authorities on his library shelves. Every practitioner who would adopt a similar plan would find it equally pleasant and profitable, and the one who denies himself such experiences has something yet to learn.

THE BRITISH MEDICAL ASSOCIATION.

It would seem that in the matter of management the British Medical Association is not very unlike a similar organization of our own. We quote the following extract from an editorial on the recent meeting in London, published in *The Doctor*, a leading journal of that city:

"It was remarked to us by those who sat near, that the arrangements were evidently intended to stifle discussion, and scant courtesy was shown towards those who offered any remarks on the management of the Journal, the proposed alteration in the laws, the report of the reform committee, or the finances of the Association. It was patent to every one that the wire-pullers have no idea of representing the profession, except through themselves, and they therefore openly manipulate the members in order to retain their position."

The Journal in question is one which seems to be run entirely under the patronage and in the interests of the Association; but it would seem that none but the wire-pullers have any right to be acquainted with details. Our Association does not yet own a journal, but it has a strong desire in that direction.

In other respects, concerning the management question, the American Medical Association can enlighten our cousins, and can show them how it is possible to take a step further still and claim to be representative. Our Association does not seem to have any wires to pull; it is simply led by the nose.

THE STATE MEDICAL SOCIETY AND THE PUBLICATION OF ITS TRANSACTIONS.

Some months since we informed our readers that the New York Legislature had refused the usual annual appropriation for printing the Transactions of the State Medical Society, and expressed the opinion that it would be a blessing in disguise, in that it would stimulate the members to action in their own behalf. We then advised that the Society should publish its own Transactions, and be entirely independent of State patronage. We are pleased to hear that the Medical Society of this county has re-echoed this sentiment by a resolution published in our news columns. It is to be hoped that the other county societies will follow its lead, and adopt suitable measures to insure the publication of the annual volume in time for distribution at the next meeting in Albany.

THE CHOLERA IN NASHVILLE AND DR. PETERS.

In the item headed "Cholera in Nashville," published in the last number of The Record, certain statements appear, the intention of which not being understood, reflect unpleasantly upon our friend and fellow-towns-

man Dr. J. C. Peters. By an accidental omission of quotation-marks, it would appear that we indorsed the statement that the gentleman was a fabricator, and one liable to draw upon his imagination for scientific data. It is unnecessary for us to say that we have the fullest confidence in the statements of Dr. Peters, and believe, as we always have done, that he is honest in his convictions and above the suspicion of any attempt at making up cases to prove his point. As far as the questions of scientific fact are concerned, we offer no opinion; but as far as their statement by Dr. Peters is concerned, we are satisfied that they were founded on a conscientious conviction of right.

Reviews and Notices of Books.

CLINICAL REPORTS FROM PRIVATE PRACTICE. By JOHN HERBERT CLAIBORNE, A.M., M.D. Petersburg, Va.: Jos. Van Holt Nash. 1873.

THE author says, rightly, that "No class of medical writing is of more interest and more avail to the majority of professional readers, than correct and well-digested clinical reports," and refers to the timely and valuable aid he has derived from the works of Bedford, Elliot (spelled by him with two t's), Neligan and others. It was the appreciation of this fact that gave us anticipations of pleasure on opening this elegantly gotten-up book of Dr. Claiborne's. The author avers that for many years past he has kept a record of cases with a view to their publication when time and experience would justify him in giving them to the public, and he now offers us something over a hundred and forty selected ones, with the promise of more if these meet with the appreciation and approval of the profession.

Almost the first thing that catches our eye is the atrocious character of the English used in the work, and this is even outdone by the medical Latin. Coming as it does from one who suffixes an A.M. to his name, and who says, "In reference to the style of what he has written, the author, while acknowledging that no one has the right to palm off on the public, with any sort of apology, crudities and solecisms, the result of ignorance or carelessness," seems to think his shortcoming in this matter is quite excusable on the ground of the cases having been "collected, condensed and rewritten at night after the fatigues and interruptions of a most exacting practice—and chiefly in hours robbed from sleep,"—we would modestly suggest that this can hardly excuse such a wholesale omission of prepositions, such naming of preparations that do not exist in our own or any other pharmacopœia; such grammar as makes him say on page 24 that twelve American leaches were ordered to have a warm sitz-bath; such mistakes as puts an abbreviation for nitric acid where one calling for simple water should be; as makes chloras. potass. the Latin for chlorate of potash, or writes hyd. mit. chlor. as the abbreviated Latin name for calomel.

There is hardly a page of the book that does not give evidence in its orthography, punctuation, grammar, nomenclature, etc., that he must have been very sleepy not only who wrote it, but when the proof was read.

The author says: "The 'cases' recorded in these pages will be taken from a very different class of people from those who ordinarily constitute the subjects of clinical reports. Such reports are usually made up of the histories of the cases of applicants at hospitals, infirmaries, dispensaries, college clinics, and other public charities—applicants whose constitutions have been enfeebled by the privations of poverty, or broken by vice and debauchery," etc., and he "*suspects, greatly*, the majority of people in this land . . . who employ physicians for a fee, and who do not resort to the public charities for medical advice, are represented truthfully by the class he describes;" which may be all very well in its way, but does not alter the fact that it is mainly by the careful observation and recording of such "charity" cases that medical science is being advanced; and to this rule Dr. Claiborne's work affords no exception, despite the respectable character of his patients, since the remark appended to Case xi., "Pathology uncertain, but treatment effective," might as well be employed in numerous other instances. Indeed, the treatment is almost invariably so effective that one is led to suspect that too much "selecting" has been done in the choice of cases.

The loose way of making a diagnosis renders some of the cases reported absolutely worthless. For example, Case vii., of "Azoturia;" Case xv., which the author mentions as one of Bright's disease recovering under treatment, but which presents no diagnostic symptoms of this affection; Case xxii., of "Acute Ovaritis," which might just as well have been called constipated bowels; Case xxx., of Hepatitis, which might have been one of pleuritis or peri-hepatitis complicating pleuritis, for all that we learn to the contrary; and Case xxxi., of "Weed," which seems to us quite as likely one of threatened mammary abscess.

Under the term "Cholera Infantum," the writer designates all the summer diarrhœas of the first three years of life; and in the dozen or so of cases of summer diarrhœa which he has selected, he cuts the teeth of the baby more times than physicians whom we know have had occasion to do in a practice of several years, almost exclusively among children, and averaging over fifty a day during summer months.

Dr. Claiborne makes no mention of having used pepsine in any form in the bowel affections of infants, but has an evident regard for the virtues of calomel, which is the result of years of use. Oxide of silver is, in his hands, a potent remedy in cases of menorrhagia, and he looks with great disfavor upon the growing tendency to employ the obstetrical forceps.

Finally, to return again to the preface, the writer says: "In my experience, one of the first and most important lessons to be learned by the young practitioner, after leaving the clinics of the schools and the wards of the hospitals, is to know how to discern between the physical and moral condition of the patients whom he meets for the first time in private practice, and of those whom he has left behind him. His success will depend no little on the skill and discrimination which he exhibits in changing his practice with the changed conditions and relations of his patients." In other words, to acquire the *art* of practising medicine. This, judging by the book before us, Dr. Claiborne has done, and we have no doubt that he is possessed of that *savoir faire* which makes the successful practitioner; but as for his ability as an accurate and reliable observer and writer on medical subjects, we question very much if his efforts will prove as successful. We cannot finish without complimenting the publishers upon the exceptionally elegant manner in which their work is done.

REPORT OF THE COLUMBIA HOSPITAL FOR WOMEN, AND LYING-IN ASYLUM, Washington, D. C. By J. HARRY THOMPSON, A.M., M.D., Surgeon-in-Chief. With an Appendix. Washington: Government Printing Office. 1873.

A CAREFUL survey of this work shows it to be about the best example of "padding" that has come to our notice. A few fairly-reported cases are made the excuse for a mass of excerpts from well-known and frequently-consulted authorities, and we cannot avoid the impression that, under cover of the annual report of a hospital sustained by the General Government, the reporter has done his best to win notoriety at public expense.

The book is published in the style of the *Medical and Surgical History of the Rebellion*, and comprises over four hundred pages, profusely illustrated with cuts, many of which are taken, without acknowledgment, from such text-books as Tyler Smith's Lectures on Obstetrics, etc.

Who J. Harry Thompson is, that he should have been selected as a recipient for official favor by being advertised in such an elegant manner, we know only from the work itself and from an advertising circular of an institution called the College of Obstetrics and Gynæcology, Washington, D. C., which has been kindly furnished, no doubt in anticipation of such necessity. We feel that the publication of such a work by the General Government is not only uncalled for, but positively wrong, when the progress of the *Medical and Surgical History of the Rebellion* is delayed for want of funds.

In the preface it is boasted that gratuitous medical and surgical relief has been furnished to at least twenty per cent. more patients, in proportion to the fixed population, than are relieved at the hospitals of New York, Philadelphia, and other large cities. As it is well understood that the abuse of medical charities in our large cities is the source of just complaint on the part of young and struggling physicians, we do not envy the officers of this institution the opinion in which they must be held by the medical men of their neighborhood.

The Appendix purports to contain reports of the Department of Diseases of Children and the Department of Diseases of the Eye and Ear. The former comprises seventy-eight pages, of which *one* page only is essentially a report of the doings of this department. The balance is made up of three articles by Dr. Samuel C. Busey on Febris intermittens, Entero-colitis, Cholera infantum, Dysentery, Difficult Dentition, and the value of certain drugs in bronchitis, none of which papers have any necessary connection with the report of a public institution, but which in a very much abbreviated form would have answered as magazine articles.

The same remarks will apply to the so-called Report of the Department of Diseases of the Eye and Ear. Twenty-five pages are devoted to some remarks by Dr. D. Webster Prentiss on herpetic keratitis and trachoma, which, so far as they contain anything original, might all have been taken from some text-book, and about two pages are devoted to a report proper.

The whole work is evidently intended more for the class who usually receive Congressional favors in the way of Public Documents, than for members of our profession generally.

CIVIL MALPRACTICE: A Report presented to the Military Medical Tract Society at its Fifteenth Semiannual Meeting. M. A. MCCLELLAND, M.D. Chicago: W. B. Keen, Coke & Co. 1873. 8vo. pp. 74. $2.00.

THIS little work, although it by no means gives over a tithe of the medico-legal questions of interest to the physician, does, nevertheless, comprise a well-condensed statement of the questions involved in the greater proportion of suits for malpractice, and quotes a number of typical cases, some of which have the charges and rulings of the courts in full.

It is divided into two principal portions, in the first of which the terms "negligence and skill" are treated from a legal, and in the second from a medical, standpoint. There are in both numerous citations of ancient and modern authorities, and the book concludes with a list of the reputable works on medical jurisprudence.

In the dearth of instruction in our medical schools regarding the legal responsibilities of medical practitioners in the discharge of every-day duties, the advent of a work so convenient and comprehensive as this is a source of congratulation for both students and practitioners.

A GUIDE TO URINARY ANALYSIS, for the Use of Physicians and Students. By HENRY G. PIFFARD, A.M., M.D., etc. New York: William Wood & Co. 1873. pp. 88.

THIS is a carefully written and well-arranged handbook of urinary analysis, by what is known as the "approximative method," or that performed by means of standard solutions, the amount of the various substances being estimated by the bulk of their precipitates. Though scarcely so accurate as the methods which would be employed in a laboratory, it is practically the one most available to the class for whom the book is written, and is sufficiently exact to answer all clinical purposes; its chief recommendation being the shortness of the time required for making an examination.

The apparatus to be employed is well illustrated, and the formulæ for the test-solutions, and tables to aid in estimating the percentage and weight of the different substances, are introduced.

Correspondence.

THE INVENTION OF TUNNELLED URETHRAL INSTRUMENTS.

A LETTER FROM PROF. J. W. S. GOULEY, M.D.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—It is well known to the profession in the United States that I have, since 1864, claimed to be the inventor of tunnelled urethral instruments, and that this claim was never disputed until 1870. As long as these instruments were, by some persons, considered of little use, not a word was said about their authorship; but the moment their success was firmly established, and that practitioners in New York and in other cities recognized their value, the invention was claimed on behalf of Dr. W. H. Van Buren, who himself has twice acknowledged to me that he had never laid any claim to the invention, and who had nothing to do with it, even by way of a suggestion.

I have remained silent, in spite of the several attacks that have been made upon me, in obedience to the urgent request of Dr. Van Buren; but as the subject has lately been reopened—and assuredly not by myself—I feel compelled in justice and self-defence to break this long silence by giving a succinct account of the

history of the invention of tunnelled urethral instruments, which I have the honor to submit to the judgment of the profession.

My attention was called in January, 1870, to a paper on stricture of the urethra, by Dr. Bumstead, published in *The American Practitioner* for January, 1870, in which the author attributed to Dr. Van Buren the invention of tunnelled sounds, with the full knowledge that I had claimed it in two publications in 1869, and without giving me or my friends the opportunity of making any statement on the subject. I then called upon Dr. Van Buren, requested him to read the article, and asked him if the remarks relating to tunnelled sounds were made on his authority. He replied in the negative, said he had never claimed to be the inventor of these instruments, and promised to correct the error (or what I thought at the time might have been an error on the part of Dr. Bumstead). But as the same appeared in a new edition of Dr. Bumstead's book a few months after, I addressed a letter to Dr. Van Buren, of which the following is a copy:

"NEW YORK, November 19, 1870.

"To W. H. VAN BUREN, ESQ., M.D.:

"MY DEAR DOCTOR:—There appeared in *The American Practitioner*, vol. i., No. 1, January, 1870, a paper on the treatment of stricture of the urethra, etc., by Dr. F. J. Bumstead—a copy of which I sent you soon after its publication. In this article Dr. Bumstead alludes to one of my devices for catheterism upon a conductor, attributing the same to you as follows: 'One of these inventions, original, I believe, with that eminent surgeon, Professor W. H. Van Buren, M.D. . . . . .' The same expressions are used at page 283 of the third edition of his book, which has just been issued. I do not know upon what evidence or authority he persists in this course. The first instance might have been a mistake, an oversight; not so the last; for the Doctor reads, and he must have noticed the direct claim I made to the invention in my lecture published in THE MEDICAL RECORD, March 15, 1870. He also read the description of my retention catheter (based upon the tunnelled sound), published in THE MEDICAL RECORD, May 15, 1869; *The Lancet*, June, 1869; *The New York Medical Journal*, August, 1869, and reprinted in pamphlet form. This article describes an instrument of *my own*, and no one else is mentioned in connection with it. *Had I borrowed the idea* from you, I should have been happy to *acknowledge* it. You have never, to my knowledge, made any *public* claim to the device, nor have you done so *privately* to me. After our conversation of last Winter, about the remarks in Dr. Bumstead's paper, I said no more to you upon the subject, as I hoped that you had *corrected the mistake*; but it is now clear that you have either *forgotten* to do so, or, if the error was rectified by you, it has been overlooked by the author in question. Nevertheless, in the minds of those who read the book, by this oversight of a 'small matter,' I stand in the light of a plagiarist. Whether the question of priority is a 'slight affair,' or the instruments and the method are good or bad, is not the point at issue. I have *asserted*, and do now *maintain*, that they are mine, and *no facts* have been adduced to *disprove* my claim. Bald statements are made, but such dicta are not usually accepted in argument and in science. *Your denial of any right to the invention will settle the point.* I am not willing to stand accused (though by implication) of a breach of trust, however small, toward my preceptor or any one else, without defending myself. *Had I not made my claim public, I would most cheerfully yield to you*; but it is now too late. Let me remind you of your connection with the *construction** of the first tunnelled sound.

"I remember well what passed between us when we conversed, one evening in January, 1864, on the topic of difficult catheterism. You informed me that you had a patient suffering from stricture of the urethra, with false routes, which prevented the passage of metallic sounds, but that English filiform bougies could be introduced into the bladder. I then told you that *I had an idea of using such small instruments* as conductors for steel or silver sounds, *each opened at the vesical extremity, and having a short canal* for the lodgment of the minute guide; and that thus false passages might be avoided and dilatation carried on by means of larger instruments of the same sort and on the same principle. I even drew a rough sketch of such a sound, *and asked you* to have it made at Tiemann's. Expecting soon to leave town, *I could not go myself* to give the order. On my return you showed me the instrument made by Tiemann & Co., which perhaps you still have in your possession. You tried it, *but thought it would not do.* I also used it a few times, and found the canal entirely too long; the instrument was altogether so clumsy that it was set aside.

"*I afterwards went* to Tiemann's and *gave directions* for an improved pattern. Several were made during the Spring and Summer, *but I rejected them after trial*, and it was not *until November* 30, 1864, that I received from Messrs. Geo. Tiemann & Co. a properly made instrument which fulfilled the intended indications. *I subsequently named it the tunnelled sound*, and gave the account already referred to. *I have since adapted the same principle* to the English flexible catheters made by Eshman, of London.

"*There has been ample time for reclamation, but none* save Dr. Bumstead has seen fit to speak.

"Now, my dear doctor, that I have stated what I believe to be the truth in this matter, will you be *so good as to set it right* before the profession?

"Hoping soon to hear from you,

"I am very respectfully

"Your friend and obedient servant,

"J. W. S. GOULEY."

This letter, which I endeavored to write clearly in order to avoid any misunderstanding, required a categorical answer, yes or no. Yes, the invention is mine, and I do claim it; or No, it is not mine, and I have not claimed it.

But the doctor did not quite understand some portions of the letter, and avoided committing himself, one way or the other, on paper, and asked me, nine days after the date of my letter, to come and have a talk with him.

The subjoined is a copy of his letter:

Nov. 28th.

"DEAR GOULEY:—I have not been able to get at the meaning of some portions of your letter of the 19th inst., and would be very glad to have some light from you on the subject.

"Can you not step in and see me about it? I was in the country the greater part of last week, and have but just returned.

"Yours truly,

(Signed) "WM. H. VAN BUREN."

I complied with Doctor Van Buren's request, and went to see him. He then repeated to me that he had never claimed to be the inventor of tunnelled urethral

* Construction, not *invention*.

instruments. He did not state that he had, or had not had, any communication with Dr. Bumstead upon the subject, but was very urgent that I should abstain from writing to Dr. Bumstead. He (Dr. V. B.) evidently wished to avoid a controversy; in fact, he finally said so.

Our relations had always been of such a cordial nature that I yielded to his request, and for old friendship's sake I let the matter drop, and would perhaps never have taken it up, but for the publication of the following communication in the *Lancet* of July 12th, 1873:

"TUNNELLING THE END OF URETHRAL INSTRUMENTS.

"To the Editor of The Lancet.

"Sir:—Whatever may be the value of 'tunnelling the end of urethral instruments,' as described by Mr. Teevan in the last number of *The Lancet*, and attributed by him, as it has been by others, to Professor Gouley, of New York, the credit belongs to that eminent American surgeon, Professor W. H. Van Buren, and not to his former pupil, Professor Gouley. Professor Van Buren had made, and was in the habit of employing, instruments constructed upon this principle many years ago, and prior to the time when Doctor Gouley first became a student of medicine in his office.

"This statement of the authorship of the invention was made to the writer of these lines by Professor Van Buren himself.

"I enclose my card, and remain, Sir, yours faithfully,

"Honor to whom Honor is Due.

"July 7th, 1873."

A few days after reading the above, I sent to the editor of *The Lancet* the annexed letter:

"56 West 28th Street, New York, August 9th, 1873.

"TUNNELLING THE END OF URETHRAL INSTRUMENTS.

"To the Editor of The Lancet.

"Sir:—I beg leave to state that the communication to *The Lancet* of July 12th, 1873, page 63, bearing the above title and signed 'Honor to whom Honor is Due,' contains misstatements which I desire to correct.

"1. I never was 'a student of medicine in Dr. Van Buren's office.'

"2. Dr. Van Buren had never seen tunnelled urethral instruments until I made them known to him.

"3. Dr. Van Buren stated to me, early in 1870, that he had never claimed to be the inventor of the tunnelled sound or of any other tunnelled urethral instruments.

"I have the honor to be, very respectfully,

"Your obedient servant,

"J. W. S. Gouley, M.D.,

"Surgeon to Bellevue Hospital, etc."

The writer in *The Lancet* of July 12th, 1873, who signs himself "Honor to whom Honor is Due," asserts that Professor Van Buren had made, and was in the habit of employing, instruments constructed upon this principle many years ago, and prior to the time when Dr. Gouley first became a student of medicine in his office. But I never was "a student of medicine in Dr. Van Buren's office." I was a student of medicine visiting the medical and surgical wards of Bellevue Hospital (in 1851 and '52), where I first met Dr. Van Buren and made his acquaintance. After my graduation (1853) I became an interne at Bellevue Hospital, and have since always spoken of the attending physicians and surgeons of the hospital, whose clinics I attended faithfully, as my teachers, or preceptors; surely I listened to their teachings, their precepts, therefore I was their pupil. Dr. Van Buren was at that time (while I was externe and interne) one of the attending surgeons of the hospital. He has, ever since, taken especial pride in calling me his old pupil, and I have called him my preceptor; but I never was "a student of medicine in his office." It is evident that "Honor to whom Honor is Due" means to say that Doctor Van Buren had used "instruments constructed upon the principle" of my tunnelled sound before he (Dr. V. B.) knew me.

If Dr. Van Buren had ever devised or used instruments constructed upon this principle, for the treatment of urethral stricture or for any other purpose, prior to 1851, it is strange indeed that he should not have made them known in some way or another, for he was then young and ambitious, and his asserted invention would have been noticed and tried by others, who would doubtless have given him due credit. But there is no printed record that Dr. Van Buren had ever invented anything like a tunnelled sound. If he had done so, and had any motive to conceal the fact, he now deserves great censure for withholding from the profession a device which has proved so efficient in relieving the sufferings and saving the lives of so many men. But where is the evidence that the invention was made before Dr. Van Buren knew me, or before I became a student of medicine? Though not "a student of medicine in Dr. Van Buren's office," no one has had better opportunities than myself (from 1851 to 1868) to know what the Doctor has done in surgery, both in public and in private practice. While I was associated with him in the Anatomical Department (Demonstrator of Anatomy) of the University Medical College, I assisted him in nearly all his surgical operations, and have done so until 1868 (two years, 1861 and 1862, excepted); but, during all these many years, he never once made mention to me of having invented anything like tunnelled urethral instruments, nor did I ever see him use any such instruments. Never until January, 1864—when I spoke to him of my invention and explained it to him—had he thought of it, for he then said that the idea was entirely novel to him, though he questioned whether it could be carried out.

Dr. Van Buren has never published a word about tunnelled urethral instruments, or anything bearing the slightest resemblance to my tunnelled sounds. (See his Clinical Lectures on Stricture, in The Medical Record, vol. i., 1866; his paper on Stricture, in *The New York Medical Journal*, December, 1868.)

During "our friendly talk" in November, 1870, Dr. Van Buren treated the question of priority as a "small matter," and said it made very little difference whether the invention was attributed to himself or to me. But he still said that he had never claimed it. Considering that he had "never claimed" this "indifferent small matter," he did not offer to yield to me, as I said I would cheerfully have done to him if I had not already made my claim public. In the Spring of 1869 I read to Dr. Van Buren, from my manuscript, all that is contained in my pamphlet of August, 1869; he listened with great attention, and never made the slightest claim to my devices, but gave the whole his unqualified approval.

In his paper on the Treatment of Stricture, published in *The New York Medical Journal* for December, 1868, Dr. Van Buren never made the faintest allusion to tunnelled urethral instruments, though he gave what he then supposed to be the most advanced views and the most recent improvements in the treatment of

urethral stricture. Had he then considered his the idea, or even the suggestion, of the tunnelled sound, he would naturally have made some reference to this instrument.

Ever since 1864, I have been in the habit of using the tunnelled sound at my public clinics and in private practice, and no one, until 1870, has ever questioned that the invention was mine.

By referring to chapters 3, 4, 5, 7, and 8 of my recent work on Diseases of the Urinary Organs, and to the illustrative cases (most of which were published in THE MEDICAL RECORD in 1870) appended thereto, the reader will readily see by the dates of the operations that no such method was ever before made known to the profession at large.

Catheterism upon a conductor is of ancient date. I have traced it back to Desault, and have so stated in one of my published lectures and at page 54 (footnote) of my book.

I am not indebted to Dr. Van Buren for a single suggestion in the invention or construction of the tunnelled sound, but I do owe something to an English surgeon, Mr. Wakley,* for it was after reading an account of his method of catheterism upon a conductor that I was led to devise my own simpler instrument, the tunnelled sound, and it gives me much pleasure to make this acknowledgment.

56 WEST THIRTY-EIGHTH STREET, NEW YORK,
September 10th, 1873.

THE CARE OF FOUNDLINGS.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—The publication in THE MEDICAL RECORD of Sept. 1st, by Dr. Foster, of "A Minority Report on Foundlings and Foundling Asylums," reminds me of a failure on my part to perform a duty naturally belonging to the chairman of the committee appointed by the State Medical Society for the purpose of investigating the subject of foundlings and foundling institutions. I hasten, therefore, to request you to insert a very brief addition to the former report of that committee which has appeared in full in THE MEDICAL RECORD of Nov. 15th, 1872. This addition was read before the State Medical Society on the second day of its meeting, at Albany, in February, 1873.

In referring to THE RECORD of February 15th, I find the following report: "Dr. A. Jacobi, of the Committee on Foundling Asylums, which was continued from the previous year, made the final report, and Dr. Joel Foster, who was last year added to the committee, read a minority report. The former was accepted by the Society, and adopted as an expression of their views on the subject."

As far as I know, the final report of the committee has never been printed, except in a single medical journal. At all events THE RECORD, after having given due attention and ample space to the subject of foundlings, never contained that paper. While I plead guilty to my neglect in not communicating to you the final report, I still hope you will insert, at this late hour, the conclusions arrived at in the former extensive report and in this addition. Your readers will find no difficulty in deciding upon the merits of both the reports of the committee, carefully prepared in the course of a few years, and the "few remarks on the subject hastily offered," which Dr. Foster publishes as "A Minority Report."

Yours, very respectfully,
A. JACOBI, M.D.,
Chairman Committee on Foundlings and Foundling Institutions.

NEW YORK, Sept. 9th, 1873.

REPORT.

Two years ago, this Society appointed a committee consisting of Dr. White, Buffalo; Dr. Dean, Rochester; Dr. Th. Hun, Albany; Dr. Hutchison, Brooklyn; and Dr. Jacobi, New York, to investigate and report, in the meeting of 1872, upon the following subjects:

1. The causes of the fearful mortality of abandoned infants in general, and those in large public institutions in particular.

2. The reasons for the giving up of large institutions, and the success of the dispersing system for abandoned infants in every country of Europe, where the preservation of lives was an object.

3. The causes of the unusually large infant mortality in the institutions in charge of either public or self-constituted authorities in New York City and State.

4. The plans and means for improving the condition of foundlings and abandoned children in New York City and State—

a. During their infancy, when they are most subject to disease and death.

b. During childhood and adolescence, when they require an education sufficient to make them useful members, and prevent them from becoming enemies of and dangerous to society.

That report was presented here a year ago. When parts of it, and the final conclusions of the same, had been read, it was, after a short discussion, resolved to accept the report, to continue the committee, and to add the name of Dr. Joel Foster, New York, who had participated in the discussion and appeared to promise valuable contributions to its working and results.

The committee again appears before you to claim your attention, this time for a few minutes only, but for some final expression of your appreciation of its motives and endeavors.

The report was published in THE MEDICAL RECORD of Nov. 15th, 1872. Thus it has been before you for some time, and may have been read by not a few. Those who have read it, we fully believe, will feel as positive as we do of the absolute conclusiveness of the final results of our investigations. Those who have not read it, are well prepared by their knowledge as medical men, and their sentiments and convictions as practical humanitarians, to judge of their merits. Thus we again submit to you the conclusions of the report of last year for your adoption and support.

They read as follows:

"In accordance with the facts and conclusions contained in this report, which we have the honor of presenting to the Medical Society of the State of New York, we desire to propose the following:

"That the life and health of every infant is, both economically and morally, of paramount importance to society and to the commonwealth:

"That it is the duty of society and of the State to grant every infant the possibility of living and obtaining an education:

"That it can under no circumstances free itself of its responsibilities by throwing them upon private individuals; but should take care of every infant deprived of its parental protectors by death or incompetency:

"That science and experience have united on certain principles to be observed in the raising of the young:

* Diseases of the Urinary Organs, by J. W. S. Gouley, page 54, footnote.

"That human breast-milk is more appropriate than artificial food; the country more wholesome than a large city; and an inferior private dwelling better adapted than a large, overcrowded institution, to the raising of an infant:

"That the practice of uniting lying-in asylums with infant asylums or hospitals is a direct source of dangerous disease and fearful mortality:

"That the accumulation of many infants under one roof, under the best possible circumstances, and with as gentle care as is observed in New York State and City, is conducive to ill-health and unavoidable mortality; this system having been given up in Europe for this very reason:

"That according to the statistics of our own large infant asylums, especially the Infant Hospital, under the charge of the Commissioners of Public Charities and Corrections; the Catholic Foundling Asylum, under the charge of the Sisters of Charity; and the Nursery and Child's Hospital, under the charge of a Board of lady managers—all in New York City—their infant mortality is immense, and equal to the mortality of the large foundling hospitals of Europe before a radical change in their system of management was instituted:

"That the necessity of distributing abandoned infants among private families, especially in the country, is urgent:

"That the Medical Society of this State recommend such a change in the manner of caring for abandoned infants:

"That the State should see that this change be made as speedily and fully as possible, by all the public and self-constituted authorities concerned in the care of foundlings; inasmuch as it has positive responsibilities towards every member of society in general and the young and feeble in particular:

"That, however, the State should not interfere with private charity towards foundlings, so long as the interests of the infants and the Commonwealth are not injured:

"That the State ought not to be held responsible for expenditures not incurred by itself nor under its own control; that private charitable societies should not assume duties beyond their own means; and, in particular, that, while private charity and enterprise must be encouraged, private ambition and officiousness must not be indulged in at the expense of the taxpayers:

"That therefore, when private individuals or corporations ask the Commonwealth for permission to administer charity on a large scale, under the rules and regulations of a charter, this permission and charter does not involve that the State should be tributary to such individuals or corporations:

"That, as medical men and citizens of the republic, we are of the opinion that the maintenance of large institutions for the care of foundlings, by the payment to them by the State of eight dollars per head per month, is not productive of good results:

"That the probability, or possibility, of frequent changes in the administration of such institutions, which are, moreover, liable to be placed under the charge of persons whose qualifications for the solution of questions of the greatest difficulty and importance is frequently doubtful, is a source of great danger to both the infants and to the Commonwealth:

"That the supervision and control of all the abandoned infants of the State belongs alone to the State; no matter whether they are sustained by the State, or by private individuals or corporations:

"That we see in such supervision and control no unrepublican centralization, but the performance of a duty of the Commonwealth towards the feeble and dependent young."

Your committee recommend that the conclusions of their report be adopted by the Medical Society of the State of New York, as best adapted to the requirements of humanity and science, and laid before the legislative body of this State as the expression of its views.

We might go further and say that we, citizens and taxpayers, protest against squandering our and the people's means on institutions gotten up, indeed, in good faith and for laudable ends, but abortive in their results, dangerous through their effects, and destructive both to the public treasury and the life of the young. Year after year time and efforts of both individuals and corporations are spent in the attempt at obtaining a large share of the public income for private charitable, or so-called charitable, institutions. All of us who have studied the list of such establishments as participate in the bountiful distribution of public funds, know with pangs of sorrow and disgust that this distribution, in many of the items, is injudicious, and better adapted to serve private ends than the requirements of charity or the public good. We do not pretend to legislate for the consciences of our legislators as elected by the people, but we insist upon public resources not being deereed away upon the recommendations, pleadings, and lobbying of private individuals. We insist upon our voice being heard in those matters which we, strengthened by our knowledge of the scientific facts, and by a careful study of the results of both scientific and unscientific experiences, believe to understand better than those who, not fortified by knowledge, are easily misled by sentimental representations and high-phrased eulogies of alleged or supposed charity. At all events, we insist upon the State Board of Charities, or another appropriate and well-informed Board, to have full power to investigate the claims of those who mean to thrive at the public expense, or pretend to carry the load of public duties on private shoulders. And we beg and pray that the Legislature of this State may not forget that the taxpayers in the community may be remembered when public funds are distributed broadcast in mistaken liberality, and that the earnest humanitarians will never be the importune leeches of the treasury. And we also beg that when the claims of private persons or societies are considered valid, because of the praiseworthiness of their undertaking, before their requests be granted and large amounts of public funds legislated away, the question be answered, if those amounts are, or are not, in an undue proportion to the results promised, claimed, or obtained.

All of which is respectfully submitted, and, together with our report of last year, recommended for adoption.

Dr. Thomas Hun, Albany,
Dr. White, Buffalo,
Dr. Dean, Rochester,
Dr. Hutchison, Brooklyn,
Dr. Jacobi, New York,
Committee.

Medical Items and News.

Medical Society of the County of New York.—A meeting of the Society was held on Monday evening, September 22d. Professor E. M. Moore, of Rochester, President of the State Medical Society, was present by invitation, and a paper was read by Professor Austin Flint, Sr., on "The Tolerance of Diseases."

Prof. Moore made some remarks upon consecutive dislocation of the radius and ulna backwards, for the purpose of asking the experience of members upon the subject. He had not been able to find any account of the occurrence in the books; but as the result of persistent inquiry three cases of the sort had been given him. That such a thing was possible, he was enabled to prove by direct experimentation, in one case which had been under his care. In a word, he had found that the patient, being under ether, and the dislocation reduced by allowing the limb to drop to an angle of 130°, both the forearm bones slipped very easily backwards. He did not, however, say whether the coronoid process had been broken in this case.

The following gentlemen were nominated to hold office during the ensuing year, the election to take place at the next stated meeting:—

For President—Ellsworth Eliot, Frank H. Hamilton, John C. Peters, Henry B. Sands, T. G. Thomas.

For Vice-President—Henry B. Sands, John C. Peters, Robert A. Barry.

For Recording Secretary—Alfred E. M. Purdy.

For Corresponding Secretary—F. A. Castle.

For Treasurer—Jos. E. Janvrin.

For Censors (five to be chosen)—H. F. Hanks, S. Caro, A. H. Smith, G. M. Smith, R. J. O'Sullivan, T. C. Finnell, James Ross, H. P. Farnham, M. H. Henry, John C. Peters, A. Jacobi, J. J. Crane, J. S. Monell.

For Delegate (to serve for one year to fill a vacancy)—R. A. Barry, L. de F. Woodruff, F. A. Castle, W. B. Wallace, W. L. Richardson, Geo. Bayles, E. Peugnet.

The following gentlemen were granted certificate of membership:—

Thomas F. Healey, M.D.; Haynes L. Richardson, M.D.; Mathew C. O'Connor, M.D., and Gabriel Grant, M.D.

The following preamble and resolutions were presented to the Society by the Comitia Minora, through Dr. J. C. Peters, and unanimously adopted:—

"WHEREAS, The Legislature of the State of New York did not provide for the publication of the Transactions of the last meeting of our State Society,

"*Resolved*, That the Medical Society of the County of New York is of the opinion that the Committee on Publication of the State Medical Society should at once proceed to publish the same at the expense of the County Medical Societies, or in any other manner that they may think more favorable for securing the immediate publication of the Transactions.

"*Resolved*, That this Society will pay its proportionate amount of the expense that the Committee on Publication may find necessary.

"*Resolved*, That a copy of this preamble and resolutions be sent by the Corresponding Secretary to the Acting President of the State Medical Society, and to its Committee on Publications."

DEATH OF HENRY STUART HEWIT, M.D.—At a meeting of the House Staff of Charity Hospital, held August 21st, 1873, the following resolutions were unanimously adopted:

Whereas, It has pleased all-wise Providence to remove by death Dr. Henry Stuart Hewit: Therefore,

Resolved, That we are called upon to mourn the loss of one whose counsel and advice have been sources of profit and pleasure to all.

Resolved, That in his official relations to this Hospital, as President of the Medical Board and Visiting Surgeon, he has shown a high classical and medical culture, which, combined with integrity and personal affability, has endeared him to many by ties of personal friendship, and gained the respect of all who knew him.

Resolved, That copies of these resolutions, duly authenticated, be sent to the family of the deceased, and printed in the medical journals of this city.

W. OLIVER MOORE, M.D.,
W. E. FORD, M.D.,
G. O. MORRISON-FISET, M.D., } *Committee.*

The following series of resolutions were unanimously adopted by the Medical Board of Charity Hospital:

Whereas, Dr. Henry S. Hewit, our late President, and for a long time our colleague in the Medical Board of Charity Hospital, has been suddenly stricken down by the hand of death while in the active discharge of his professional duties: Therefore,

Resolved, That in the death of Dr. Hewit, the Hospital has lost a faithful and efficient officer.

Resolved, That having endeared himself to us his colleagues by his frankness, sincerity, and earnestness of character, united to the many other virtues he possessed, we mourn in him the loss of a true friend and a zealous co-laborer.

Resolved, That as a memorial to our late President, the Medical Board request the Commissioners of Public Charities and Correction to have the following inscription placed upon the tablet in the hall of the Hospital: "Henry S. Hewit, M.D., President of the Medical Board of Charity Hospital, died August 19, 1873, while on duty as one of the attending surgeons."

Resolved, That we tender to the family of the deceased our sincere sympathy in their deep affliction.

Resolved, That these resolutions be entered in full upon the Minutes of the Medical Board, be published in THE MEDICAL RECORD and the *New York Journal of Medicine*, and that a certified copy of the same be forwarded to the family of the deceased.

ALEX. W. STEIN,
Secretary *pro tem.*,
Medical Board Charity Hospital.

THE CANADA LANCET nearly doubles its former capacity with the issue of the number for Sept. 1st.

A STRANGE MEAL.—At a meeting of the Medical Society of Victoria, held in June, 1872, the following collection, taken from the stomach of a lunatic, upon whom a post-mortem examination had been made, was exhibited: Twenty-five pebbles, sixteen pieces of glass, twelve nails, one screw, two bones, a button, five bits of tin, a peach stone, six fragments of a pipe-stem, and a whole cutty pipe.

THE SIXTH ANNUAL MEETING OF THE CANADA MED. ASSOCIATION was held at St. Johns on the 6th of August. Dr. Marsden, of Quebec, was elected President, and Dr. David, of Montreal, General Secretary.

MEDICAL SOCIETIES IN SWITZERLAND.—There are forty medical societies in Switzerland, including practitioners in all the cantons except Tessin and Wallis. The largest is the cantonal society of Zurich, with 149 members. One—the Oberamergau Medical Society—is more than a hundred years old; and five others have existed more than fifty years. About half of them hold twelve or more meetings in the year; the remainder meet less frequently—from one to seven times in the year. The cantonal society of Bern possessed a fund of 9,500 francs at the end of 1871; the subscriptions to the others vary from one to five francs yearly. —*London Medical Record.*

VOLTAIRE'S DEFINITION OF A PHYSICIAN is, "An unfortunate gentleman expected every day to perform a

miracle; namely, to reconcile health with intemperance."

Petroleum Champagne.—*The Doctor* gravely says: "The acute commercial element of the Americans—that part which we may suppose sent over the wooden nutmegs—has discovered that by the aid of flavoring it is possible to dispose of mineral oil as champagne; and we are assured on the testimony of those who may be supposed to know—viz., American mineral-oil refiners and brokers—that they sell large quantities to champagne-makers. The 'stuff' is said to be sweetened with glycerine, as sugar does not answer, aerated by a soda-water machine, and sold for ball-room consumption. It produces terrible headache, and often severe diarrhœa and other evil effects. Let us hope that it is not true that a consignment of this stuff has reached England *viâ* a French port."

[We wonder if *The Doctor* has heard of a disease called *Hæmatuprosis*, which a physician now resident of this city, but formerly of Philadelphia, first described. The patient—a German—had been addicted to excessive use of lager-beer, and at last manifested symptoms of poisoning, which were attributed to some of the principles of the lager. His physician directed the use of hot baths, for the purpose of aiding the elimination of the poison, and a remarkable thing in connection with this portion of the treatment was, that the water of the bath became effervescent on account of the amount of carbonic acid which it absorbed. The wife of the patient—a frugal German woman—took advantage of this phenomenon to bottle the water and sell it for ginger-pop; but we are not able to say whether she sent any of it to England. Our cousins would do well to look out for it.]

The Lord Mayor's Reception of the members of the British Medical Association, on the 5th of August last, in London, is particularly worthy of note. The State Drawing-room and Long Parlor of the Mansion House were filled with works of art; the Justices' Room and the Venetian Parlor were converted into dark rooms for electrical and other luminous experiments. The Egyptian Hall was arranged as a concert-room, and vocal music was furnished by Mesdames Nilsson and Patti, Signori Foley and Rizzoli, Mr. Stanley and others; the Old Ball-room was fitted as a refreshment-room. The supply of microscopes, spectroscopes, photographs, portable aquaria, polariscopes, minerals, etc., was large; and altogether everything appears to have been done to render the evening delightful to every one of the immense crowd of visitors, numbering 3,400; several hundred being ladies.

Green County Medical Society.—The following officers were elected for 1873: *President*, Walter B. Chase, M.D.; *Vice-President*, Bradley S. McCabe, M.D.; *Secretary and Treasurer*, Silas W. Dean, M.D.

Dr. Moritz Heinrich Romberg died of chronic cardiac disease on the 16th ult. He was born at Meiringen, and graduated in medicine at Berlin in 1817. Dr. Romberg's life appears to have been a laborious one, since he held the position of medical officer to the poor of Berlin from 1820 to 1845, and in 1830 and 1836 he was director of the cholera hospital in the same city. In 1838 he was elected extraordinary professor, and in 1845 ordinary professor, to the university at which he graduated. He is an instance of a physician successful in a special branch of medicine, although doing a more or less general practice and writing upon other subjects. He was the author of a work on cholera, and of various contributions to the periodical press, but will be chiefly remembered on account of his treatise on the "Nervous Diseases of Man," which was first published, in three parts, in 1830, 1833, and 1836, and was in 1853 translated into English by Dr. Sieveking for the late Sydenham Society. At the date of its appearance it was undoubtedly the best book extant upon the subject upon which it treats. —*Med. Times.*

Professor Sharpey, of England, has recently been successfully operated on for cataract.

A New Use for Old Stockings.—A plan of putting up simple fractures of the leg, which is not, we believe, generally known, and which country surgeons may sometimes find convenient, has lately been practised at University College Hospital. The broken limb is first bandaged with an ordinary roller; this is well coated with the gum and chalk mixture; a stocking is slipped on over this, and similarly coated; another stocking is put on over this; and a final layer of gum and chalk over all. Thus, for a case of transverse fracture with little displacement, or of fracture of one bone, two or three stockings and a little starch or plaster-of-Paris supply a very neat and serviceable splint.—*British Medical Journal*, May, 1873.

A Cholera Panic.—A writer from Jonesboro, Tenn., in the St. Louis *Globe*, says that that town has ordinarily about one thousand five hundred inhabitants, but at present there are not twenty-five people left. The rest have run away to the various mineral springs in the neighborhood. The town is a picture of perfect desolation. It has been deserted for nearly three weeks, and the streets are overgrown with grass. I went the whole length of the place, and did not meet a man, woman, or child; no, nor a horse, cow, or dog. The people went away in such haste as to forget almost everything; and left the dogs chained, the cows in the lots, and the calves in the stalls. Some of the chained dogs starved to death; most of the stock was driven out of town to, and put in, pasture by the few men who stayed, and the dogs that were loose were so lonesome and howled so dismally that the men took their guns and shot them all. Every store is closed, and even the hotel cook, sole occupant of the building, refused to admit me as a guest. I did not intend to stop in town, but wished to go to my relations, some five miles out. I could get no conveyance. I got one of the grave-diggers to guide me, and walked a part of the way, until I could get a rattle-trap buggy to take me the remainder. But the country people were afraid of us both: some refused him admission to their houses, and others wondered if I were not afraid to ride with him. He told me he recently went to a country house where the occupants refused him admission, and rather than have him near, sent his dinner out to the fence, and told him to eat it and travel. He had been using carbolic acid as a disinfectant. They perceived the peculiar odor, and supposing it to be the smell of the cholera, held their noses and beat a precipitate retreat.

The Michigan University, at Ann Arbor, has matriculated eighty-eight girls for the coming year, thirty-seven of them being in the medical department.

Maine Medical Association.—The officers of this Association for the ensuing year are as follows: *President*, Dr. A. T. Page, of Bucksport; *Secretary*, Dr. O. C. Hunt, of Portland.

The University of Nashville.—Professors Bowling, Winston, and Lindsley have resigned their chairs in the University of Nashville. They are succeeded by Drs. Maddin, Nichol and Callender.

THE OLDEST PRACTISING PHYSICIAN.—A correspondent of the *Medical and Surgical Reporter* writes, in answer to a query, that Dr. Ahl, of Baltimore, continued in active practice until he was ninety-six years of age; Dr. Bernardus Van Leer, of Chester Valley, did the same until he was one hundred and two years old. He died at the age of one hundred and four.

UNIVERSITY OF MICHIGAN.—Dr. Eugene W. Hilgard, a native of Germany, is the new Professor of Geology, Zoölogy and Botany in the University of Michigan. He has been for the last eighteen years a professor in the State University of Mississippi.

NEW YORK SOCIETY FOR THE RELIEF OF THE RUPTURED AND CRIPPLED.—The Tenth Annual Report of this Society, for 1873, gives the following particulars: Since the opening of the Institution in May, 1863, 21,814 have been relieved—the first year 828; the present year 4,023. In the dispensary department 3,858 received treatment, and nearly all of them required surgico-mechanical appliances. Of the number afflicted with rupture, 1,047 adults and 489 children were supplied with trusses. The next most common ailment was varicose veins, the result of arduous labor. *Resident Physician and Surgeon*, James Knight, M.D.; *Assistant Physician and Surgeon*, Virgil P. Gibney, M.D.; *Resident Junior Assistants*, Truman S. Sumner, M.D., and Thomas H. Hawkins, M.D.

VERMONT INSANE ASYLUM.—Dr. Wm. H. Rockwell has resigned the superintendency of this institution, in consequence of permanent disability from fracture of the thigh. Dr. Joseph Draper, of the New Jersey State Asylum, has been appointed to fill the vacancy.

MASSACHUSETTS MEDICAL SOCIETY.—At the late annual meeting of this Society, the following officers were elected for the ensuing year: *President*, Dr. G. C. Shattuck; *Vice-President*, Dr. E. Cotting; *Corresponding Secretary*, Dr. C. W. Swan; *Librarian*, Dr. D. H. Hayden; *Treasurer*, Dr. F. Minot; *Orator*, Dr. Nathan Allen; *Anniversary Chairman*, Dr. R. L. Hodgdon; *Committee of Arrangements*, Drs. R. Amory, A. H. Nichols, C. J. Blake, T. Dwight, Jr., J. C. Warren.

Drs. Wm. Bushnell, Milton Fuller, Herman L. H. Hoffendahl, Geo. Russell, Israel T. Talbot, David Thayer and Benjamin H. West were expelled from the Society for being irregular practitioners, after a long and fair trial.

HARVARD MEDICAL SCHOOL.—C. Ellis, M.D., Dean of the Medical Faculty of Harvard University, takes, in a letter to the *Phila. Med. Times*, a very hopeful view of the success of the Harvard Medical School, and states that the receipts from students were only $3,600 less in 1871–72 than in 1870–71. One hundred and fifty students under the new plan gives a considerably larger revenue to the school than 300 did under the old. He thus concludes: "If five or six of the other leading medical schools in this country would join the Harvard school in making the changes in the system of Medical Instruction, which Dr. Stillé and all other intelligent physicians who honor their profession admit to be desirable, there would be no question in any one's mind about the success of the reform."

STRICTURE OF THE URETHRA.—The reprint from the *N. Y. Medical Journal*, containing the "Remarks on Strictures of the Urethra," by F. N. Otis, M.D., of New York, has much that is instructive to practitioners concerning strictures of extreme calibre, with cases, and a description of new instruments for their treatment.

NORMAL OVARIOTOMY.—At the 24th Annual Session of the Georgia Medical Association, held recently, Dr. Robert Battey, of Rome, Ga., delivered an excellent paper on "Normal Ovariotomy," which appears in the form of a reprint from the *Atlanta Medical and Surgical Journal*.

YELLOW FEVER AT SHREVEPORT AND MEMPHIS.—Shreveport, La., on the Red River, was visited during the latter part of August with yellow fever of the most malignant type, the disease having been brought, so it is thought, by a travelling circus company, ten of whose members died at Vernon. The place was quite destitute of any sanitary precautions, and its spread appears to have been entirely beyond human control, and exceedingly fatal. A despatch from Shreveport, dated Sept. 16th, placed the deaths from Sept. 1st to that time at one hundred and twenty-six, and the number of cases then in existence at from six to eight hundred. On the 19th the population, by deaths and removals, had been reduced from 5,000 to 3,000, and of this number it was estimated that fully 1,000 were sick or convalescent. The utmost destitution prevailed, and was the cause of as much suffering as the disease itself. Telegraph operators had all died, and their places, as well as relays of physicians, nurses, and apothecaries, had to be supplied from New Orleans, where the Howard Association have organized a system of relief and received subscriptions, which, up to the time of going to press, have been pouring in from all parts of the country.

The latest despatches say that the disease is decreasing from want of material, and that it is extending in the suburbs, attacking negroes and acclimated persons, even such as had the fever in the epidemic of 1867.

On the 16th the disease was reported at Fulton, the terminus of the Cairo and Fulton R. R.

On the 18th Natchez was quarantined against all outsiders, and no cases of the disease have as yet been reported there.

On Sept. 14th the Board of Health of Memphis announced the presence of the disease in that city, where it was most prevalent in the north-west part of the town. Having started in the neighborhood of Wolf River, on that day (the 14th) eleven interments were made, the total up to that time having been thirty.

On the 16th the authorities commenced to burn coal-tar in the infected locality, and many of the citizens, by the advice of physicians, were leaving for places of safety.

The disease in Memphis is reported to be of a milder type than in Shreveport, and it is said that nearly all properly managed cases recover.

DEATH OF NÉLATON.—Auguste Nélaton, the famous French surgeon, died at his house, in Paris, on the 20th of September, of disease of the heart. He was born on the 17th of June, 1808, and after a thorough preliminary education studied medicine under Dupuytren, and received the degree of Doctor of Medicine from the University of Paris in 1836.

Soon afterwards he became surgeon to the hospitals in the French capital, and a member of the Faculty of Medicine. He was chosen Professor of Clinical Surgery in the University in the month of April, 1851, and in 1856 was admitted to the Academy of Medicine in the section of Chirurgical Pathology. He was a close observer, a practical student, and a careful and enlightened practitioner. Decorated with the Legion of Honor, in 1848, he was promoted to the rank of officer June 16, 1856, and to that of commander on the 24th of January, 1863.

It was he who introduced the bilateral operation

for stone, and since his voyage to Caprera, and the extraction of Garibaldi's bullet, he had become one of the most, if not *the* most, popular of the French surgeons. His reputation was much heightened by the fact of his having been the only practising medical man made a Senator and Grand Officer of the Legion of Honor during the Empire.

He was voluminous as a writer and publisher on subjects connected with his profession. The Doctor was made a member of the French Academy of Sciences on the 3d June, 1867, and soon afterwards retired from his professorship on account of ill-health. His reputation is world-wide, and his character universally esteemed.

More than six years since he began to suffer from cardiac disease, which became aggravated after the overthrow of the Empire. Still, with strict attention to his diet and habits, he was able to attend to some professional work until about two months before his death, when his health failed him entirely, and he was obliged to return to Paris on the 10th of August. For more than a month before his death the papers published a daily bulletin of his condition, and the subject was everywhere talked of as a threatened national loss.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from Sept. 5, 1873, to Sept. 18, 1873.

PAGE, CHAS., Surgeon.—Relieved from duty at Fort D. A. Russell, Wy. Ty., and assigned to duty at Omaha Barracks, Nebr. S. O. 140, Department of the Platte, Sept. 12, 1873.

RANDOLPH, JNO. F., Surgeon.—Relieved from duty at Omaha Barracks, Nebr., and assigned to duty at Fort D. A. Russell, Wy. Ty. S. O. 140, C. S., Department of the Platte.

WOODHULL, ALFRED, Assistant Surgeon.—Granted leave of absence for twenty days, with permission to leave limits of Department. S. O. 157, Department of the South, Sept. 6, 1873.

KIMBALL, J. P., Assistant Surgeon.—After completion of duty assigned him in Department, S. O. 190, C. S., to report in person at these Headquarters for further orders. S. O. 189, Department of Dakota, August 25, 1873.

YEOMANS, A. A., Assistant Surgeon.—Ordered to Washington, D. C. S. O. 178, A. G. O., Sept. 6, 1873.

BYRNE, C. B., Assistant Surgeon.—Granted leave of absence for sixty days, with permission to apply for an extension of thirty days. S. O. 182, A. G. O., Sept. 11, 1783.

New Publications.

BOOKS RECEIVED.

THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY, from 1775 to 1873. Compiled under the direction of the Surgeon-General, by HARVEY E. BROWN, Ass't Surg. U. S. Army. Washington, D. C.: Surgeon-General's Office, 1873.

DISEASES OF THE PROSTATE AND THEIR PATHOLOGY AND TREATMENT. By Sir HENRY THOMPSON, F.R.S., etc. Fourth edition. Philadelphia: Henry C. Lea. 1873.

HAND-BOOK OF PHYSIOLOGY. By WILLIAM STENHOUSE KIRKES, M.D. Edited by W. MORRANT BARKER, F.R.C.S., etc. A new American from the eighth enlarged English edition. Philadelphia: Henry C. Lea. 1873.

SIX MONTHS UNDER THE RED CROSS, with the French Army. By GEORGE HALSTEAD BAYLAND, M.D. Cincinnati: Robert Clarke & Co. 1873.

BODY AND MIND: An Inquiry into their Connection and Mutual Influence, especially in Reference to Mental Disorders. To which are added Psychological Essays. By HENRY MAUDSLEY, M.D., etc. London: Macmillan & Co. 1873.

DIGESTION AND DYSPEPSIA, a complete Explanation of the Physiology of the Digestive Process, etc., etc. By R. T. TRALL, M.D. New York: S. R. Wells, Publisher. 1873.

Original Lectures.

CLINICAL LECTURE ON PUERPERAL CONVULSIONS.

By Prof. W. T. LUSK, M.D.

DELIVERED AT BELLEVUE HOSPITAL.

(Phonographically reported for The Medical Record.)

In cases of puerperal convulsions, sometimes prodromata warn us of the impending explosion, but often enough they are entirely absent, so that whether they exist or not it is well to occasionally examine the urine of a pregnant woman.

When any of the ordinary prodromata are present, such as œdema of the feet and hands, puffiness of the face, singing in the ears, dimness of vision, and, what is very suspicious, the existence of certain inveterate neuralgic ailments, and at the same time albumen is detected in the urine, a shrewd guess may be hazarded that the woman will have convulsions. But even with these conditions convulsions do not necessarily take place. However, it is well to accept the warnings, and place the woman upon such treatment as shall tend to prevent the development of eclampsia. The best means for the accomplishment of this end consist in most cases in the employment of remedies likely to improve the condition of the blood, which is usually watery and much impaired in quality. Among our most reliable agents, in addition to good food, are the muriated tincture of iron and the chlorate of potash. Milk should enter largely into the diet, both on account of its nutritive properties and its special action upon the kidneys. The skin should be maintained in a healthy condition by warm baths. Diuretics and hydragogue cathartics are indicated only when the diminution in the quantity of the urine, or the lowering of the specific gravity, threatens the patient with an immediate pressing danger.

As exceptions to the foregoing directions are those cases where the women are plethoric rather than hydræmic. In these a reducing diet, saline cathartics, and sometimes even venesection to a moderate extent, may be resorted to. Formerly all women were bled during pregnancy, and many an old woman will tell you nowadays that in her time, when bleeding was the rule, they never had puerperal fever, or any of the dreaded accidents of the present day. Now we have passed to the opposite extreme. Cazeaux has convinced us all that the condition of a pregnant woman is either that of anæmia or chlorosis. There is, however, some doubt, in spite of the chemists, whether this rule is sweepingly correct. In some primiparæ gestation appears to occasion an enormous increase of appetite, and I confess that I have at times found it impossible, in the absence of any physical signs, to associate with the rosy lips and brilliant coloring of many of these patients any idea of anæmia. In such cases, should there be manifested any marked evidences of cerebral hyperæmia, I should strongly incline toward the employment of the lancet, for the sake of the immediate relief venesection occasions.

That bleeding is not necessarily the fatal operation which it is assumed to be to-day, is shown by the case reported by Cavalli, of Maria Besana, who was bled in twenty-eight years three thousand five hundred times.

The treatment of the convulsions proper depends somewhat upon our views concerning their origin.

The popular belief undoubtedly is, that they are due to the accumulation of urea in the organism, and that the presence of albumen in the urine during the seizure is to be accepted as the evidence that such an accumulation has been in progress. In connection with this theory, however, the following facts are to be borne in mind: 1. A considerable number of observations where the urine presented no traces of albumen either before or after the convulsions. 2. A still larger collection of cases in which the albumen appeared subsequent to, but not previous to, the outbreak. The observation of this peculiarity is often ascribed to Braxton Hicks, though, as a matter of fact, his paper published in the "Obstetrical Transactions" of 1867 simply shows that he was at the time ignorant of the extent to which the matter had already been discussed in Germany. 3. When the kidneys are examined after death, the changes found in them are usually very trivial. 4. Bright's disease existing before pregnancy is far from giving occasion to an unfavorable prognosis. I know one lady who had Bright's disease previous to her marriage, and has now had four children, yet she has never had convulsions. Another lady had one child after the disease of the kidneys had reached an advanced stage, yet there were no convulsions, though she died from the kidney affection about eighteen months afterward. Scyfert found that out of eighty pregnant women suffering from confirmed Bright's disease, only two had convulsions. 5. Patients suffering from carcinoma uteri may die from hemorrhage, septicæmia, marasmus, peritonitis, etc.; but in many cases the cancerous infiltration invades the bladder and produces occlusion of the ureters, so that death results from suppression of the uretero. Many cases of death from this cause, among them fifty-four reported by Cornil and Ranvier, stand recorded as having terminated without convulsions. Each new case of this description is usually reported with a certain species of surprise by the attending physician.

Notwithstanding these facts, however, I am not to be understood as altogether rejecting the uræmic theory. Clinically it remains true that albumen in the urine during pregnancy is a frequent precursor of convulsions. Often I have found, in cases of eclampsia to which I have been summoned, a total suspension at the time of the urinary secretion. Not long since I saw a patient who had already had three convulsions, and was then in the fourth. As the head was low down on the perineum, I determined to use forceps and deliver at once. On introducing the catheter as a preliminary, I drew off three pints of retained urine from the bladder. After that the convulsions ceased. In order that uræmic phenomena should be produced, it is necessary that the accumulation of urea in the tissues and fluids of the body should have gone on to a certain non-determinable extent. In cases where little food is taken, and the patient is quiet in bed, the production of urea may be very small, so that in the patients suffering from cancerous affections noted, death may take place from the pain caused by the distention of the ureters before a sufficient amount of urea is stored up in the system to give rise to uræmic symptoms.

Certainly all cases, however, are not due to blood-poisoning. In some women the pregnant condition induces an undue excitability of the nervous system. All the tissues of the body are depreciated, and the nervous system acquires an excessive reflex susceptibility. Pressure upon the peripheral nerves during labor becomes the direct exciting cause of the explosion.

Traube and Rosenstein look upon puerperal convulsions as due to anæmia of the brain. The first

step in the production of this condition is an hydræmic state of the blood. An increased pressure in the capillaries of the brain arises from hypertrophy of the heart which is a constant accompaniment of pregnancy, and the interference with the venous circulation due to the gravid uterus. Œdema of the brain results, and as the skull is unyielding, secondarily the vessels of the brain suffer compression, and the consequent anæmia gives rise to convulsions.

On the other hand, plethoric women do have convulsions, which perhaps are due to congestion of the spinal cord.

Probably we are nearest the truth when we adopt the view that causes of puerperal convulsion are multiform. When we come to treatment, we find that even on theoretical grounds beneficial results are to be expected in many instances from venesection. In uræmia, bleeding helps to unload the system temporarily of a part of its poison; in plethoric persons it relieves the congestion; in threatened œdema of the brain it may ward off permanent damage to the cerebral organ. In nervous anæmic persons, where the origin is due to reflex excitability, it can only aggravate the disorder, and exposes such women afterward to peritoneal inflammations. Its virtue lies, it is to be remembered, however, purely in the fact that in the face of an immediate threatening danger a little time may be gained by its employment. Therefore, unless my patient is not already greatly depressed, I do not hesitate to draw from the arm twelve to sixteen ounces of blood.

Then I resort to anæsthesia, pushed to an extent sufficient not only to destroy sensibility, but likewise to overpower the voluntary motor-nerves of the body. Hypodermic injections of morphia (gr. ¼, repeated, if required, once or twice) support the action of the anæsthetic, and render much less of the agent necessary. Anæsthetics and narcotics, I am sure from experience, often succeed, after moderate venesection, where previously they had failed.

But anæsthesia must not be maintained indefinitely. When kept up for from twenty-four to forty-eight hours it is pretty certain that the child will fall a victim to such prolonged employment. It therefore becomes incumbent to empty the uterus as soon as practicable. If labor has somewhat progressed, this is to be accomplished by forceps or version, according to the nature of the case. In the earlier stages the Barnes dilators render us excellent service. If the cervix is too narrow to admit the smallest size, I begin with a sponge-tent. Manual dilatation is at all times a detestable practice. After dilatation the cervix is often œdematous, and then, if the head has not descended, forceps are to be used with the greatest caution.

After the labor is over, if the convulsions continue, they may be controlled by hypodermic injections of morphia. Chloroform, after confinement, is no longer a safe agent.

The patient* whose delivery you witnessed has, since her confinement, been put upon the following mixture:

℞. Infusi. Digitalis..... ℥ iv.
Potassæ Acetat..... ℥ i.
Solv.

Tablespoonful every four hours. Her kidneys are now acting freely.

SOME REMARKS ON CLIMATE.

By Wm. H. BENNETT, M.D.,
NEW YORK.

Although in the treatment of phthisis the influence of climate has of late received considerable attention, and the effects of its different elements have been more faithfully studied, yet the mind of the medical profession is still unsettled as to which of the several climatological agencies proves most beneficial, and which is most pernicious, in this disease. The humid climates of Florida and the West Indies have their advocates as well as that of the cold North-west, while there are many who have no preference; avoiding extremes, they consider one climate about as good as another, and attach great weight to frequent change of air and scene, which, by increasing the appetite and favoring assimilation, they think does all the good. There are still others who select different climates for different cases. Where such a variety of opinions exists I do not presume to decide; I venture, however, a few remarks on this subject, which I consider an important one.

The great difference of opinion regarding the influence of temperature and moisture, the principal elements of climate, on the progress and result of pulmonary consumption, arises from the circumstance that many well-marked cases have been benefited or cured in localities where cold, or heat, or moisture was the predominating feature, and well illustrates the fact that the sources of fallacy in all departments of medical science are numerous, and that we must exercise great care in trying to guard against them. There is a class of persons who seemingly possess immunity from phthisis, and although living under the most favorable circumstances for developing the disease, they remain uninjured. Others less strongly constituted, under the same conditions, are attacked sooner or later; but originally possessed of considerable vitality, and the functions of the other organs being normal, or but slightly impaired, they have only to avoid the exciting cause to check the progress of the disease, and if favorable circumstances are brought to bear upon them they get well—very frequently in the same locality. They probably give up their occupation, avoid their former excesses, and protect themselves as far as possible from every source of evil; if now to all this some add a change of residence to a place possessing only slight climatological advantages over their former abode, their recovery may be hastened; but the influence of the climate frequently gets credit for more than it deserves. If the change happens to be to a moist climate, both patient and physician may be led to think the evils of moisture overrated; or if it is to a cold climate, cold may be looked upon as no drawback to the favorable termination of phthisis. Unfortunately, all cases are not such favorable ones for treatment; the majority are below par in every respect, and many of them were so when they were born. The removal of all sources of irritation and debility is not sufficient to arrest the disease in these patients, and it will not suffice simply to send them to a better climate than the one in which they reside; they need the best that exists, and even then we are but too often mortified to find them sink.

What part climatological agencies may play in the causation of phthisis I am not prepared to discuss,

although I think it proven that the greatest number of deaths from consumption occurs in humid climates, where the extremes of heat and cold are greatest, and sudden changes frequent, notwithstanding many go abroad to die. But that climate has a decided influence over the progress and result of this disease, after it is once developed, is what the teachings of physiology would lead us to expect, and what daily experience demonstrates beyond a doubt.

It must be admitted that the selection of a climate may be determined in a great measure by the peculiarities of the case, and that certain patients may do well in a climate which would only hasten the disease to a fatal termination in others; but this is no argument in favor of the theory that, as a rule, the peculiarities of individual cases require the influence of different elements of climate; the fact being, that patients in the first stage of phthisis, or those possessing considerable vitality, may be able to resist the evil influences of a climate as well as take advantage of the favorable ones, which cannot be done by cases more advanced or more debilitated. I think it may be stated that there are certain peculiarities of climate, which, if they could be secured together, would constitute a standard climate, suitable for nearly all cases; and these peculiarities would be: 1st, a comparatively dry atmosphere; 2d, absence of extremes of temperature; 3d, no great diminution of atmospheric pressure. Frequent winds, if not too high and cold, and if the patient could be properly protected from them when necessary, would be rather beneficial than otherwise. Slight variations of temperature also would be rather favorable than prejudicial.

Temperature, with its variations, is generally considered of first importance in the selection of a climate; and in seeking mildness and uniformity great drawbacks are frequently overlooked. But the agencies heat and cold cannot be discussed without at the same time considering the effects of moisture. This latter agent is an evil at all temperatures when present in considerable quantity, and its pernicious effects are increased as either extreme of temperature is approached.

A moist warm climate can, of course, only be endured during the winter months; and although, compared with that from which certain patients may have removed, it may be beneficial, and although some patients may improve in such a climate, it is certainly not the proper one for the consumptive; for, aside from the fact that exhalation from the skin and lungs is diminished, and the effect on the general health pernicious, owing to the continued high temperature of the body, due to imperfect evaporation from the surface, and the fact that the functions of the different organs are interfered with, causing debility, loss of sleep and appetite, the immediate effect upon the local disease itself is injurious, particularly if softening have already commenced. The secretion from all diseased surfaces is increased in a warm, humid climate; for the blood-vessels of every part with which the moist atmosphere comes in contact are dilated, and the circulation through them is retarded. If there exist a cavity secreting muco-purulent matter, this latter is augmented and cicatrization hindered or prevented. Diseased tissues absorb moisture from the air, when it is in excess, at all temperatures, and become swollen and tumefied. This fact is well demonstrated by watching bad cases of chronic bronchitis or nasal catarrh on days of excessive humidity; even though the sun may be shining brightly, these patients will complain of feeling "stuffed up." The first effect of a sudden great increase of moisture in the atmosphere is a swelling of the affected membranes, and after some hours the secretion is apparently increased. This apparent increase is partly owing to accumulation, as none, or but little, of the water is evaporated; there is, however, a real increase of secretion. If the Schneiderian membrane only be diseased, the swelling and hypersecretion will be confined to it; but if the mucous membrane of the larynx and the mucous membrane of the bronchi be also affected, they will likewise feel the change. I think cases of true catarrh of the Eustachian tube still better illustrate this fact. The prevalence of phthisis among the natives of warm, humid climates is too well known to require comment.

A cold, moist climate is universally acknowledged, both by the profession and the laity, to be the very worst in which a consumptive can reside; but cold climates, where the atmosphere is comparatively dry, are beneficial to a certain class of cases, for even extreme cold is well borne in the absence of moisture. Although the function of the skin is less active than in a milder climate, its activity may be increased in a measure by exercise and warm clothing, and the extra strain on the kidneys consequently diminished. The secretion of the mucous membranes of the air-passages, and all morbid secretions which are at all affected by contact with the air, are lessened rather than increased; for the pulmonary exhalation is facilitated and the capillaries are contracted. But such a climate is only suited to patients who have vitality enough left to react against the cold and take advantage of out-door exercise, for confinement to the house must certainly prove injurious; and these will be mostly cases in the first stage of phthisis, uncomplicated by renal disease. Chronic catarrhs are also benefited by a cold, dry climate, but in all cases the risk of acute attacks must not be lost sight of. Moreover, during the spring months in these cold climates, after the thaws commence, the atmosphere cannot be called dry, and both consumptive patients and those suffering from catarrhal affections of any part of the air-passages are better off somewhere else.

In all localities where the mean temperature for the winter months is high and the atmosphere comparatively free from moisture, the summers are excessively hot, so that all the organs except the kidneys are unduly stimulated, and the excitement is too great, particularly if there is any disposition to hæmoptysis. Such localities are, however, eminently suited as winter residences for consumptives, particularly for those in the third stage of the disease. Exhalation from the skin and lungs is greatly favored, and the tissues being robbed of their moisture, contract, while the capillary circulation is quickened throughout the entire body. Morbid discharges are consequently diminished or checked, and cicatrization aided. In all such climates there is a marked difference between the temperature of the day and the temperature of the night, for the locations are generally more or less elevated, and are always situated in the interior; the radiation is therefore rapid during the night; and at sunrise, the period of minimum temperature, the mercury may stand 30° or even 40° lower than at mid-day. Strictly speaking, these climates cannot be called uniform; but the periodical variations of temperature do not seem to be injurious to those suffering with phthisis, if they are properly protected. The prevalence of high winds is probably a greater drawback. Unfortunately, localities possessing warm, dry climates are mostly all arid wastes, where the comforts necessary to the well-being of invalids are not to be had; and, moreover, they are not easy of access, particularly to advanced cases, which are the ones most in need of the influence of such climates.

Moist, temperate climates, although far superior to either warm or cold humid climates, are certainly less beneficial to the majority of consumptives than comparatively dry ones. Yet where there are advantages to make up in a measure for the evil humidity, patients in the first stage of the disease, particularly those with a tendency to hæmoptysis and an over-active circulation, dry cough and dry catarrh of the air-passages, do very well. It is a question, nevertheless, whether even this class of patients would receive more benefit from a prolonged residence in such a climate than in a drier one, other things being equal.

Climates which are mild during six months of the year, or during the whole year, are not to be confounded with those which are mild only for a couple of months during the winter. These latter may properly be called warm climates during the greater part of the spring and fall months, and that of Florida may be given as an example.

Elevated regions, where other conditions are favorable, are said to be peculiarly free from phthisis; but after the disease has once been developed, any great elevation must certainly prove injurious, and a location above 3,000 feet is not to be recommended: for the more elevated a consumptive's residence, the rarer the atmosphere, and the more rapid must be the action of the heart and lungs. Besides, diminished atmospheric pressure admits of hæmoptysis where it would not otherwise occur, and if phthisis be complicated by cardiac disease, matters are made worse. Furthermore, at great elevations high winds are very prevalent during the winter months, and pneumonia is exceedingly common.

Valleys, if surrounded by high mountains, are not desirable locations; for in the evening, the moment the influence of the sun is gone, the mountains radiate heat rapidly, and when the atmosphere is cooled off a few degrees, the suspended moisture is condensed and falls down, while the warm air from below rises; and this process is kept up until the air is uniformly cooled, the consequence being that the low country is overhung by a mist more or less perceptible, which remains until dissipated by the sun on the following morning. The proximity of the locality to the sea, and the presence or absence of snow on the surrounding mountains, make, of course, a great difference as to the amount of moisture thus precipitated; for instance, at San Bernardino, Cal., eighty miles from the coast, and surrounded by high mountains which in winter are capped with snow, this process of condensation and precipitation takes place every evening, at least during the winter and spring months, and to such an extent that the whole town is enveloped in a mist during the night.

To recapitulate: 1. There are but few cases of phthisis in any stage capable of improvement, that would not be benefited by a residence in a warm, dry climate, other circumstances being favorable, during the winter months; provided they had strength enough left to stand the journey back and forth. Such a climate might prove too exciting to some few cases, but the number would be very small indeed.

2. A cold, dry climate is a good climate for uncomplicated cases of phthisis that can endure out-door exercise, and have vitality enough left to react against the evil effects of the cold. But for patients already debilitated or subject to frequent acute attacks, who would be confined to the house, such a climate is not to be thought of.

3. Patients from cold, damp climates may frequently be benefited by a winter residence in a warm, humid one, and this latter may be superior in many respects to that from which they removed; but warm, moist climates must be looked upon as rather prejudicial than beneficial to all persons with phthisis, and those who do well are for the most part to be considered as having been very favorable cases.

4. Although many consumptives are markedly improved by a residence in a moist, temperate climate, they are mostly patients in the first stage of the disease, who are benefited because they have strength enough to resist the pernicious effects of the moisture, and at the same time take advantage of the favorable circumstances. The more advanced a case, the less likely it would be to receive benefit.

A mild, dry, uniform climate, at a moderate elevation, is not to be obtained; for unfortunately mildness and uniformity can only be secured at or near the sea-shore, or at least there are no locations on our continent which are at present accessible to the majority of invalids that are not so situated; and here we must encounter that formidable enemy of the consumptive—moisture. As a place of resort for the winter months even, there is no mild and equable climate within the reach of those not prepared to "rough it," unless it is near the ocean. The greater number of those affected with phthisis, therefore, must choose between a cold, dry climate and a mild, humid one. For those who are capable of receiving benefit from the former, the climate of Minnesota may be recommended; but the selection of any particular locality for those who would be better off in the latter, is attended with more responsibility. Various places have been highly lauded, each possessing particular advantages and having also certain drawbacks.

The climate of Southern California, so favorably spoken of as a proper resort for consumptives, is a moist climate, as moist as that of Jacksonville, Florida; for the influence of the sea extends to a considerable distance inland, beyond the present limits of proper accommodations and comforts necessary for sick people, who are therefore only enabled to enjoy the climate of the coast. Even at a distance of one hundred miles from the ocean the nights in the valleys are damp, owing to the cause already mentioned. Compared with other moist climates, however, this offers some advantages. It may properly be called a mild climate during all seasons of the year, having a mean temperature of 53° F. for the winter and of 68° F. for the summer months; and it is probably as equable as any on this continent, the average maximum and minimum temperature for the coldest month (January) being 56–47°, and for the warmest month (August) 72–65°. There is a considerable difference, however, between the mean for the night and the mean for the day, particularly during the summer months, amounting to 8° to 10° F. The annual rain-fall averages about twelve inches, all of which falls between the 1st day of November and the 1st of March, about one-half the quantity precipitated in Florida (referring to no particular locality) during the same time. Unlike most other localities, the amount of moisture suspended in the air here bears no proportion to the quantity precipitated as rain; and this anomaly has undoubtedly misled many, for the climate is generally spoken of in the newspapers and journals as extremely dry during the spring and summer months especially, referring to the absence of rain. The land is mostly high and dry along the sea-coast, rising gradually from the shore to the foot of the mountains, which are from four to ten miles distant. It is a climate in which the consumptive invalid may remain during the whole year, for the days in summer are seldom hot, and the nights are always cool. It is not therefore a debilitating climate.

The accommodations at the principal places of resort are good, and the means of exercise ample. The great number of pleasant days during the winter, enabling invalids to pass a good part of their time out of doors, is a decided advantage. Against this climate it must be said that, besides being humid, high winds are somewhat frequent, and during the months of April, May, and June they occur almost daily, blowing mostly from the north-west, and raising a terrible dust in the towns, which is very annoying, if not absolutely injurious. Furthermore, frequent light fogs may be expected during the early morning hours in May and June. As a class, consumptive invalids, in the early stages of the disease, do very well in this climate; but it is not suitable for advanced cases, although superior to that of Florida.

110 East 30th St., New York.

ON

THE LOCAL TREATMENT OF VENEREAL ULCERS BY MEANS OF IODOFORM.

By G. O. MORRISON-FISET, M.D.,

HOUSE-SURGEON, CHARITY HOSPITAL, N. Y.

The use of iodoform in the treatment of venereal ulcers is not of long date; but its great efficacy, and the results accrued from its extensive employment in this and other hospitals, will make it almost indispensable as a therapeutic agent in this class of cases. For many other forms of ulceration but the venereal, iodoform has been found to act well—*e.g.*, lupus non-exedens, acute ulcers, ulceration of the rectum, etc., etc.; and in chancroids or syphilitic ulcerations it is one of the best agents to use. A few cases of chancroids will be found reported below; they are few in number, having been selected out of the many of those only who were discharged from the wards cured. As is the case with the majority of hospital patients (especially venereal), they will depart as soon as they begin to improve; therefore this latter class of cases is not fair for publication. The chancroid when first seen is usually cauterized with nitric acid, if it be simple and of medium size, covered with a tenacious and abundant yellowish secretion; if, on the contrary, it be small and its secretion slight, no cautery is applied. For phagedenic cases the actual cautery is generally employed. One application of the potential cautery is usually sufficient to destroy the virus. As soon as the slough caused by the cauterizing agent has separated, the application of the iodoform (either once a day, every other day, or twice a week, as the case may be) to the surface of the sore is commenced.

Iodoform may either be applied in form of powder, or suspended in glycerine, as in the following formula:

℞. Pulv. iodoformis..... gr. xlv.
Glycerinæ..... ʒiij.
Alcohol..... ʒi.
M.

The powder, when used, is simply dusted upon the ulcer with a camel's-hair brush, after carefully removing all secretion present. If situated on the glans penis or prepuce, a piece of lint is placed over it to separate the diseased from the healthy parts. If the iodoform be used suspended in some menstruum, a dossil of lint is dipped into the mixture and applied to the ulcer. The former method is preferable, the powder adhering to the surface to which it is applied; but if used in the other way, it is apt to slip from the surface of the ulcer, especially in cases of chancroids of the vulva. The sores are also directed to be washed with a solution of carbolic acid (ʒi. to Oi.) before the application of the iodoform is made.

Case I.—Michael S——, admitted April 9th to Ward 10. Three weeks before admission he contracted a chancroid upon the corona glandis, which was found to be about one-half an inch in diameter. Cauterized with nitric acid the next day. Pulverized iodoform applied three times a week. On April 21st the patient was discharged perfectly cured.

Case II.—Margaret S——, æt. 19. Admitted to Ward 14 April 14th. Three weeks before admission, she noticed a sore on her genitals. On examination, a simple chancroid was seen upon the fourchette, measuring about a half-inch in diameter. The next day the chancroid was cauterized with nitric acid, followed on the 16th by the application of the iodoform in powder once a day. April 22d, patient discharged cured.

Case III.—Albert D——, æt. 47; single. Admitted on April 8th to Ward 10. A single chancroid with ragged edges, and of about one half-inch in diameter; had contracted it four weeks before his admission. Nitric acid was applied to it, and on the next day was dressed with iodoform powder, and this continued daily. Discharged cured on April 17th.

Case IV.—Matilda K——, single, æt. 23. Admitted to Ward 14 on April 14th. Three weeks before admission she noticed a small sore on her right natis, which commenced to grow larger; it did not give her much pain. She finally was admitted to this hospital, and on examination I found a phagedenic sore with ragged edges, and covered by a tenacious, yellowish slough, emitting a very offensive odor, measuring about five inches in diameter, and greatly excavated, situated on the inner surface of the right buttock. The ulcer was thoroughly cauterized with nitric acid the day of her admission, and poultices of equal parts of pulverized linseed and animal charcoal, saturated with a carbolic acid solution (ʒi. to Oi.) were ordered to be applied three times a day. This was continued for three days, at the end of which period it was discontinued. On the 18th, the slough having separated, pulverized iodoform was ordered to be applied to the sore once a day. On the 22d the secretion had decreased, but still continued to a sufficient extent to retard the healing process; therefore the sore was again cauterized with nitric acid. The next day pulverized iodoform was resumed as a daily dressing. The patient, being anæmic, was also ordered to take cod-liver oil, chalybeates and cinchonia. Discharged cured on May 14th.

Case V.—Patrick C——, single, æt. 27. Admitted to Ward 10 April 21st. This patient contracted two chancroids upon his penis three weeks before admission; one was situated on the prepuce and the other on the frenum, both being of about the size of a nickel cent. The sores were cauterized with nitric acid, and the next day they were dressed with iodoform, this being continued every day until the 28th of April, when the patient was discharged cured.

Case VI.—Minnie B——, single, æt. 23. Admitted to Ward 14 April 22d. The patient noticed a sore upon her genitals, she says, one week before admission. A simple chancroid was found upon the fourchette, of about one inch diameter. Iodoform was applied to the sore daily, and the patient discharged cured on the 28th.

Case VII.—Joseph M——, single, æt. 32. Admitted to Ward 10 on April 24th. The patient contracted the present chancroid, which is situated upon the meatus, about three weeks before admission, it being about one inch in diameter. Chancroid dressed with pulverized

iodoform once a day. Patient discharged cured on May 12th.

Case VIII.—Terence B——, single, æt. 26. Admitted to Ward 10 on April 24th. The patient states that six weeks before admission he noticed two sores upon his genital organs. Two simple chancroids are seen, one upon the dorsum of the penis, and another on the scrotum, both being of about one half-inch in diameter. There was very little secretion. Pulverized iodoform as a dressing was ordered to be applied once a day. Discharged cured on May 1st.

Case IX.—Eliza C——, married, æt. 29. Admitted to Ward 14 on April 28th. Seven weeks before admission the patient noticed two sores upon her genitals. On examination, two simple chancroids were seen, one situated in front of the meatus, and the other in the fourchette. They were both of small size, and only a slight secretion covered their surfaces. They were both treated by iodoform in the usual manner. On May 3d the patient was transferred to another ward for uterine disease, her chancroids having healed perfectly.

FREQUENTLY RECURRING EPISTAXIS RELIEVED BY ERGOT AFTER LOCAL TREATMENT HAD FAILED.

By ANDREW H. SMITH, M.D.,

of New York.

Mr. C., aged 37, civil engineer, applied to me in the latter part of May on account of bleeding at the nose, recurring daily, and sometimes two or three times a day. The amount of blood lost each time was trifling, but the resulting annoyance was very great. The patient, naturally of rather a delicate organization, was performing an excessive amount of mental labor, and his health had suffered considerably in consequence. Digestion was slowly and imperfectly performed, and he was much annoyed with flatulence disturbing his rest at night.

Direct and rhinoscopic examination showed no abnormal condition of the nasal mucous membrane, except that the portion covering the septum on the left side was for a part of its extent unduly red.

A variety of astringents were applied locally by means of both the brush and the syringe, and such general treatment was resorted to as the symptoms demanded. This course was followed persistently for two weeks, when the general health had somewhat improved, and the congested appearance of the nasal mucous membrane, as far as open to inspection, had disappeared. Still the hemorrhages recurred as frequently as ever, being often apparently provoked by the very applications intended to prevent them.

I then prescribed the fluid extract of ergot, twenty drops to be taken three times a day. This was continued for ten days, with the effect of entirely restraining the bleeding from the time the first dose was taken. The medicine was then omitted, but in a few days the bleeding began anew. It was immediately arrested by a return to the medicine, and has not since returned, the drug being continued at gradually increasing intervals for nearly a month, when it was entirely discontinued.

The Peninsular Journal of Medicine.—This journal is again published at Detroit, Michigan, Henry F. Lyster, M.D., being the chief editor.

Reports of Hospitals.

ROOSEVELT HOSPITAL.

Notes of Practice and Peculiarities in Treatment.

THE TREATMENT OF ULCERS.

The luxuriant granulations in a specific ulcer receive nothing but firm strapping, with adhesive plaster, and over this a firm bandage. It is not deemed necessary to make any caustic application to the granulating surface, the stimulating pressure of the straps being considered sufficient.

The straps are changed as soon as pus commences to make its appearance under their edges. The constitutional treatment varies with the particular indications.

SPECIFIC OZÆNA.

Constitutional treatment consists mainly in the administration of iodide of potassium. As a local application the patients enjoy the luxury of a hand-atomizer, using carbolic acid and bromo-chloridum.

PLASTER-OF-PARIS SPLINTS.

Plaster-of-Paris is most commonly employed where a fixed apparatus for retention is required. In the application of these splints, rollers made of the ordinary mosquito netting are employed instead of the muslin bandages; the advantages claimed for the netting being, that more plaster can be carried in its meshes, hence a lighter and more delicately formed splint can be obtained, with equal firmness, than by the old-fashioned method. The netting also is sufficiently elastic to permit its perfect adaptation to the inequalities of the limb, without reverses or wrinkles in the bandage. This is a very elegant method of applying the plaster-of-Paris splint.

FRACTURES.

In a case of fracture of the femur there was considerable inflammation during the first few days, and the patient was placed in bed and a Buck's extension apparatus applied, the foot of the bedstead elevated, thus securing counter-extension by the weight of the body. In this way the thigh was left free for inspection, free for such applications as might be desirable—a most convenient and satisfactory method of managing such cases. No retentive splints whatever were used, the limb simply lying upon a firm posterior plane surface.

SYNOVITIS.

The treatment for synovitis consists of rest, ice-bags, perhaps leeches, and anodynes if necessary. In subacute and chronic synovitis, with joint filled or partially filled with fluid, the best results are obtained by the use of sponges and a firm roller-bandage.

In this hospital, where constant pressure and fomentation are desired, the hot sponges are the agents most commonly employed, and they serve a most excellent purpose. This is also the usual method of treating sprains. Apply about the joint, as soon as possible, sponges which have been wet in hot water, and secure them by a snugly applied roller-bandage. After they are firmly secured, they may be wet again. Change every twenty-four hours.

FROST-BITE.

An interesting case of frost-bite was seen, which afforded another example of the use of these sponges.

The parts over the patella had been frozen, and when the slough came away it made an opening into the knee-joint. The limb was immediately placed upon a long posterior splint, and compression kept up steadily by the use of sponges, and not a single untoward symptom had manifested itself.

BURNS.

For these difficulties, in way of treatment, carron-oil—ol. linim. et aquæ calcis, āā—has the preference. If something can be added to correct the smell of the oil, and not detract from its virtues, it would be well.

EPITHELIOMA OF EYE.

A patient with this disease experienced great relief from the pain by the application of citric acid in moderately strong solution. The value of this remedy for this purpose has been known for some time, and this case demonstrated that it was yet virtuous.

NIGHT-SWEATS IN PHTHISIS.

When sulphuric acid, dilute or aromatic, has failed to give relief in these cases, the following is given every night in the form of pill. It sometimes acts very well.

℞. Zinci oxid..... grs. ij.
Ext. hyoscyami..... grs. iij.
M.

For the diarrhœa of phthisis, when present, persulphate of iron or injections of tr. opium and starch are used.

ERYSIPELAS.

The good old-fashioned liq. plumbi et opii is relied upon as an external application. Internally, tr. ferri muriatis is administered regularly.

"If he live, he live; if he die, he die." But he usually gets well.

PNEUMONIA.

The plan of treatment generally adopted in the treatment of this disease consists in administering quinine in six-grain doses night and morning, plenty of stimulants, and plenty of nourishment in the form of milk and beef-tea.

All the cases which have been admitted to the hospital have received this treatment, and almost all have done exceedingly well. This, it will be seen, is a substantial and vigorous treatment for an acute inflammatory affection, yet it receives the fairest of compliments.

SUBACUTE PLEURISY.

The diuretic ordinarily used is the iodide of potassium; the form of counter-irritation ordinarily employed is blisters, and lastly paracentesis.

Tapping is not resorted to until other remedies have failed.

Tonics do not appear to form any special part of the treatment; but it is fair to infer that they would be administered, at least in the advanced stages.

It is favorably received that tonics are to be regarded as an essential part of the treatment, and that they should be administered from the first, in connection with the diuretics and counter-irritation.

Quinine and iron are probably the most serviceable.

PARAPLEGIA.

A woman has been the subject of this infirmity for six or seven years, and has been taking medicine almost constantly in the hope of obtaining relief. About six or seven weeks ago she began to receive hypodermic injections of strychnia. At first they were given in $\frac{1}{60}$ gr. doses night and morning. These doses have been gradually increased up to $\frac{1}{30}$ of a grain night and morning. Since the use of the strychnia the improvement in her case has been very marked. She is now able to draw her limbs up in bed quite well, one or both, as may be desired. Electricity, which had been employed in connection with the treatment she had previously been receiving, was continued in connection with the treatment by hypodermic injections of strychnia.

ACUTE ARTICULAR RHEUMATISM.

The constitutional treatment adopted in this hospital for this disease is essentially alkaline. Rochelle salts are very commonly employed. Effervescing draughts are also ordered, as being more agreeable to some patients and equally efficacious. The local application ordinarily used is what is known as Fuller's lotion, which consists of bicarbonate of soda and laudanum, and over this cotton and oil-silk.

MORBUS BRIGHTII.

The chief elements entering into the treatment of this disease are tonics, diuretics, and diaphoretics. It is quite commonly the case that the patient is not seen by the physician until some dropsical symptoms have made their appearance, such as slight puffiness about the eyes, or slight swelling about the ankles. It is the "dropsy" that has alarmed the patient. In such cases quinine and tr. chloride of iron, associated with infusion of digitalis in combination with bitartrate or acetate or citrate of potassa, constitute the remedial measures ordinarily employed. If there is much œdema, the hot-air bath is called in to assist, and occasional doses of the triplex pill,

℞. Pil. hydrarg.,
Res. scammon.,
Pulv. aloes..... āā grs. x.
M.

Div. in pill No. x.

are administered.

PURPURA.

A most marked, a classic case of this disease was present. It was one of those cases which physicians are inclined to call beautiful, sometimes much to the chagrin of the patient. The lower extremities, particularly, were covered with an eruption which made them model specimens. The treatment of the case consisted in the administration of citrate of iron and quinine and bicarb. potass., given in the form of effervescing draughts. The patient was also ordered to eat large quantities of cabbage and spinach.

CHARITY HOSPITAL.

STRANGULATED HERNIA AND THE ASPIRATOR.

Another of these hernia cases was discovered about three hours after the patient had been admitted to the hospital for some other difficulty. In her journey to the hospital the hernia had come down enormously and become strangulated. The hernial tumor was as large as a child's head. It was hardly possible to determine what kind of hernia it was, the tumor, when freed, was of such size and tension. Taxis was unavailing, and probably would have been equally unavailing had a correct diagnosis been made, and taxis been made in the proper direction. Taxis was made in the direction proper for the reduction of an *indirect* inguinal hernia, but the sequel proved it to be

a *direct* inguinal hernia. This is a mistake not so infrequently made as may be supposed. Taxis in this case being unsuccessful, the tumor was aspirated, and fully ℥viij. of serum drawn off. The gut was not aspirated. The removal of this quantity of fluid rendered the tumor sufficiently flaccid to permit a much more easy and extended manipulation, assisted in arriving at a correct diagnosis, and by a little careful and well-directed handling the hernia was reduced. An operation was probably avoided by means of the aspirator.

NOCTURNAL PAINS.

A majority of the cases of nocturnal pain can be rid of their remorseful reminders by the administration of iodide of potassium in free doses; but occasionally one presents itself in which either the demon's fang has penetrated more deeply, or the patient is more susceptible to grievances, and these "nocturnal aches" will scarcely yield to the single-handed onset of iodide of potassium. In these rebellious cases Dr. Drake, now in charge of the venereal service, administers with the happiest results a combination of three iodides. The formula which at present is used is as follows:

℞. Potass. iodid. ..... ℥ iv.
Sodæ iodid. ..... ℥ iij.
Ammonium iodid. ..... ℥ ij.
Tr. gentian co. ad. ..... ℥ ij.
M.
S. ℥ i. t. i. d.

HYDROTHORAX.

With regard to the operation of paracentesis thoracis there is a difference of opinion relating to the time of its performance. One class of observers are of the opinion that the fluid should be drawn off, unless it yields to treatment, within two weeks, for the danger is that the fluid may become purulent instead of remaining serous. There are many cases, however, in which pus-corpuscles can be found in the fluid, but which would not be entitled to the term empyema. Other observers, on the other hand, are of the opinion that drawing off the fluid should not be resorted to early. Their reason is, that purulent effusion into a pleural cavity is fatal in nearly one-half of the cases, and when spontaneous opening of the wall of the chest takes place, a very large proportion of those cases get well, while less than one-half of those cases operated upon recover.

Progress of Medical Science.

DOSMETRIC MEDICINE.—Professor Burggraeve, of Ghent, has devoted himself lately to the extension of what he has called dosmetric medicine. This consists in the administration of remedies of the most potent kind in doses ready prepared by pharmacists in the most convenient form. They are, in fact, very tiny pilules, and a case of these may very easily be carried in the pocket. The learned professor—says the editor of the *Med. Press and Circular*.—has quite taken the wind out of the sails of the homœopaths.

His idea is that immense improvements should be introduced in practice—the employment of simple medicines of the *highest purity* and of *strictly uniform composition*, prepared with the greatest care and administered with almost mathematical precision. The form of granules, as he calls these little pilules, renders the medicines easy of administration to even the most delicate patients.

PRESERVATION OF HUMAN REMAINS.—In the Italian section of the Vienna Exhibition, Dr. Marini exhibits, among an assortment of human feet, hands, legs, arms, and busts of shrivelled proportions and deep-brown color, a large, round plateau, evidently of hard and polished material, which has been likened to stale gelatine or potted boar's-head. It is a conglomerate of specimens, illustrative of an art invented by him—the petrification and mummification of human corpses. It was this Dr. Marini who petrified Mazzini, and executed the work so well that the admirers of the arch-conspirator proposed to set up the corpse in the Capitol and save economical Italy the expense of a statue. The doctor's preparations are weather-proof, and will not only stand wear, but take on a high degree of polish. His mummified specimens, by a process known to him alone, can be restored to their original size and elasticity; while the petrified ones are as hard, and possibly as durable, as granite. The top slab of the table is composed of muscles, fat, sinews, and glandular substance—all petrified together in a block, the surface of which has been planed and polished till its face resembles marble. Certificates from Nélaton and others are attached to the specimen limbs, setting forth that the limbs in question had, for the satisfaction of the certifiers, been restored to their pristine softness and pliability by Dr. Marini.—*The Lancet*.

WHAT ARE THE SIGNS OF CONGENITAL SYPHILIS?—In a paper read before the Harveian Society of London (*Lancet*, May 24), Dr. Thomas Ballard discussed the subject of congenital syphilis, and endeavored to show that those conditions before birth, at birth or some time after birth, which have been supposed to depend upon a syphilitic taint, can be explained by simpler and more obvious means. Acknowledging that a woman infected with syphilis is apt to abort and bring forth dead children, he denies that this is from the direct effect of the virus upon the fœtal organism, and asserts that "the death of the fœtus in utero is the consequence of some defect in the maternal system, resulting from its contamination by the syphilitic virus, and that it is not necessary to infer, neither is there evidence to prove, that the organism of the child is intrinsically affected by it." He believes pemphigus and other forms of erysipelatous disease, occurring within a fortnight after birth, to be pyæmic affections resulting from unhealthy suppuration of the umbilicus; and the coryza, thrush, and ophthalmia of newborn children to be due to external irritants, as cold air, sore nipples, and exposure to light. He thinks the cutaneous inflammations about the buttocks and thighs are usually caused by the contact of moist and frequently unclean flannel, and relates cases where such troubles disappeared in a few weeks after the mere removal of the napkins, though they had resisted anti-syphilitic treatment for many months. He concludes that "the records of cases of living children having been born with manifestations of syphilitic disease are so few as to allow of the supposition that they are not trustworthy," and that "the symptoms which are developed some weeks after birth, and are relied upon as pathognomonic of syphilitic contamination of the system of the child, are mere accidents arising from certain unfavorable conditions to which the child is exposed, and that they are all preventable or easily cured when the cause producing them is recognized."

Arsenical Disease, or the Disorders produced by Arsenical Papers and Colors.—In the *British Medical Journal* of June 21, a paper appears by Wm. M. Clarke, Esq., of Bristol, on the above subject, who says: "I had not, until the last two years, traced any disease to the use of these colors. During that period, however, I believe I have met with several cases, and have become convinced that arsenical pigments are very frequently the cause of troublesome complaints, which, unless the cause be detected, are very difficult to cure.

"There are two principal ways in which they do harm: in the first and most obvious way they produce the disorder for which the patient comes under treatment, and there is nothing else the matter; but in the second, the danger is more insidious, and on that account the greater. The patient is laid up by some ordinary malady, confined to the room infected with the arsenic, and then there are gradually, and in a most deceitful manner, added the symptoms that the arsenical contamination produces. In this class of cases, in which the poison merely modifies some other disease, it is difficult to define the characteristics; but the most marked I have noticed have been sickness and vomiting, sore throat, sore eyes, and occasionally eczema and diarrhœa. On the other hand, in the first class the signs are well marked. First, there are the cases in which the patient suffers the usual symptoms of dyspepsia; there are more or less nausea or sickness, a troublesome cough, capricious sore throat, and redness or soreness of the conjunctivæ. In a second group nervous symptoms predominate; there are headache, prostration, and marked restlessness and excitement at night; generally, also, more or less decided gastric symptoms, and especially a very coated tongue. As regards a third group, and the most common, I must say that until the last year or two I should not have attributed the mischief to arsenical poisoning, but should have called the cases low fever, or perhaps have supposed them to have been cases of aggravated dyspepsia. I have more than once isolated such patients, thinking they were about to have typhoid; or when sore throat has predominated, scarlatina; and finding them become worse when confined to their bedroom, I have had them removed, and they have recovered. In these there have been great prostration, headache, wakefulness, great nervous excitement, often an irritable stomach, and always a very coated tongue with red edges—very much the symptoms of slight typhoid, but without elevation of temperature and with only slight quickening of the pulse. . . . .

"These three classes include the most of the cases that I have seen; but other conditions are, I believe, sometimes produced, such as violent and intractable sneezing, eczema, and sores of the mucous membrane of the nose.

"In the case of one patient, whose illness was due to this cause, a careful analysis of excreta from the patient, and dust from the bedroom, which was decorated with arsenical paper, showed the following results:—

	White arsenic.	Scheele's green.
1. 100 grains of dust from top of wardrobe =	0.2	.36
2. 100 " " " " same room..... =	0.16	.30
3. Expectoration.....	Trace	Trace
4. 48 ounces of urine..... =	0.26	.5 "

Etiology of Hereditary Syphilis.—Frederick R. Sturgis, M.D., of New York (*N. Y. Med. Journal*, July, 1873), in a lengthy paper on "Etiology of Hereditary Syphilis," shows that the paternal transmission is impossible on these grounds:—

1. Because the reported cases are wanting in such details as to render them convincing.

2. Because this theory is entirely opposed to our present knowledge of the contagious properties of syphilis and its mode of propagation; and

3. Because our knowledge of infantile syphilis has not kept pace with our progress in the other branches of the disease.

He thinks the proposition stands thus: Both sides grant the contagions of a primary lesion and of mucous patches; one side further argues that the semen of a person in whom the disease is either present or latent is also capable of conveying the poison; the other side demurs, and offers as proof against this argument the fact that many cases exist where the syphilitic father has perfectly healthy children, and in this connection the mother is found free from disease. The first side say this is possible, and go further yet; notwithstanding that this poison is eminently virulent and dangerous for those previously free from its influence, they insist that a perfectly healthy woman may and does receive this poisoned semen into her body, a diseased fœtus is carried by her for the nine months of intra-uterine life (the relations between the two being of the most intimate character for that length of time), she nourishes this rotten product, which, when born, may become a centre of contagion to those about it, and yet escapes contagion. If this be true, then one of two things: either we are ignorant of the real condition of the mother, or else syphilis is not the contagious disease which we have been accustomed to consider it. He urges new and independent observations. Both the parents and the children should be examined and watched for some time before we may conclude one way or the other; but above all things let physicians cease copying old and poorly reported cases, and observe anew for themselves. In this way only can we hope to arrive at some definite conclusions upon this important subject.

Compression of the Brain.—S. W. Gross, M.D. (*Am. Jour. Med. Sciences*, July, 1873), remarks that the treatment of compression from depressed bone is still a matter of much dispute. That a man may recover from a very considerable and very unequal displacement of the tables of the skull, is attested by numerous examples; but that such cases survive in greater proportion than those in which the pressure has been relieved by the resources of art, is another and highly important question which has not been sufficiently examined by writers on army surgery. Of 224 depressed gunshot fractures of the skull, and in 90 operative measures, of these 45 or 50 per cent. died. Of 134 instances, on the other hand, in which the treatment was purely conservative and antiphlogistic, and in 43 of which the signs of compression were very doubtful, 61 recovered, and 73, or 54.47 per cent. died; or if the doubtful cases, which resulted in 10 deaths, be excluded, 91 cases of compression from depressed fractures, treated expectantly, afford 63 deaths, or a mortality of 69.23 per cent., a result in favor of operation by 19 per cent.

These statistics show, that when symptoms result from depressed bone, the chances of saving life are on the side of surgical interference. The trephine was applied in 49 of the above 90 operations, with 26 deaths, the mortality being 53.06 per cent.; fragments of the shattered bone were removed by the forceps in 28 instances, with a fatality of 14, or 50 per cent.; the elevator was resorted to in 10, of which 3, or 30 per cent. were mortal; while in 3 instances Hey's saw was followed by death in 2, or 66.66 per cent. An

examination of these facts does not disclose that the operation of trephining is more dangerous than other operative procedures. More patients recover after than without surgical interference, and many lives might have been saved by a timely resort to it.

A Little-recognized Cause of Relapse of Vesico-vaginal Fistule.—M. Bourdon speaks of a newly recognized cause of recurrence of this affection which merits attention. It is pregnancy, which in the early months can cause spontaneous rupture of the cicatrix of a vesico-vaginal fistula, even so long as six years after its cure. This relapse is owing to the changes in the nutrition of the tissues belonging to the pregnant condition. The vagina becoming varicose during gestation, the rupture of the cicatrix of a vesico-vaginal fistula resembles the spontaneous rupture which takes place in the cicatrix of a varicose ulcer of the legs. This varicose condition of the vagina, moreover, favors the production of phlebitis and pyæmia, and for this reason the author advises refraint from operative procedures during pregnancy and for some time thereafter.—*Gaz. Méd. de Paris*, No. 30.

Simple Method of Detecting Impurities in Water.—Dr. Reynolds, of Dublin, recommends a simple method which, he says, serves to detect the presence of organic matter in water. A pint of the water to be examined is to be placed in a clean bottle of white glass, together with a piece of white loaf-sugar the size of a pea. Being then exposed to sunlight in the window of a warm room, if at the end of eight to ten hours the water is cloudy it contains organic matters, probably derived from sewage, which have been developed owing to the presence of the sugar.

Tuberculosis and Humanized Lymph.—In a correspondence of the *Gaz. Méd. de Paris* of April 26th, there are some propositions formulated by Drs. Paraskera and Zallones, of Greece, concerning repeated experiments made by them of inoculation on rabbits, of vaccine virus taken from persons in the second stage of phthisis. From these they think that it seems as if tuberculosis were transmissible by vaccine.

Here are their words:—

"1. The animals on whom the experiments were made were in the most healthy condition.

2. Vaccine taken from a tubercular person may produce tuberculosis in one (animal) that enjoys perfect health.

3. The blood of persons with cavities in the lungs carries with it the tubercular virus, and this poison is found in the liquid and solid part of the blood.

4. Fourteen days sufficed for the development of the tubercle in the animals affected."—*The Doctor*, July 1.

Galega Officinalis as a Galactagogue.—Dr. Oettinger (*Il Morgagni*) recommends the employment of this legumen to excite the secretion of milk in nurses, being convinced by a great number of observations that the *galega officinalis* not only augments the quantity but also improves the quality of milk in women who are nursing. It is given in the form of syrup, to the amount of several teaspoonfuls during the day.—*Lyon Méd.*

Use of a Goose-quill for Catheterization of a Female.—Dr. Grabinski writes to the *Lyon Méd.* that in an emergency a goose-quill three inches long enabled him to draw more than two *litres* of urine from the over-distended bladder of a female. Ordinarily if the proximal end of the quill is not cut, its conical form will enable it to be introduced without difficulty; but in this case the only quill available had to have a plug of wood adapted to it in order to prevent its sharp edges catching the mucous membrane of the urethra.

Fractures of the Inner Extremity of the Clavicle.—Delens understands this to mean such as take place within the inner third of the clavicle, that is to say, in the limits of insertion of the clavicular fascia of the sterno-mastoid. In 1864 this writer published two cases of this nature in the *Gaz. des Hôp.*, since when he has observed six others, which together with the twenty already published make twenty-eight cases, of which twenty were males. Of the eight cases observed by him, in seven the fracture was on the left side. The fracture is more often oblique above than below, the periosteum is more frequently intact, and consequently overlapping and shortening is less marked.

Among the known causes, indirect violence—such as a fall on the shoulder—has been the most frequent of those due to external violence, two cases having been mentioned in which the blow occurred at the seat of fracture; but the most common cause was muscular contraction, being mentioned in eleven cases; the contraction of the sterno-cleido-mastoid is the best condition for producing the fracture, which ordinarily occurs in a violent effort to raise a heavy body by the aid of both hands. Twice the accident has occurred in giving a stroke with a whip. Tumefaction and deformity are most pronounced in the fractures produced by muscular contractions and are scarcely marked in the others. Mobility and crepitation are to be noted in almost all cases.

Pneumatic Aspiration in Hydrarthrosis of the Knee-joint.—Dr. Rasmussen, of Copenhagen, describes seven cases in which he practised aspiration in eight knee-joints. In none of these cases did the slightest trace of inflammatory reaction follow the operation. Even in the cases where there had been severe pains and considerable tenderness of the joint, it was so free from both for several days after the operation that treatment by *massage* could be employed for the removal of the remainder of the effusion. He advises the operation in both the chronic and acute forms of this affection.

The following is Dr. Rasmussen's mode of operating: Broad strips of adhesive plaster, clipped at the ends, are applied above and below the joint, and are then gradually tightened according as the evacuation of the fluid by suction, which takes place very slowly, proceeds. By the continued application of adhesive plaster the fluid is forced towards the canula.

This should, as a rule, have a diameter of from .08 to .06 of an inch, so that the viscid portion of the fluid can pass through it. At first Dr. Rasmussen made the puncture through the extensor muscles, in the highest pouch of the capsule, for fear that the fluid would continue to ooze through the comparatively large opening if the latter were to be made at a lower level. This subsequently, however, was found to be both unnecessary and inexpedient, for by this plan the fluid could with difficulty be all drawn off, and the puncture is now made in an upward direction at the external edge of the patella. After the removal of all of the fluid, the opening is closed with charpie and collodion, and the last strip of plaster is applied in the centre, and thus the joint is compressed and placed at rest. To secure rest more completely, the leg is bandaged and an ice-bladder is applied to the knee, although the latter is thought to be, perhaps, superfluous.

Occasionally slight œdema of the foot and ankle follow the operation; but clipping of the plasters, and so loosening them, causes it to disappear. The band-

age may be removed at the end of three or four days, and the fluid will commonly have disappeared. When it has recurred it is in less amount, and the joint is quite free from pain.

The utmost care is essential in disinfecting the trocar, and in operating in a locality where there is neither pyæmia nor erysipelas.

Carbazotate of Ammonia.—Dr. Dujardin Beaumetz recently reported to the *Société de Thérapeutique de Paris* the results of his investigation of the character of this combination of ammonia with carbazotic, pieric, or trinitrophenic acid, and especially with reference to its use as a substitute for sulphate of quinia. After mentioning the successful employment of this salt in the treatment of intermittent fever by several persons, Dr. Beaumetz detailed six cases treated with like result by himself, and also mentioned the results of experiments made upon both men and animals. Like quinine, carbazotate of ammonia diminishes the strength of the pulse and induces languor, cephalalgia, and even delirium, and finally is eliminated by the kidneys. The Doctor thinks that one-third to two-thirds of a grain daily will suffice to suppress the paroxysm of intermittent fever, and says that, given in these doses, the drug has not been known to produce bad effects; indeed, it seems to be better tolerated than sulphate of quinine, the physiological action of which it resembles.—*Med. Press and Cir.*, May 7.

Transplantation of the Marrow of Bone in Sub-periosteal Amputations.—Mons. G. Félizet, at the meeting of the *Acad. des Sciences* of June 30, presented the results of two series of experiments of the above nature,—the first, in the case of an operation upon a wounded man, twenty-six years old; the second, experiments upon dogs.

1. Transplantations of marrow in a "muff" formed by the periosteum of long bones, presented the condition most favorable for the success of the graft.

2. The occlusion of the grafted marrow in this manner, under a "muff" nicely closed with sutures, results in covering the bony stump by an anatomo-pathological process identical with that which governs the formation of a calculus, first cartilaginous, then osseous, in simple fractures.

3. The accidental opening of the "muff" does not render the success of the graft impossible, but makes it incomplete, and favors the exit of a portion of the transplanted tissue, preventing the formation of the cartilaginous masses. It also excites osteomyelitis in the same way as simple sections of bone in ordinary amputations when exposed to the air.—*Mouvement Médicale.*

Albuminuria as a Symptom of Meningitis.—Professor Rosenstein has noticed the coincidence of albuminuria with meningitis. The analysis of their urine demonstrates in nearly all patients, whether old or young, attacked with meningitis, the presence of albumen in the early days of the cerebral affection; and in a considerable number of these cases is found at the same time, among the products of the renal secretion, epithelial cells, blood-globules, and fibrinous casts, exactly the same as in Bright's disease. The lesions discovered by post-mortem examination of the kidneys are likewise similar to those of albuminous nephritis. The kidneys are increased in size—the hypertrophy being chiefly in the cortical substance; the renal tissue is markedly injected; the glomerulæ gorged with blood, and there are extravasations of blood into the urinary tubules. Professor Rosenstein attributes these lesions to troubles in the circulation due to functional alteration of the vaso-motor nerve-filaments. This fact is likely to be of considerable value in diagnosis.—*Lyon Méd.*

Experiments on Blood-corpuscles.—At the recent meeting of the British Medical Association, Dr. Norris, of Birmingham, showed some beautiful experiments illustrative of his views regarding the formation of rouleaux by the blood-corpuscles, and the passage of the corpuscles through the capillary walls. A number of thin cork disks were so weighted with shot that, when placed in a jar of water, they maintained a vertical position below the surface, exhibiting no tendency to form rouleaux. When removed from the water, dipped in paraffine oil, and again placed in the water, the disks formed rouleaux, just like the blood-corpuscles. This phenomenon Dr. Norris ascribed to the repulsion between the paraffine and the water, and the cohesive attraction which the disks covered with paraffine had for each other. He inferred from this experiment that when the blood was withdrawn from the body the corpuscles underwent some alteration which led to repulsion between them and the plasma, and the corpuscles ran together in virtue of cohesive attraction. Sometimes, however, the blood-corpuscles do not run together in the form of rouleaux, but give rise to irregular, conglomerate masses, which Dr. Norris imitated very successfully by means of soap-bubbles side by side on a piece of glass. Dr. Norris maintained that the passage of the blood-corpuscles through the capillary walls was not due to amœboid movements, but to the action of cohesion. That it is not due to the former is supported by the fact that red corpuscles, which possess no amœboid movement, penetrate vascular walls equally well with leucocytes. He produced a soap-film about a foot in diameter, and permitted a large soap-bubble to fall upon it; the bubble passed half through the film. He then applied the mouth of a wet beaker to the bubble, and, in virtue of cohesive attraction between the wet glass and the bubble, the latter, as it were, crawled through the soap-film into the cavity of the beaker, leaving the film intact. A wet orange was repeatedly dropped through the film, and the doctor also passed his hand through it and removed it without producing any rupture. The film was compared to a capillary wall, the bubble to a corpuscle, and the beaker to the interstice of some organ outside the blood-vessel.

Experiments upon the Brain.—At the same meeting Dr. Ferrier experimented upon the brains of a cat and monkey. After removing the calvarium and dura mater he faradized various portions of the convolutions in succession. In applying his electrodes to the several convolutions, Dr. Ferrier predicted movements, for example, of the foot, the shoulder, the ear, the mouth, the eye, the head, etc.; and almost always the predicted movement occurred. According to Dr. Ferrier, instead of the cerebral convolutions being exclusively the seat of the intellectual operations, it appears that they are for the most part the nerve-centres for various muscular movements which can be called forth by stimulating them with electricity, just as if they had been excited by volition. The cerebellum, whose function has been much disputed, is found by Dr. Ferrier to be the motor centre for the muscles of the eyeball.—*Br. Med. Jour.*

Hoppe-Seyler's Process for Detecting Bile-salts.—"Precipitate with subacetate of lead and ammonia; wash the precipitate somewhat with water; boil precipitate with alcohol, and filter hot. (The alcohol takes out the bile-acid salt of lead.) To this solution, after filtration, add enough solution of caus-

tic soda to decompose all the bile-acid salt of lead. (We now have a bile-acid salt of soda.) This solution is to be evaporated to dryness; residue to be extracted with absolute alcohol. (This takes up the bile-acid salt of soda, leaving the lead behind.) Filter. Precipitate filtrate with excess of ether; allow to stand; pour off supernatant fluid; dissolve precipitate in water, and apply Pettenkofer's test. Much care is needed in this; for some lead flows on closely throughout."

Prognosis of Syphilis.—F. R. Sturgis, M.D. (*Am. Journal of Medical Sciences*), in an important article on this subject arrives at the following conclusions: 1st. That syphilis is a self-limited disease, and the patient, if blessed with a sound constitution, will, in the average of cases, get well, even if left untreated; but this course exposes to great and serious risk. 2d. That some general idea may be formed as to the future from the character of the earlier lesions; this rule, however, is not absolute, as some cases do occur where the early stages are slight and the subsequent ones severe. They are, nevertheless, he thinks, exceptional. 3d. That as the disease progresses, the prognosis is less favorable, more especially where important organs are attacked, such as those of the nervous or arterial systems; and, 4th. That in forming an opinion, due regard must be given to the age and general health of the patient; and in the treatment attention must be paid, besides the proper use of specific remedies, to strengthening the patient, if debilitated from any cause whatsoever.

The "Wet Pack" in Eclampsia connected with Albuminuria.—Isaac G. Porter, M.D., New London, Conn. (*Am. Jour. Med. Sciences*, July, 1873), in a paper "On External Diaphoretics, particularly the 'Wet Pack' in Eclampsia connected with Albuminuria," states the "wet pack" is not inconsistent with the simultaneous use of other active medication. Bleeding may be practised when called for, as in any other disease; cupping the loins may precede, to relieve hyperæmia of the kidneys; cold may be applied to the head, or hypodermic injections of morphia administered, or œnemas of chloral hydrate, or, if the patient can swallow, bromide of potassium or tartrated antimony.

The author, in closing, remarks as follows: "My object will have been attained if I have brought prominently forward a remedy in puerperal convulsions not entirely novel, yet one too much neglected and overlooked, and valuable, doubtless, in all cases attended by albuminuria. Where labor is nearly completed we may not care to resort to it; but it is eminently useful when other means are exhausted, or are inappropriate to the case."

Hypodermic Injection of Strychnia in Progressive Locomotor Ataxia.—W. B. Drinkard, M.D., Washington, D. C. (*Am. Jour. Med. Sciences*, July, 1873), infers from the facts of a single case, that strychnia offers at least as much chance of amelioration in locomotor ataxia as any other remedy that has yet been tried in this disease, and that its benefits may be more promptly and decidedly obtained by the hypodermic method than by its internal use. The amount may be increased far beyond what he used in the case recorded, gr. $\frac{1}{32}$ twice daily, and with proportionate increase of beneficial effect.

That without denying to morphia, especially as administered hypodermically, its place as the sheet-anchor in this terrible disease, whose characteristic pains will yield to nothing else apparently, the practitioner must yet be even more on his guard in administering it than is usually done. For even if there be not a special tolerance of opium and of all sedatives and narcotics in locomotor ataxia, as there probably is of strychnia in this and other conditions of nervous tissue-change, the severity of the pain itself may increase its toleration and encourage the continued use of larger and larger doses, until, finally, relief can only be obtained by an amount conceivably incompatible with life, or the patient sinks, killed as much by the drug as by the disease.

Absorption of Two Inches of the Shaft of the Femur.—Frank K. Paddock, M.D., Pittsfield, Mass. (*Am. Jour. Med. Sciences*, July, 1873), reports a case of this character—the patient being a female, æt. 59—because he believes it establishes the fact that there may be local osteitis, with absorption of the mineral portion of an entire section of a long bone, without the formation or deposition of any fibrinous or plastic material, or other product of inflammation, either in or adjacent to the diseased bone.

Ergot in Nervous Diseases.—Daniel H. Kitchen, M.D., Asst. Phys. to the N. Y. State Lunatic Asylum (*Am. Jour. Insanity*, July, 1873), after repeated investigations, finds that ergotine and Squibb's fluid extract of ergot are beneficial in nervous diseases. In the following forms of headache he has used ergotine with much benefit and comfort to the patient: (1.) Headache depending on plethora or fulness of blood. (2.) Headache from anæmia. (3.) Headaches depending on changes in brain-substance and the membranes. (4.) Epileptic headaches. (5.) Migraine. (6.) Headache depending on disordered menstruation. The author presents ten cases of epilepsy and insanity in which marked and beneficial effect was noticed following the use of Squibb's fluid extract of ergot and ergotine, either alone or in combination with sulphate of quinine and other remedies.

Ergotine may act in two ways: first, directly on muscular fibre, in the same way as any other stimulant; second, through the nervous system, principally the ganglionic. The immediate effect of ergotine on the blood-vessels is marked and rapid; the pulse is increased in force and volume; the slow and wavering pulse becomes full and strong. The power of ergotine is manifest, from its value as a hæmostatic in reducing the size of blood-vessels.

Presence of Alcohol in the Human Urine.—After having shown that urine on putrefying produces alcohol, M. Béchamp has sought to discover alcohol in the urine of persons who had previously been subjected to a *régime* of abstinence from wine and alcoholic drinks. In the urine collected in these conditions, and in which fermentation had been prevented by the addition of a little creosote, M. Béchamp has found enough alcohol to be able to set it on fire. In one of the experiments there was enough alcohol in two litres of urine to be determined by the alcoholometer. The author believes that the liver produces alcohol physiologically.—*Bordeaux Méd.*

A Peculiarity in Hospital Construction.—In announcing the inauguration of a new hospital at St. Petersburg, designed by the architect Bernhardt, the *St. Petersburg Journal* remarks a disposition shown by the physicians of Northern Europe to attribute value to the influence exerted by a sojourn among animals upon phthisical persons. The division of the hospital occupied by phthisis patients is to be in constant communication, day and night, with a stable in which fine breeds of milch cows are kept.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month, by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, October 15, 1873.

THE MEDICAL CHARITY QUESTION.

Our remarks upon the abuses of medical charities have called forth considerable correspondence from many of the younger members of our profession. The number of letters from different quarters, not only shows how widespread is the evil, but how universal is the desire for some remedy. If many of the epistles were presented to our readers, it would be seen that we have made a very mild statement of facts, and that the troubles of the young and struggling practitioners were far from being exaggerated. In referring to some of these we shall only confine ourselves to the statements of those gentlemen known to us whose opinions are founded upon extended observation.

One of these gentlemen complains that, although having a dispensary class, and doing more than his share of charity business, his income from private practice is so ridiculously small that he actually envies the profits of the cartman who is his next-door neighbor. He attributes this condition of things mainly to the fact that he is not allowed to reap any advantage whatsoever, directly or indirectly, from his dispensary class; that patients who are regular attendants upon him during his class-hour, and who are willing to pay something, must not know from him how they can enjoy such a privilege. In this regard he sacrifices his needful pecuniary gains to what the directors call a point of honor; and that these directors, bent upon what they call the prosperity of the institution, are too apt, by the manner in which they ignore any outside privileges of the young physician, to quench any desire on the part of such patients to pay their small fees at his private office.

Another gentleman, while complaining of the same thing, suggests a remedy which strikes us is a good one, and which would apply equally to those who are able to pay good fees and to those who would like to give what they could afford to help discharge their obligations to the doctor. It aims, in the first place, at preventing any unworthy patient from gaining admission to the physician's room. The particular person —be he house-physician, trustee, or director—who enters the name of the applicant and assigns him to a particular class, can generally judge whether it is a true charity case or not. If he have any doubts concerning the matter, he is warranted in asking the question as to the means of the patient, or in stating his suspicions, and if satisfied that his suspicions are well founded, to refuse the benefits of the institution to that individual. In many cases there may be a good excuse for a patient applying for relief at a public institution who would be willing to pay the physician for his services. Take, for instance, a stranger who comes from the country for advice, and whose only means of knowing that he will not fall into the hands of a charlatan is the application to a public institution of standing and reputation. If such a person can pay, he can very easily be satisfied that he can get the advice of any of the physicians of the institution at their private offices. In order that no partiality be shown to the different members of the staff, it could be so arranged that all paying applicants should be evenly distributed. A simple and satisfactory way to do this would be to give all such patients who might apply a given day to a given physician or surgeon. This is a suggestion which comes from a gentleman who has served long enough in one of the public institutions to know what is wanted in the premises, and we commend it to the consideration of his brethren.

Another gentleman complains that those physicians in his neighborhood who are accustomed to large fees, are in the habit of sending the patients, who cannot come up to their tariff of prices, to the public institutions rather than to the poor practitioner around the corner. He very reasonably remarks that this is wrong, no matter what might be said of the necessity of keeping up the dignity of professional labor. The practitioner who makes a great deal of money, throws away his crumbs to a false charity, which would be the very sustenance of the struggling brother. It is unfair to suppose that this is done out of jealousy or malice, but from pure thoughtlessness and unpardonable forgetfulness on the part of these same nabobs of their own wants when they commenced business. We cannot see how the dignity of professional services would suffer by allowing a poor but honest patient to pay what he could towards discharging a debt of gratitude to one whose very bread and butter depends upon an aggregation of just such small fees. The poor practitioner is willing to accept the situation, and the patient is made to feel the better for it. No one has a right to say that if a patient cannot pay a particular price for a purely professional service, he must have it for nothing; but if the physician is not satisfied with any

thing less, his duty is to refer the case to a younger brother, whose want does not make him suffer in his conscience for an occasional violation of an arbitrary rule. The fact is, he is willing to take what he can get, rather than get what his dignity allows him to take. The moral of all this is: Medical aristocrats, men who despise small fees, recollect your younger brothers around the corner, and do not forget how you had to commence practice yourselves.

Another "Struggling Practitioner" wishes to call attention to the relations which the druggist holds to the question of medical charity. He maintains that while the medical man is willing to take small fees, the druggist makes no allowance whatever, adheres to a standard price, and that not unfrequently the medicine costs more than the advice. There is altogether too much truth in this. Pharmacists as a rule are not considerate enough to those who cannot afford to pay their prices. They place a high estimate upon the skill necessary to compound a prescription, and this gives them a wide latitude of conscience for exorbitant charges. When it comes to the question of skill in compounding, is a higher estimate to be placed upon that than upon skill in diagnosis or treatment, for which the poor physician is willing to take what he can get? We believe that there is always an opportunity for the pharmacist to make a decent allowance for the poor; for in the majority of cases the medicines used in a prescription cost very little indeed, and not unfrequently the bottle and cork are the most important items. The abstract profits from prescriptions are immense, and when we consider how adverse pharmacists generally are towards lowering their standard of prices to the poor, we often feel as if they should not enjoy the patronage of the profession. In fact, the physician, knowing how little of mercy he can expect from some of these pharmacists, is compelled to cut down even small fees to make it bearable to his poor patients. Moral: Struggling practitioners, do not prescribe much medicine for those who cannot afford to pay much for advice; generally it will hurt none but the druggists.

Reviews and Notices of Books.

MIND AND MATTER, OR, PSYCHOLOGICAL INQUIRIES. SIR BENJAMIN BRODIE, Bart. With notes by an American Editor. William Wood & Co. New York, 1873.

THE new edition of this little volume is of less value, coming as it does after the much more complete works that have recently appeared on the same subject,—notably Tuke's discussion on Influence of the Mind upon the Body. We do not agree with the author that "the method of dialogue seems to be especially adapted for inquiries of this description." We think, on the contrary, that it tends to encourage a vague and rambling style of thinking that does not even propose to itself to arrive at any definite conclusion, unless indeed the dialogue be controlled by the strict rules of the Socratic method,—and even then it is only adapted to the successive deduction of principles, rather than to the exposition of facts. These Dialogues touch upon the processes of mental exertions, the relations of the mental principle to the organization, the nature of memory, the various functions of the brain and spinal cord, the mental faculties of animals, and finally the science of human nature as a whole. The view is accepted, which has been so forcibly expounded by Brown-Séquard in one of his lectures at Harvard, that the brain must be considered as a congeries of organs, as distinct as those existing in the abdominal cavity. It is inferred, merely from analogy, that special parts of the encephalon exercise the special functions of perception of colors or musical sounds, of memory, or speech; yet the mass of positive evidence that exists in regard to the localization of an organ of speech is not involved in the discussion. A distinction is made between an impression made upon the brain to which the attention is directed, and that to which it is not, the former alone being remembered. A too rapid succession of ideas or impressions, with incapacity of attention, is incompatible with correct reasoning, is in fact the very essence of intellectual insanity. The difficult question of moral insanity is touched upon, but not much elucidated. It is admitted, on the one hand, that a person may be under the influence of moral illusions quite analogous in nature and impetuosity to the propensity described as bulimia, which has led people to eat a leg of veal at a sitting, or even to devour raw cats, rats and dogs. But on the other hand it is "absurd and dangerous to hold that any one whom the dread of being punished might deter from the commission of crime is not a fit subject for punishment." A curious inquiry is raised concerning the possible utility of dreams, "one of whose effects may be to increase the activity of the imagination during waking hours." The theory of James Mill, that evolves the highest moral principles from the repeated association and combination of instincts and ideas, is substantially accepted in the chapter on the Social Instinct. This is superadded in man to those instincts which he shares with the inferior animals, and which relate to the preservation of the individual and continuation of the species. "The social instinct is in many respects in antagonism to the others, and is more efficient in proportion as the intellectual faculties are more perfect." The science of human nature is freed from the pretensions of phrenology, in some acute criticisms, but not very well defined, for the author admits that "it is a department of knowledge in which I will not say we recognize no leading principles," but in which none are laid down for the guidance of the student. On the whole this book, though well suited to amuse the summer afternoon of a cultivated amateur, will not add much to the information of either a physician, or physiologist, or psychologist.

HANDBOOK FOR THE PHYSIOLOGICAL LABORATORY. By E. KLEIN, J. BURDON SANDERSON, MICHAEL KOSTER, T. LANDER BRUNTON. In two volumes. Philadelphia: Lindsay & Blakiston. 1873.

THE book is divided into four sections. The first is devoted to Histology, and is written by Dr. Klein, the last three to Physiology. Of these, the first directs experiments in regard to the blood, the circulation, respiration, and animal heat (Burdon Sanderson); the second is on the functions of muscle and nerve (Michael Koster); the third finally discusses digestion and secretion (Lander Brunton).

The section on Histology is again divided into two parts: The first is on preparation of elements, blood-corpuscles, epithelium and endothelium, connective-tissues, muscular tissue, tissues of the nervous system. The second describes the preparation of compound tissues and organs, the vascular and lymphatic system, the organs of respiration, digestion, special senses, skin, cutaneous glands, genito-urinary apparatus; finally a special chapter on embryology, and another on inflamed tissues. The care and minuteness with which directions are given may be seen from a mere enumeration of the details considered. Thus, in regard to the elements of the blood, the student is taught how to observe the amœboid movements of the white corpuscles, to distinguish their varieties, to examine them on the warm stage, to feed them with coloring matters or fatty substances, and to study the effect on them of different reagents, including electricity. The demonstration of the sarcous elements of muscular fibre is thus detailed, "according to the method of Colnheim:" A muscular fibre of a frog, Hyrophilus, or crayfish, is exposed in a platinum capsule to a freezing mixture at a temperature of 6° C. to 8° C. After a short time the muscle acquires the consistence of wax. Fine sections are then made with a cooled razor, and are at once examined in a drop of serum under a thin-cover glass, care being taken to introduce slips of silver paper to avoid pressure. Such a preparation, seen under Hartnack's immersion objective, No. 10, exhibits the following facts: Circular or oval disks present themselves (cross-sections of muscular fibres), the margins of which are sharply defined and possess a double contour (sarcolemma). Within the sarcolemma a beautiful mosaic is seen, in which the triangular, four-sided, or pentagonal areas appear to consist of a dull-looking material, separated by lines which are brighter, more transparent, and refract light less strongly. A fresh section, obtained as above, may be placed for a few minutes in diluted serum, and then transferred for from 10 to 30 seconds to a half per cent. silver solution; finally washed in water slightly acidulated with acetic acid, covered in glycerine and exposed to the light. A preparation is thus obtained in which the sectional disks are colored of various shades, from clear yellowish brown to dark brown; clear white lines on a brown ground are seen with great distinctness, which correspond completely with the trellis-work of transparent lines seen in the fresh preparation, from which appearance we learn that the spaces of the mosaic are stained brown by silver.

In Part II., devoted to the preparation of the compound tissues, the first chapter contains a general but minute description of the various methods employed: sections of fresh tissues (for which Dr. Klein condemns the use of pith supports); sections after freezing; methods of hardening in chloride of gold, osmic acid, chloride of palladium, alcohol and chromium compounds; methods of embedding in wax and oil, or in gum and gelatine; methods of coloring with carmine, Beale's solution, aniline, picric acid; methods of mounting in glycerine, Canada balsam, Dammar varnish. An entire chapter is given up to methods of injection, during life and after death, of frogs and of mammalia, with Prussian blue, with carmine, with silver; finally is added a description of the instruments employed. After the chapters that describe the special examination of each tissue and organ, the study of embryology is outlined, "such points only being noticed as are of importance to the beginner." "According as the germ and the yolk exist separately from one another, or form a single body, eggs are subdivided into two large groups, mesoblastic and holoblastic eggs. The first include those of the bony fishes, scaly reptiles and birds; the second those of cartilaginous fishes, amphibia and mammals." The process of cleavage of the entire ovum is first studied in the mesoblastic eggs of the trout, then their cleavage cavity, then the cleavage cavity and lamellæ of the blastoderm of the chick.

The chapter on inflammation contains rules for the observation of changes going on in inflamed epithelium, endothelium, cartilage, bone, liver cells and cornea; finally in the tongue of the frog and in the tadpole's tail.

Dr. Burdon Sanderson's paper is characterized by the same minuteness and technical accuracy, by means of which the reader could almost imagine himself a student in the laboratory of the master, receiving verbal directions to guide him in each step of his experiments; directions that forestall all the difficulties he could imagine, and many that he would never think of. He is taught how to filter the blood of frogs and of mammalia, how to illustrate the properties of plasma and of fibrine, and of the so-called fibrine factors, the paraglobulin and fibrinogen. The deductions made from the ordinary classical experiments are corrected by the details of Heynsius's experiment, intended to demonstrate that "a considerable quantity of fibrine-producing material is contained while the blood is circulating, in the colored or colorless corpuscles."

Very careful rules are laid down for procuring hæmaglobin, methæmaglobin, hæmin, hæmatin, hæmatain, and for studying their chemical and optical properties, also for making quantitative analyses of the blood with reference to its corpuscles, serum, fibrine, principal coloring matter, albumen and salts. Another section describes the gases of the blood, the method of obtaining the blood for gaseous analysis, and the various apparatus used in the process; Alvergniat's, Geissler's, Frankland-Sprengel's. In the study of the circulation, much space is devoted to the kymograph and sphygmograph, and to the precautions to be observed in their use. Afterwards type experiments are detailed to demonstrate the effects of the influence of the nervous centres on the vascular system. These details include minute rules for destroying the cerebro-spinal nervous centres; for exciting the spinal cord in the frog or rabbit; for section of the medulla oblongata in the rabbit; for reflex excitation of the medulla in frog or mammalia; for excitation of the nerves of the external ear, of the cervical, sympathetic, and the splanchnic nerves. The sixth section is upon endocardial pressure; the seventh on the intrinsic nervous system of the heart; the eighth on its inhibitory and accelerator nerves. The last section is supplementary, and contains methods for investigating the mode of absorption by veins and lymphatics.

In the Part II. of the Physiological Manual, Dr. Koster "has aimed to limit the directions as much as possible to such observations and experiments as the student may be reasonably expected to perform for himself under due supervision." The ordinary phenomena of muscle and nerve are consequently dealt with at far greater length than are the properties of the central nervous system. The latter are imperfectly known, and the experiments upon which our knowledge rests are difficult and complex. "The former, on the other hand, may be studied with appropriate exactitude; the methods of experiment and observation are becoming year by year more physical in character, and the observations themselves fundamental in their nature, and having the widest bearing on all the higher branches of physiology, may for the most part

be conducted on frogs, be repeated any number of times without difficulty or expense, and so serve usefully as a means of training students in physiological study and inquiry."

The first chapter tells how to make a "nerve-muscle preparation, how to employ a lever to study muscular contraction, how to construct a moist chamber that shall keep the preparation damp without permitting the moisture to come directly in contact with it; finally how to select and arrange electrical apparatus, with details upon the electrodes, commutator, rheochord, marking lever, tuning fork, metronome, etc. The next chapter formulates the general properties of muscle at rest, its elasticity, reaction, transparency; the third describes various modes of stimulation; the fourth studies the phenomena of muscular contraction; the fifth, its wave; the sixth, tetanus and exhaustion. Other chapters demonstrate the natural electric currents in muscles and nerves, and in the latter the phenomena of electrotonus, stimulation, and negative variation. Experiments are prescribed to exhibit the functions of nerve-roots, recurrent sensibility (only existing in the higher animals), reflex actions (best studied in the frog), finally, certain functions of the encephalon.

Dr. Brunton's share in the manual is not less valuable, nor the information given by him less varied and precise. A long chapter is given up to the properties of albuminous compounds, of which a synopsis is quoted from Hoppe Seyler. This includes albumens proper, globulins, fibrines, albuminates, acid albumen or syntonin, amyloid and peptones. To these are added leucine and tyrosine, and for all are given modes of preparation, reactions, and tests. In the next chapter, on the chemistry of tissues, are found rules for the analysis of the constituents of muscle, existing in its aqueous extract, the albumens, myosine, creatine, creatinine, sarcine, xanthine and inosite. In the chapter on digestion, the student is taught how to analyze saliva, and to perform experiments on the nerves of all the salivary glands; how to obtain gastric juice, test the effect of pepsin, prepare the components of bile, procure glycogen, etc. The rules for the examination of urine are an epitome of such important information as is more usually found scattered through theoretical treatises, where it is given with far less precision, because written with less view to practical application by the reader. Hoppe Seyler's Handbuch is the basis of much in the entire section, but this is no adaptation, nor even compendium, but every sentence bears the stamp of practical experience, sincerely anxious to encourage new experiments. It would be faint praise to say that a medical student who should conscientiously "go through" this manual, would know a hundred times as much physiology as it is now possible for him to attain by two years' attendance upon the best physiological lectures. Indeed we have no more sincere wish in regard to the important problem of medical education, than to see such a course of practical personal study rendered obligatory upon every one, man or woman, who is permitted to unveil the secrets of the animal frame. We have thought that even an allusion to the details considered by such competent authorities to be within reach of the "beginner," may be useful to many, who on the one hand regard practical physiology as something too formidable to be attempted, and on the other hand do not hesitate to announce and to base their practice upon physiological theories, of which a little practical knowledge would have shown the futility.

The second volume of the manual is devoted to plates of physiological apparatus, and of microscopical preparations.

GUIDE TO THE MICROSCOPIC EXAMINATION OF ANIMAL TISSUES. Von DR. SIGMUND EXNER, Privat Docenten für Physiologieu nd Assistenten am Physiologischen Institute zu Wien. Mit 3 Figuren in Holzschnitt. Leipzig: Wm. Engelmann. 1873. (8vo, 93 pp.)

THE author of this little work has a large class of students at the Physiological Laboratory in Vienna, and to avoid the trouble of repeatedly dictating to them the directions for microscopical manipulation he has had the latter printed. Although the book is well adapted to the purpose for which it was designed, we are nevertheless inclined to agree with Dr. Exner's remark in his preface, that, "even with the aid of this little book, it is very injudicious, if not impossible, for the beginner to attempt to teach himself without the help of a text-book on histology and the assistance of a teacher." The directions for the various manipulations are so short as to be in many cases almost useless for one not already accustomed to microscopic work. For example, in speaking of chromic acid for decalcifying the ossicles of the ear (p. 80), the strength of the solution and the manner of using it are not mentioned. It is recommended (p. 49) to transfer the melted paraffine to the box in which the preparation is to be embedded by means of a pipette. Why not avoid obvious and unnecessary difficulties by pouring it directly from the dish in which it is melted? Reference is made, at p. 87, to a new method of embedding without previously dehydrating the specimen: crude transparent soap is to be dissolved in ½ to ⅔ its volume of alcohol (not absolute) by the aid of heat. The mass becomes hard on cooling, and may be cut after one or two days. Sections are to be made with a dry knife, and the soap washed out of the section with water. This method was recommended by Flemming (*Max Schultze's Archiv*, Bd. ix., S. 123), who states that a transparent soap should be selected which *does not contain glycerine*. Again, in describing the process of tingeing with carmine, no mention is made of acidulated water for fixing the carmine in the preparation. The omission of many of these little practical points will cause some embarrassment for beginners, though the book is undoubtedly useful for those who have had more experience.

Though most of the methods are given at length in other works on the microscope, there are a few which we do not remember to have met with before, and it may be of interest to refer to some of them.

Absolute alcohol may be very readily and cheaply obtained from ordinary alcohol in the following manner:—Sulphate of copper is to be heated until it becomes white and the water of crystallization is driven off. It is then to be placed in a bottle of alcohol. After standing for a day or so, with occasional shaking, the alcohol has become absolute. When the salt resumes its blue color, it requires another roasting to be again fit for use. Sulphate of copper is insoluble in alcohol.

Some preparations are very difficult to embed, as, from their shape, air-bubbles become entangled in them. This may be readily obviated by placing the embedded specimen, while the medium is still fluid, in the receiver of an air-pump, and exhausting as rapidly as possible.

Salivary corpuscles are recommended as test objects for microscopes destined to anatomical use.

"A microscope which shows distinctly the molecular movements in the interior of fresh salivary corpuscles suffices for most investigations."

REVUE DES SCIENCES MÉDICALES EN FRANCE ET A L'ETRANGER. A Quarterly Analytical, Critical, and Bibliographical Summary. Edited by GEORGES HAYEM, Fellow of the Faculty of Medicine of Paris, and Physician to the Hospitals. Paris: G. Masson. 1875.

THE first two numbers of this noble work are before us, and certainly do great credit to the originators of, and the colaborators on, the work. Although the announcement is that each number will contain about 400 pages, the first one has 448, and the second 1,037. The execution is very good, the page having a clean and tidy appearance; many of the articles are quite extensive, and with each division is placed with biographical notices, under the heading *travaux à consulter*, the titles of less important articles, or of those to be noticed at greater length subsequently.

The editor calls attention to the previous lack in France of any quarterly or annual medical reviews, such as have long been possessed by Germany and England, and which are now rendered especially necessary by the increasingly rapid advance in all that pertains to medicine as a science. The subjects are arranged under the following general heads:—Anatomy, physiology, medical chemistry, therapeutics, hygiene, internal pathology and clinical medicine, obstetrics and diseases of women, diseases of infants, cutaneous diseases and syphilis, alcoholism and mental medicine, legal medicine and toxicology, external pathology and clinical surgery, operative medicine, ophthalmology and otology, and general pathology.

We cannot see that the editor is at all open to the objection of having shown a bias in favor of French literature to the exclusion of that of other countries, and if the promise made in the prospectus is carried out, viz., that "the *Revue* will take note of everything that is published in France, or abroad, in the domain of medical science," it will be a welcome addition to the libraries of many gentlemen who can read French but have not yet conquered the German.

A complete index at the end of each year is promised, in addition to the table of contents contained by each number.

The price (in gold) for subscribers in the United States is forty francs, irrespective of custom duties.

CONTRIBUTIONS TO PRACTICAL SURGERY. By GEORGE W. NORRIS, M.D., late Surgeon to the Pennsylvania Hospital; Vice-President of the College of Physicians of Philadelphia; Member of the Société Médicale d'Observation of Paris, etc.

ESSAYS from the pen of this author have always found a welcome in the profession. The subjects selected are of that important class which so frequently cause anxiety to the practitioner, which are but cursorily referred to in general works on surgery, and concerning which there has been so much diversity of opinion. To bring order out of chaos, Dr. Norris has adopted the statistical method, and by careful analysis of his tables has furnished us with results which will prove of inestimable value in practice.

The researches on which these tables are based are from foreign and home sources; they have been made with laborious care, and the analyses and deductions, those of a master in surgery, have been made in such a spirit of fairness that they cannot fail to convince; several of the essays appeared originally in the *American Journal of Medical Sciences*, and we are under additional obligations to the author for the trouble he has taken in presenting them in their present form.

The first hundred and eleven pages are devoted to the subject of non-union after fractures; after an exhaustive inquiry into causes and treatment, are the following recommendations:—

"1st. To apply the method of cure by compression and rest. If the fracture has been regularly treated, and is not consolidated at the usual period, replace the limb in the apparatus, and insure to it a state of complete immovability; if the treatment of the injury has been altogether neglected, or been inefficient, apply proper splints and moderate compression with a roller, and renew these as soon as they become in any degree lax.

"2d. If, from want of action in the seat of injury, rest and compression are in themselves inefficient to produce a cure, continue the state of immovability in which you have placed the limb, and apply blisters, moxas, iodine, or some other stimulant to the seat of fracture.

"3d. If both of these modes fail in producing deposition of callus, employ frictions.

"4th. If the methods mentioned fail to produce a change, or the patient has already been suffering from his injury for eight or ten months and there is no contra-indication to it, resort to the seton.

"5th. If the case be one to which, from its long-standing or state of the injured parts, the seton is inapplicable, expose the fracture and apply caustic potash to the fractured ends.

"6th. If all the above means have been carefully resorted to unsuccessfully, and not till then, resect the ends of the bones.

"7th. Never resort to amputation of the member until fair trials have been made of all these methods, and then only at the request of the sufferer, after he has found that the limb can be of no possible service to him.

"In employing any of the above means, the obstacle to the occurrence of union which may exist, arising from the state of the constitution, should be carefully sought for and combated by appropriate treatment."

The author gives a very complete table of one hundred and fifty cases, culled from foreign and home sources, and a summary, from which the following conclusions are drawn:—

"1st. That non-union after fracture is most common in the thigh and arm.

"2d. That the mortality after operations for its cure follows the same law as after amputations, and other great operations on the extremities, viz., that the danger increases with the size of the limb operated on, and the nearness of the operation to the trunk; the mortality after them being greater in the thigh and humerus than in the leg and forearm.

"3d. That the failures after operations for their relief are most frequent in the humerus.

"4th. That after operations for the cure of ununited fractures, failures are not more frequent in middle-aged and elderly than in younger subjects.

"5th. That the seton and its modifications is safer, speedier, and more successful than resection or caustic.

"6th. That incising the soft parts previous to passing the seton augments the danger of the method, though fewer failures occur after it.

"7th. That the cure by seton is not more certain by allowing it to remain for a very long period, while it exposes to accidents.

"8th. That it is least successful on the femur and humerus."

The Essay on Compound Fractures is replete with sound practical advice, and has appended to it a statistical account of the cases of amputations performed at the Pennsylvania Hospital from Jan. 1, 1850, to

Jan. 1, 1860, with a general summary of the mortality following this operation in that institution for thirty years.

The statistics of the mortality following the ligature of arteries are full of interesting detail, and will well repay an attentive consideration.

FRACTURES OF THE ELBOW-JOINT. An Essay to which was awarded the Second Prize of the Boylston Medical Society, for eighteen hundred and seventy-three. By WALTER ELA, second-year student Harv. Med School.

FIFTY-SEVEN pages on a subject, the importance of which the crippled limbs we occasionally meet with fully attest, will well repay perusal, if only that it brings back and more accurately defines our knowledge obtained from general and special works on surgery. The author's statistics are obtained from the fracture-books of the out-patients' department of the Massachusetts General Hospital, and relate principally to the ordinary fractures of the bones entering into the composition of the joint. They comport generally with those of other authors; but the pith of the essay is the description of a dissecting-room specimen obtained from the body of a female twenty-two years old, an epileptic, who died in the State almshouse. The injury, which involved the right elbow-joint, must have occurred some years before death, inasmuch as the deceased had free use of the limb, and was engaged as "helper" in a ward. A first impression was that it was one of those cases, so common in every museum, of chronic rheumatic arthritis; but a more careful analysis of the specimen proves it to be one of "Fracture of the coronoid process, partial fracture of the olecranon, impacted fracture of the neck of the radius, and separation of the internal condyle."

The essay is illustrated by an albertype taken from a drawing made by Dr. H. P. Quincy.

Correspondence.

NOTES ON THE MEDICAL SCHOOL OF BERLIN.

HOW TO COMMENCE.—FEES FOR LECTURES.—PROF. VIRCHOW; HIS COURSE ON POST-MORTEM EXAMINATIONS AND MICROSCOPY.—THE METHOD OF CLINICAL INSTRUCTION.—INFLUENCE OF HOLIDAYS ON STUDY.

BY ISAIAH DE ZOUCHE, M.D., Q.U.I., M.R.C.S. Eng.,

OF NEW YORK.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Thinking that some notes on the medical school of Berlin might be of use to American students intending to spend the winter abroad, I take the liberty of addressing you on the subject. Although the announcement says that the lecture term begins the middle of October, most of the professors do not commence their courses before the first week in November, closing on the last day of February. Deducting a fortnight's recess at Christmas, it will thus be seen that the working *Semester* is only three months and a half. The *Kladderadatsch* jocosely notices the fact, and says that every year the Semesters are shorter, the vacations longer, and the graduates cleverer, and the natural deduction is, that when the Semesters are reduced to *nil* the doctors will attain their highest degree of perfection. Professor Virchow is one of the first to commence his course, and one of the last to close.

It is well for the American or English student to be in Berlin some little time before the opening. By doing so he will be able to ascertain who are the professors, their days and hours for lecturing, and the places in which the lectures are held, and also he can fix definitely what courses he will attend, and inform himself generally; otherwise there is a loss of several days in marking out the work and ascertaining where the various professors are to be found—not an easy matter for a stranger, unless he has some friend to give him information. There are so many subjects, and so many subdivisions of these subjects between the ordinary professors, extraordinary professors, and private teachers, of whom there are fifty-four in all, that the foreign student may well be puzzled to know how to spend his time to the greatest advantage.

There are, besides, many things of interest to be seen in Berlin, and they ought to be seen by the student before he settles down. Another advantage of being there early is, that one of the front places at any of the cliniques or courses which the student may wish to attend can be secured; and these places are the best, being nearest to the professor—a matter of importance to those who are listening to lectures in a foreign language for the first time. I would recommend those who know something of the language to be there a month before the lectures commence; for those who are unacquainted with it (and there are many such who go to the University of Berlin), this is still more important.

The foreign student is generally invited to matriculate at the university. This means simply the paying of about ten thalers, part on entrance, and the remainder when obtaining certificates for attendance at lectures. There is no matriculation examination, as it is presumed the student's own alma mater has seen after his general education. There are some advantages in being matriculated, as the certificates will bear the official stamp, and will probably be acknowledged by the American colleges, as they are by several of the English, but the foreign student is not *obliged* to matriculate, and can obtain private certificates from the professors whose courses he may attend.

The fee for each course or lecture is generally twelve thalers (nine dollars). The matriculated student pays all fees at the Quästur of University, having first entered the titles of the lectures in his Anmeltungs-Buch. The unmatriculated pay the fees to the several professors.

The greatest number of foreign students, who, by the way, are mostly men holding diplomas in medicine and surgery, go to attend the pathological courses of Professor Virchow. In the winter of 1871–72 there were about 30 English-speaking students at his demonstrative course of pathology and pathological anatomy, of whom about twenty were Americans, six or seven from Scotland, two from England, and one from Ireland. There were, of course, a good many English and American students attending the various other lectures.

Professor Virchow gives a demonstrative course of pathology and pathological anatomy on Mondays, Wednesdays, and Saturdays. (All his lectures are given in the Pathological Institute, which is situated in the grounds of the Charité.)

Monday mornings are devoted to autopsies. The object is to teach the proper mode of making an autopsy, how and what to observe, and to describe what one sees. In the early part of the session Prof. Virchow himself makes the post-mortem examination, but afterwards, when the students are supposed to be familiarized, theoretically at least, with the proper

mode, he allows one or two of them to make the section. Every step of the proceeding is worth watching. The subject is minutely examined externally, and described, before any incision is made, then the cavities are opened in order, and the viscera examined. The student is made to describe the exact *appearance* of every part, without any reference to its pathological state. He is taught the order in which the various incisions should be made, and even the manner of holding his knife. Nothing is slurred over hastily, so that two, two and a half, or even three, well-spent hours are consumed over a single autopsy. When the *appearances* have all been accurately noted, Professor Virchow sums up in a few words their relation to the pathological condition. He constantly impresses on his class the value of "naked-eye pathology." He says that in almost every instance the microscopical appearances of a part may be premised by a careful examination with the naked eye. This observation is important, coming as it does from so distinguished a microscopical pathologist.

On Wednesdays and Saturdays a number of specimens, selected by the assistants from the autopsies made during the week, are placed on dishes and handed round the class after the morbid changes in them have been demonstrated. The whole of the organs from each subject are shown, also sections of the muscles and bones, if they have been involved in the diseased process. Professor Virchow points out the seat of the primary disease, and the secondary changes induced by it in other parts. Three or four, or more microscopes, showing sections of the diseased tissues, are sent round on a tramway, so that all the students present have an opportunity of examining them. The number of specimens supplied is wonderful, and not to be equalled at any school of pathology I know of. This course is, perhaps, the most numerously attended of all Professor Virchow's lectures. There are perhaps between 130 and 150 in it this winter. The lecture lasts about two hours.

The zealous student may, by application to Prof. Virchow, obtain permission to be present at the autopsies of patients who have died in the Charité, and which are made daily between 11 and 2 o'clock by the assistants, Drs. Wegner and Poufick. There is much to be learned in this way. Dr. Wegner, who by the way speaks very distinctly, describes each part or organ as it is exposed, and then lays it aside, when it can be examined by those present. He has the gift of being able to convey information in a clear, succinct manner.

Dr. Poufick dissects with such rapidity that he appears to be unable to keep up with himself in describing what he is doing. I have frequently heard him describe (and quite accurately) the appearances observed in the subject which he had just dissected, while he was making another autopsy in a different room. This shows a wonderful power of observation and memory; but few of those present were equally blessed, and did not derive much advantage from the section actually being made. Dr. Wegner's system is *better*.

On Tuesdays, Thursdays, and Fridays Professor Virchow gives a course of microscopical pathology from 8 to 10 A.M. Microscopes are provided for those who have none, and the necessary chemical reagents. Many bring their own microscopes. Virchow's assistant, Dr. Poufick, gives a full explanatory lecture on the subjects for examination, illustrated by drawings in colored chalks on the black-board. Each student is supplied with a piece of pathological tissue or organ to be examined, and when he has made a section and placed it under the microscope, Dr. Poufick goes round to see that the preparation is properly shown, and also to point out its pathological peculiarities. Professor Virchow comes later, and visits each microscope, answering questions and giving instruction. A great deal of pathological ground is got over at this class during the session. Permission to work during the day in the laboratory of the Pathological Institute can probably be obtained by application to Professor Virchow, who is very approachable and urbane in manner, and always ready to assist the industrious student.

On Mondays, Tuesdays, Thursdays, Fridays, from 1 to 2, Professor Virchow holds a sytematic course of lectures on general pathology and pathological anatomy.

The clinical instruction in Berlin is conducted chiefly by lectures. Let us take Professor Frerich's clinic, for example. This is held daily from 11 to 12 o'clock, in Professor Frerich's theatre, which is situated in the Charité, on the second floor of the front or entrance building. The theatre is a long room with seats arranged across, rising gradually from the front to the back seats. The patient is carried in and placed on a bed, or it may be he is brought in in his own bed if too weak to leave it. Those students who are in the front row can see the patient distinctly; those in the back seats have something less than a bird's-eye view. Only the student in charge of the case (praktikant) receives the benefit of the really *clinical* information to be obtained from watching and examining the case from day to day. It is right to state that a notice is placed in the theatre inviting students who wish to become praktikanten, to enter their names in a book kept there for the purpose. These, however, devote their attention to the cases on which they are expected to report, not to the others which may be lectured on. A short history of the case is read by an assistant, and the patient is briefly examined by the professor and the praktikant. Then the professor delivers a lecture (which appears to be addressed to the praktikant), not immediately on the case before him, but on the *disease*, merely taking the patient for a text. The lecture is the chief attraction of the clinic. It is seemingly exhaustive of the subject; a valuable summary of all that is known as to the symptoms, pathology, and treatment of the disease in question. If the whole series of Professor Frerich's lectures were copied down and compiled in a book, they would make an excellent work on the theory and practice of medicine. During the fifty minutes which the clinic lasts, two or three patients are usually brought in and their diseases lectured on, the students being for the most part busy with their note-books.

I made inquiries as to whether the students were allowed to go round the wards and examine the patients in bed, to verify such of the symptoms or signs as might have been called attention to, but was informed that this was not allowed. Professor Frerich's clinic is very largely attended. Professor Traube invites his class to accompany him twice a week round the wards, and to visit and examine the patients under his guidance. This is an improvement on the ordinary clinical lectures, as there is something practical to be seen. On the other days, one or two patients are brought into the theatre, and the disease lectured on as in Professor Frerich's clinic. Professor Traube has an excellent manner of conveying information, but I consider the visits to the wards the most valuable part of his clinic. It struck me that the German students were too much lectured at. To an Englishman this incessant lecturing would be intolerable; he wants to see and feel and

hear symptoms and signs for himself. Now the clinics of Berlin are very little different from the systematic lectures, except that there is a bed in the room, and that no order or system is followed in their delivery. It appears to me that there is too much time devoted to theory, and too little to practice. The theoretical and scientific branches are well taught in Berlin; but for practical medicine and surgery I prefer the British, and especially the Irish schools. The evil complained of has, it is true, been felt to some degree in England, and perhaps also in America. Although it is no part of my object to make more than a passing allusion to any other than the Berlin medical school, yet the following extract from the *Lancet* of June 28th last, so well expresses my views of the defects of clinical teaching in Berlin, that I think it will not be out of place to introduce it here:—"Certain teachers entirely overlook the imperative importance of teaching only the practical parts of the profession at the bedside, leaving the perplexities of conflicting theories to be discussed in systematic lectures. By disregarding this point, it is not at all infrequent to find students mystified rather than edified by the efforts of their tutor. Practically, it is of greater value to assist a student in discovering what exists, than to tell him what does exist, and what he ought to find in such cases. What the clinical student wants in a case of phthisis, for example, is not to be told what may be found in most cases of this affection, nor to hear learned discourse on the vexed question of tuberculosis, but to be informed of the morbid conditions of the lung of the patient lying before him, the readiest method of detecting them, and the best remedial agents employed.

Professor Joseph Meyers' clinic in Ziegel Strasse, from 1 to 2, is well worth attending. A good many out-patients are seen, and the information gained is practical.

Professor von Langenbeck also holds his clinic at the Poliklinik in Ziegel Strasse, from 2 to 3. A good many cases are disposed of within the hour, and the clinic being a practical one, is very valuable. His reputation as an operating surgeon is so widely spread that it is unnecessary to allude to it further.

Professor Martin's clinic for Obstetrics and Gynæcology is held on three days in the week at the Entbindungs-Anstalt, in Dorotheen Strasse, behind the University, and on the other three days in the Charité. The diseases of women are well taught at this clinic. A lecture is first delivered, and then the patients are called up for examination and treatment.

Each student has the opportunity of becoming a praktikant by simply coming forward when his name is in its turn read out. He is invited to examine, diagnose, and prescribe for a case, and during the session his turn may come round frequently enough to give him a good practical insight into uterine diseases. The clinic lasts from about 10 to 11.30 or 12, but the work of the out-patient department (in Dorotheen Strasse) is not generally over until 2 or 3 o'clock. Dr. Löhlein, the assistant, attends to it, and any students who remain can see as much practice as they wish. Dr. Löhlein is most polite to foreigners as well as to Germans, and very considerate towards the patients. He is the right man in the right place.

It seems strange to British and American students that no care is taken at this clinic to spare the feelings of the patients before the class, by covering their faces during examination. The patient is simply told to get up on the table and lie down on her back, when the necessary examination is proceeded with. In the case of young girls, at least, some more delicate mode might be adopted. We do these things better in England and America. However, the women, as a rule, do not seem to mind the method pursued.

Privatdocent Dr. Fraenkel holds an excellent course, theoretical and practical, on laryngoscopy and rhinoscopy, which I can recommend to any student who wishes to devote attention to these subjects. He teaches them well, and is very painstaking with the practical work. Quite a number of patients were examined and treated at these classes. Dr. Fraenkel invites diligent students to be present at his operations. His apparatus for laryngoscopy and rhinoscopy is very complete, and he has himself introduced a few instruments which are well adapted to their several purposes.

A course of auscultation and percussion is held by Dr. Fraentzel, one lecture weekly, and practical instruction in the wards on three days in the week. With the exception that there is even on the practical days too great a tendency to theoretical lecturing, the course is good.

It would be impossible to refer in detail to the many excellent courses held in Berlin; it will suffice to mention the names of Reichert, DuBois-Reymond, Lucae Liebreich (Professor of Chemistry), etc.

During the two months' recess between the closing of the winter courses and the commencement of the summer lectures and clinics, the student may occupy his time to great advantage by attending some of the private courses or clinics—thus, courses on Operative Surgery by Professor Langenbeck, the surgical poliklinik in Ziegel Strasse. Dr. Wegner has a course of Histology. In fact, a student who keeps his eyes and ears open may do quite as much work during recess as in the regular session. There is nothing to be specially remarked about the summer session, except that it commences much later and is closed much earlier than the time announced in the Index Lectionum, and the various courses are interrupted by the usual number of holidays. Now, holidays are very good institutions in their way, but there may be too much of a good thing, and for the short sessions at the German universities it appears to me that such a superabundance exists, and is a serious interruption to those who go for work.

The correspondent of the *Daily News* (London), on the 3d of June last, thus refers to the holidays:—

"The great foe to existence of an active man at this city is the holidays. Not only do the Berliners have an extraordinary number of these luxuries, includin all the Church feasts, fixed and movable, several national anniversaries, the birthdays of half a dozen princes, and a few municipal commemorations—not only do they have all these, let us say legitimate occasions of rest and recreation, but they manage illegitimately to stretch each one over half a week. A festival which falls in the middle of the week must always run along so as to take in the next Sabbath; those which fall on Sunday must never cease before Wednesday. Take, for example, Christmas. Last winter Christmas fell, if I remember aright, on Wednesday, and the observation of the same extended till the following Monday. The next week the same thing was repeated for the New Year. Holy Week was of course utterly lost; but piety might have tolerated the infliction if the interdict had only been lifted after Easter, instead of remaining in force, as it did, till the next Wednesday. A fortnight ago Ascension threw a pall over the city, and now we are in the pangs of Pentecost. Do not suppose that Church anniversaries are observed here as in other countries, where the faithful go to church, and the unreclaimed pursue their usual vocations; or that they are observed with the slightest regard to their respective characters. Good

Friday is treated exactly like Easter. It is all matter of formal regulation. The holidays are ticketed and numbered like places at the theatre. Thus Sunday is first Easter holiday, Monday is second Easter holiday, Tuesday is third, etc.; and so with all the festivals. The dulness of the city during such a period cannot be described; and, to crown the dismal accumulation of sorrows, the journals suspend for half a week, and publishers, editors, and typos take early trains for the country. To-day is Tuesday, and no newspapers have appeared since Sunday morning. I wish to criticise the social peculiarities of my hosts, the Germans, with becoming diffidence; but I must say, as a man brought up in the belief that work should be the rule, and play the exception, that I am writing on our third *Feiertag* in a state of mind tending to depression."

I have only spoken of such courses and clinics as came under my immediate observation. It would be interesting and useful if other student-visitors to Berlin and the other medical schools of Germany would give information regarding the system of instruction pursued, for many American and English students go to the Continent merely from an idea that it is the right thing to do, but without knowing how to employ their time to the best advantage. Information regarding the working of the smaller universities is much needed. These are said to offer more advantages for the study of practical branches, but of this I am unable to speak from personal experience.

One word about the ventilation of some of the theatres and laboratories in Berlin, or rather the absence of ventilation. It appears to me that the more celebrated and scientific the professor, the less was the regard paid to the hygienic necessity of fresh air; and many of the wards in the hospitals caused a feeling of oppression and stiffness which alone would be sufficient to make one wish for the end of the clinic or lecture.

POISONING BY CARBOLIC ACID.

To the Editor of The Medical Record.

Sir:—I read the account of the almost instantaneous death of Dr. R. S. C. Foster (in The Medical Record for August 1st, 1873), from swallowing by mistake about half an ounce liquid carbolic acid.

Thinking your numerous readers might like to know of a similar case, I narrate the following:—J. Welch, a shoemaker, formerly a soldier in the English army, whilst in India contracted the opium habit, and has ever since 1857 been using the drug in the form of laudanum. About two years ago, falling short of his usual supply, he called on me for a small quantity whilst waiting for his week's allowance. I left for him ℥ss. in a small phial (his usual dose), and at the same time left for him about ℥ss. liquid carbolic acid in a similar phial, to be used, diluted, as a wash and disinfectant. The acid very much resembles laudanum in color. With that eager haste peculiar to opium-eaters, and without waiting to examine the contents of the two phials, he uncorked the first that came to hand, put it to his mouth, and swallowed its contents, which, unfortunately for him, proved to be carbolic acid. He at once found out his mistake and spat out some of it. On his reaching home he took some olive-oil, and, with the exception of a severe burning pain in his throat, which lasted a few days, suffered no further inconvenience.

Not being at home at the time this occurred, I was somewhat alarmed when I heard of it, knowing the poisonous effects of the acid. I was glad when I saw him soon after, to find him not seriously affected. I attribute his escape with so little injury to his opium habit, his nervous system being under control (he having taken his laudanum after finding out his mistake), and to the olive-oil, which I find in all cases relieves the burning pain and inflammation which carbolic acid excites when applied pure—accidentally or otherwise—to the skin. I think it difficult to remove the "acid," when swallowed, by the use of emetics. Our object should be to neutralize its effects on the mucous membrane and general system.

I remain, yours respectfully,

Aggeus Outerbridge, M. D.

Hamilton Parish, Bermuda, Sept., 1873.

EXTRACTION OF RENAL CALCULUS MORE THAN A CENTURY AGO.

To the Editor of The Medical Record.

Dear Sir:—In a rather scarce book called "Mems., Maxims, and Memoirs, by William Wadd, Esq., F.L.S., Surgeon Extraordinary to the King. London, 1827," I find on page 21, the following note or memorandum:

"Mr. Paul, a surgeon at Stroud, in Gloucestershire, lately extracted from the kidneys of a woman, by an incision through her back, a rough stone as large as a pigeon's egg, and made an entire cure; it is the first of the kind ever performed in this kingdom.—*Gent's Magazine*, Aug., 1733."

This struck me as so extraordinary, and, in view of some recent cases and articles in our medical journals, so interesting, that I thought perhaps you might think it worth a place in your journal. Should you desire it, I might send you some other curious reminiscences from this same book. Your truly,

J. H. Pooley, M.D.

Yonkers, September, 1873.

CHOLERA IN NASHVILLE.

A LETTER FROM DR. JOHN C. PETERS.

To the Editor of The Medical Record.

Sir.—The points made in the Record of September 15th, p. 464, are—1st. "The disease was not contagious." I have never maintained the personal contagion of cholera, but merely that it was communicable in various ways. On p. 87 of the August No. of the *Nashville Journal of Medicine and Surgery*, Dr. Bowling says: "Hackberry Spring is near Wilson's Spring Branch, between Market and Front streets. Near this spring lived Mary Payne, colored. She was *the first to die* of cholera in this epidemic. Being in good health, she *washed* all day on Wednesday, May 28th, 1873. [Hence she was probably a washerwoman.] On Thursday morning, the 29th, at 3 o'clock, she was seized with diarrhœa and vomiting, collapsed and died at 11 A.M.; sick eight hours. In the immediate neighborhood, and on the day Mary Payne died, Mrs. Patterson, colored, *who had been with Mary Payne*, was attacked with diarrhœa, which continued through the 30th and 31st, and on the 1st day of June she had vomiting and cramps, and, going into collapse, died. On this day, Jim McKisic, *who had seen Mrs. Patterson* in her sickness, and lived near her, was seized with similar symptoms, and on the next day, June 2d, died. On this day a colored man, *at the same house*, was taken at 5 A.M., and died at 9 P.M." On page 100 we read: "Hackberry Spring, where the disease began. . . . . Mrs. Murray and family, white, lived near this spring and drank its

water. After the death of Mary Payne, Mrs. Murray moved up on Market street. . . . . She and two sons, nearly grown, a few days after occupied the same grave." . . . All these seven cases seem to have been correlated.

3d. The RECORD says, "that there is not the slightest evidence that cholera was introduced through any initial case." On page 74 Dr. Bowling admits that the first 100 fatal cases were not recorded even by the undertakers; and Mary Payne certainly seems to have been the initial case of six of them.

3d. I reported that the preferred spots and places were principally confined to the *outer limits* and low portions of the city, etc. I need only state that New Bethel, Rolling Mill Hill, etc., are in the outer limits, and that Dr. Poynor, in the very next number of the *Nashville Journal*, directly contradicts Dr. Bowling's statements about Wilson's Spring Branch, Lick Branch, and others. The high places that Dr. Bowling singles out were not clean places. The negro villages at New Bethel, Rolling Mill, etc., page 135, were dense aggregations of little huts, with eight, ten, and frequently more persons crowded into one miserable little hovel. "Any cleanly or sanitary precautions about these assembled huts was never dreamed of. The excrement of every character of this mass of unfortunate creatures was deposited *in*, between, and around these squalid shanties." My report was as correct in all its main features as it was possible for it to be made from the conflicting accounts which I received.

A large number of Nashville physicians believed it to be true Asiatic cholera, and of course that it was imported in some way. Others thought it was of malarious origin, and that there had not been a case of true cholera in Nashville during the whole epidemic. Others declared it to be pernicious fever. Some assumed that small-pox, scarlet fever, measles, whooping-cough, etc., were constantly generated anew, and so was cholera, and that the one was no more contagious than the other. Others, like Dr. Bowling, inferred that trivial errors of diet, such as taking twelve peanuts, a glass of buttermilk, an egg, a little cabbage, some string-beans, etc., were the only true and efficient causes of Asiatic cholera As the first 100 fatal cases had not been recorded, even by the sextons, there was no chance for scientific inquiry. As some of the best physicians expressed their determination to give a full account of the epidemic, the matter was left to them, as an enormous amount of time would be required to unravel the tangled details.

Yours truly,

JOHN C. PETERS, M.D.

New Instruments.

A PRACTICAL SPHYGMOGRAPH.

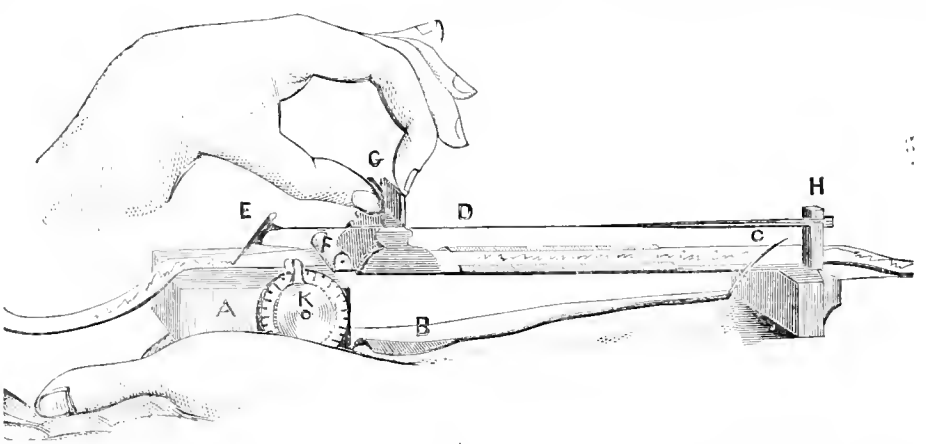
By E. HOLDEN, M.D.,

NEWARK, N. J.

SIR:—Presuming that to those medical men who have looked with sanguine expectation to the sphygmograph as a means of scientific research, and to all lovers of progress in medical science, the advent of an instrument practical as to expense, durability, and facility of application will be a satisfaction, I send you drawing and description of one which for two years has been used with gratifying success. A crude and imperfect idea of this was once presented in this journal, and since then much time and expense have developed the perfected instrument. That it has been used so long, and after several thousand tracings has required no repair, will perhaps be sufficient evidence of durability; but the profession may be interested in the conclusions grown out of so many observations, and although conscious that a greater multitude of experiments alone can determine the position of sphygmography as a distinct science, yet the following have appeared to me to be facts regarding it:

First. That it is to be relied upon in many questions of diagnosis of obscure and simulated diseases.

Second. It furnishes a means of ascertaining the condition of the arterial and venous circulation, the



ability of the heart to equalize these, and the extent of impairment in disease of the heart itself.

Third. It exhibits with accuracy the initiative action of remedies prior to any external and sensible manifestation of the same. Thus, in experimenting with quinine, a half-grain taken dry upon the tongue was found to show an effect upon the circulation as promptly, but in a different manner, as larger and repeated doses. The action of gelseminum and aconite was readily comparable by the tracings taken at intervals of three minutes. *The opening, therefore, of a new field in experimental and therapeutical medicine is at once shown.*

Fourth. The condition of the nervous system, in its relation to the economy as a vital power, is readily exhibited, and with a dictionary of tracings, such as would result from extended experiments, the instrument may prove invaluable both in prognosis in serious disorders of the brain and spinal cord, and in the diagnosis of the numerous occult affections of these structures.

Fifth. Such an instrument may prove of great value

in life insurance in ascertaining the eligibility of applicants.

Several facts of a general character have also developed during my investigations, and no one using the sphygmograph can expect to be otherwise than disappointed without fully appreciating them. Thus:

First. No tracing, however smooth and ample, is of necessity the correct record of the patient. Two tracings in the same minute, *if under different pressures, may differ widely.* Hence it is essential to take several at gradually increasing pressure, *that being accepted which is of greatest amplitude.* Others may then be continued at that degree. (The above instrument is so constructed as to allow of a pressure equal to two or more pounds, and adjustable with the greatest ease without removing.)

Second. The pressure exerted is so vital an element that tracings of patients at different degrees are rarely comparable.

Third. Tracings of radial arteries in one patient are not comparable with those of the ulnar, femoral, or carotid in others.

That the profession may have the amplest means of determining the significance of sphygmographic writings, and in the belief that with an instrument easily applied and accurately adjustable in its means of recording the compressibility of the artery (a point in which all previous inventions have been defective), —that with such an instrument a great and new field of medical science is opened, Messrs. Otto & Reynders, of New York, have undertaken to supply it at a price hardly sufficient to compensate them for their labor; the great difficulty in the way having thus far been the cost of watchwork on this side of the Atlantic, and the limited number likely to be required.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from September 19, 1873, *to October* 4, 1873.

Bailey, E. J., Surgeon.—Relieved from duty in Dept. of Arizona, to proceed to Wilmington, Del., and report by letter, on arrival, to the Surgeon-General. S. O. 187, A. G. O., September 19, 1873.

McParlin, T. A., Surgeon.—When relieved by Surgeon Irwin to report in person to the Commanding General Dept. of the Missouri, for assignment to duty. S. O. 187, C. S., A. G. O.

Magruder, D. L., Surgeon.—When relieved by Surgeon Alexander, to report in person to the Commanding Officer Dept. of Arizona, for duty as Medical Director. S. O. 187, C. S., A. G. O.

Irwin, B. J. D., Surgeon.—Relieved from duty in Dept. of the Missouri, and to report in person, for duty, to the Superintendent of the Military Academy, West Point, N. Y. S. O. 187, C. S., A. G. O.

Alexander, C. T., Surgeon.—Assigned to duty as Attending Surgeon at St. Louis, Mo. S. O. 187, C. S., A. G. O.

Weeds, Jas. F., Surgeon.—Granted leave of absence for thirty days on Surgeon's Certificate of Disability. S. O. 204, Dept. of Dakota, September 12, 1873.

Wolverton, W. D., Asst.-Surgeon.—Granted leave of absence for thirty days. S. O. 186, C. S., A. G. O.

Brown, H. E., Asst.-Surgeon.—Assigned to duty at Key West, Fla., as soon as his services at Fort Jefferson can be dispensed with. S. O. 148, Dept. of the Gulf, September 12, 1873.

Wiggin, A. W., Asst.-Surgeon.—Assigned to duty at Fort Walla Walla, and granted leave of absence for thirty days, with permission to leave limits of department, and apply for an extension of thirty days at Division Headquarters. S. O. 129, Dept. of the Columbia, September 18, 1873.

Medical Items and News.

Dr. John Byrne, of Brooklyn, has resigned his Professorship in the Long Island College Hospital, Brooklyn, N.Y.

The Newest Entozoon.—The latest contribution to our knowledge of entozoa is by no means the least curious. That a nematoid worm shall live in the blood of a man—shall multiply there, or, at any rate, somewhere in the system—shall be in such numbers that there must be many thousands at once in the body, is wonderful; but passing wonder is the fact that these thousands of active, living, feeding worms seem to do little injury. Their discoverer, Dr. Timothy Lewis, of the Army Medical Service, has given evidence which proves that some of the persons infested with them must have had these worms for years, and yet not only live, but pursue their avocations, and are in the possession of fairly good health. How is it these thousands of worms do not cause blockage and obstruction? Why do they not take the nutrition the body ought to have? What becomes of them when they die and decay, for they must do so? Where do they decay? and in what way is the structure of the blood-vessels and other parts through which they pass influenced by their passage? What a number of singular points arise, for which further investigation must find an answer! The discovery shows us, at any rate, that the entozoic diseases are not yet exhausted, and that many things must still lie over for those who have eyes to see and energy to use their eyes.—*Parkes.* —*Brit. Med. Journ.*, Aug 9, 1873.

April-fooled.—Under this title Dr. L. B. Brown, of Sheldon, Ill., narrates his experience in the *Chicago Med. Jour.* of September, of a case of labor to which he was called on the 1st of April last. Eight hours before his arrival the woman had been safely delivered of a child by an intelligent midwife. Examination showed nothing but an enormously distended abdomen, which was free from pain or sensitiveness, and the umbilical cord lying in the vagina. A very slight tension ruptured the cord, and ergot was given to cause expulsion of the placenta. No placenta followed, but the patient became sick and faint, and stimulants had to be given. Introducing a hand into the os, Dr. Brown found the back of another child presenting. By means of the hooked finger in the child's groin, and compression from without by means of a towel, the second child was readily delivered.

The size of the abdomen remaining about the same, the doctor again introduced his hand and found a sac of waters, which, being ruptured, liberated about two quarts, of fluid, and led to the presentation of the head of a third child, which was likewise delivered by the aid of the hand and the towel binder, the woman having thus far had no uterine pains. The doctor goes on to say: "I now proceeded to prospect for the placenta by introducing my hand (which was a very easy matter), and, to my utter astonishment and consternation, the head of another child, if possible, presented." In short, four children in all were born, all being female, perfectly formed, two weighing four, and two five pounds each. On July 17th all the children were

living and well, and weighed respectively eleven, ten, ten, and nine pounds.

The delivery of the placenta gave no trouble, uterine contractions being more marked than during the birth of the children.

Connecticut General Hospital for the Insane.—The Seventh Annual Report of this Institution, for 1873, gives the following exhibit: Three hundred and thirty-six patients were treated during the year; 262 were in the hospital at the beginning of the year; 74 were admitted in 1872; discharged, recovered, 11; improved, 13; stationary, 20; died, 21; remaining, March 31, 1873, 271. The occupations of the majority of the patients were as follows: Farmers, laborers, housewives, and factory employés. The medical officers are as follows: *Superintendent and Physician*, Abraham Marvin Shew, M.D.; *Assistant Physician*, Winthrop B. Hallock, M.D.; *Pathologist*, E. C. Seguin, M.D.

Madison Hospital for the Insane.—Dr. Mark Ranney, late Superintendent of the Hospital for the Insane at Mount Pleasant, Iowa, has been appointed Superintendent of the Hospital for the Insane at Madison, Wisconsin, in place of Dr. A. S. McDill, resigned.

State Lunatic Asylum, Utica, N. Y.—Dr. Theodore Deecke, of New York, has been appointed Special Pathologist in this asylum, in place of Dr. Edward R. Hun, resigned.

Bowdoin College.—Charles A. White, State Geologist of Iowa, has been elected the Josiah Little Professor of Natural History, to fill the vacancy caused by the resignation of Professor Goodall.

Hartford Insane Retreat.—The Forty-ninth Annual Report of this institution, for 1873, comprising the Forty-seventh and Forty-eighth Annual Exhibit, is neatly gotten up in cloth, covering 70 pages of interesting and valuable statistical information. Since the publication of the Report of 1868, radical reconstruction has taken place in the buildings. The first patient was received into the Retreat, April 1, 1824. There were at that time four other lunatic hospitals in the United States, all containing less than 200 patients. The number of patients in the Retreat, March 31, 1870, 134; admitted during the three years, 372. Of this number there have been discharged recovered, 147; much improved, 47; improved, 66; not improved, 43; died, 55. Total discharged, 358. Remaining at the Retreat, April 1, 1873, 148. Whole number admitted up to April 1, 1873, 5,522. Whole number discharged during the same period, 5,374. Whole number remaining, 148. Average number for the three years, 147.

An account of the proceedings of the Semi-Centennial Anniversary of the founding of the Retreat, held January 7, 1873, is contained in the Report.

Medical officers: James H. Denny, M.D., *Physician and Superintendent;* James H. Whittemore, M.D., *Assistant Physician;* Walter J. Norfolk, M.D., *Junior Assistant Physician.*

The Tariff of Drugs in Germany is compulsory, and every apotheker must strictly adhere to it. Each article has its fixed price for the current year, and this price once affirmed in the tariff must be retained to the end of that year, never mind how high or low the market prices may rise or fall. This sometimes happens awkwardly. The price of herbs, for instance, is just now double that of last year, because those who used to gather them can obtain better remuneration for their labor in other ways. During the last six months iodide of potassium was, as is well known, subject to considerable variations in price. The purchase price per pound, in November, was 60 schillings. Later it could be had at the rate of 20, and now for 30 schillings. Yet since the first of November the price for 10 grammes has been 1½ schilling, and that price will be maintained until the 1st of January, 1874, no matter what its market value may be. It so happened at the commencement of the current year that speculators laid hold of iodide of potassium, and at the same time a new method in the manufacture of aniline was introduced, which required larger quantities of iodine, and thus enhanced its price considerably. However, this new process does not seem to have proved successful, and prices have consequently receded.

The Prussian tariff not only defines the price of every article that is to be had in the apotheken, but it also states the rate to be charged for any vessel used in the dispensary, while each flask or bottle, and even each box, has a price according to size. Not less minutely are the prices regulated at which certain manipulations are to be charged, and with a painful and paltry closeness provision is made in cases where two operations, which might be sometimes charged separately, can be performed at one time for the same mixture, and are to be charged only as one. Thus under the heading Solution, we read:—

For the dissolving of one or more extracts (with the exception of fluid extracts) of sugar or gum arabic in any liquid, filtration not being necessary; for triturating electuaries and pulps, as also for triturating powders with any liquid, if the powder does not or only partially dissolves in such liquid, 1 groschen.

Note 1. If in any mixture an extract is to be dissolved, and there is also a trituration, no charge is to be made for the latter operation.

Note 2. If in one mixture a solution of salts in aqua communis is to be made, and also a solution of any extract, both operations may be charged; but no charge is to be made as for aqua communis filtrata.

For dissolving of one or more salts of sugar or manna in water or other liquid, including straining or filtering of the solution, 1½ groschen.

Note 1. If the salts are enumerated as in a crystallized and pulverized state in the tariff, the solution can only be charged according to the price of the crystallized salt.

Note 2. For a solution of salts that are to be used for making pills, ointments, and so on, no charge is to be made.

Note 3. If salts, sugar, and manna, or only two of those ingredients form one solution, the price of one operation only can be charged.

For the dissolving of phosphorus in sebacic or ethereal oils, in ether or alcohol, 1 groschen. Furthermore, the prices for decoctions, for preparing of plasters, pills, ointments, powders, etc., are determined with the utmost precision, of which a few instances are added.

The preparing of an emulsion is to cost 2 groschen; a plaster from 1½ to 6 groschen, according to size; pounding and forming thirty pills, 2 groschen; an ointment which requires no melting, 1 to 5 groschen; ditto with melting, 2½ to 8 groschen.

Each separate operation of weighing or counting out drops is priced 3 pfennige.

[We may mention that the Prussian currency is as follows:—12 pfennige = 1 silbergroschen, 30 silbergroschen = 1 thaler. A thaler (or reichsthaler, which is its full name) is worth 3s. of our money. Therefore a silbergroschen is worth not quite 1½d. of English money.—Ed. *Chemists & Druggist's Circular.*]

Medical Department of Life Insurance.

THE LAWS OF TRANSMISSION OF RESEMBLANCE FROM PARENTS TO THEIR CHILDREN.

By JOHN STOCKTON-HOUGH, M.D.,
OF PHILADELPHIA.

PART III.

MALES RESEMBLE THEIR MOTHER, AND FEMALES THEIR FATHER.

ARISTOTLE seems to have been the first to make mention of this fact, though such an observation may have been made long before his time, as many of the ancient philosophers were mere recorders of verbal traditions handed down through preceding ages. Most of the ancient authors treat of the subject of resemblance of children to their parents; many of them entered into a detail and degree of differentiation which leaves little scope, even to the imagination, to exceed them. Ludovicus Bonaciolus* considers the subject under eight different heads, four for the female and four for the male. Venette† proposes five different inquiries concerning resemblance. Mercatus, Montanus, Ambrose Paré, Mercurialis,‡ Osiander,§ and numerous others, have entered very fully into the subject, but none of them appear to have settled upon any definite prevailing law controlling such resemblance.

Niceus, whom Bonaciolus‖ calls "the noble poet," seems to have been among the earliest authors who make a distinction of sex in the resemblance of children to their parents. He says: *Mas avo materno similis.*

Aristotle¶ has it: "For the most part girls resemble their mother, and boys their father; though the contrary is often the case, and the females resemble their father, and the males their mother, and the different parts of the body resemble either parents."

Pliny** says: "In some cases the female children resemble the father and the males the mother."

According to Buffon, in general the males resemble their mother and the females their father.

Lucretius†† has the same:

> Thus oft the father's likeness does prevail
> In females, and the mother's in the male.

"We know, moreover," says Velpeau,‡‡ "since Aristotle, that the boys, as a general rule, resemble their mother, while the girls rather incline to the features of the father, etc., but there is such variation in this respect, that it is impossible to come to anything definite in regard to the mechanism of generation."

Many other authors might be cited fully confirming the same view, but they are principally statements handed down from one author to another.

Pre-eminent among those who have maintained this law, is M. Ch. Girou de Buzareignues,§§ who has done more to prove the truth of his position than any other person. His entire life was spent in experimenting on the generation of animals and plants, and his deductions are drawn from the observations and experiments of his friends as well as his own. He was probably the first to contend that this differentiation in resemblance was a law, and his deductions and observations from repeated experiments conducted during a series of years fully confirm his position. None of these authors have given a very definite explanation of the reason or cause of this law; most of them attribute it to atavism, others leave it unexplained. Further on, the author will enter into the cause of this phenomenon.

Mr. Sedgwick* calls attention to the frequency with which consumption has been observed to be restricted in its appearance to one sex. He cites a case occurring in his own practice, in which "it is to be noticed that the disease was transmitted by atavic descent from the paternal grandmother to three granddaughters, and that although there were five grandsons in the family, none of them inherited the disease." He relates another case in which the disease was limited, with one exception, to the males for three generations, being transmitted by atavic descent.

Dr. Greenhow† relates the case of an old couple who both survived their eightieth year, who lost all their sons by phthisis, while all their daughters escaped. In a second case, in which both parents survived to an advanced age, the five daughters all died of phthisis, while the sons were exempt. In a third case, six out seven daughters died of phthisis under thirty years of age, the seventh went to India, where she also died at about the same age; but the only two sons are alive and well. "In none of these cases was either parent phthisical; but it is worthy of note that all three mothers were asthmatical, the fathers being in each case healthy."

The writer knows of a case in which a daughter inherited phthisis from her father, her two brothers being free from it. In another case a son inherited phthisis from his mother, while a daughter and five other sons were free from it.

One drunkard begets another (ebrii gignunt ebrios), says Plutarch, also Aristotle, Gellius, Macrobius, and numerous others. Atavic descent is very frequently noticeable in this connection, for we often see the daughters of drunkards have drunken sons, though they may be perfectly temperate themselves. The moral of this in a matrimonial point of view is evident.

The writer's father has a mare that had in her tenth pregnancy a horse-colt resembling the mother in color, though taller; and in her eleventh pregnancy, a mare-colt (by same father), resembling the stallion in color and size.

Sedgwick, in his elaborate articles,‡ mentions the case of a man who had ichthyosis from the time he was eight years of age. "This man had three sons and three daughters. One son died at the age of five years, and another at the age of seven, both of whom were free from the disease. The other son is living and past middle age, but has shown no tendency to the disease. The three daughters have all lived to grow up and marry, and in them likewise the skin is unaffected. Two only of the three daughters have had children. The eldest daughter has had four, of whom the first-born, a girl, has had no appearance of the disease; the three other children are boys, of whom the eldest, aged fourteen years, and the youngest, aged nine years, suffer from the disease, whilst the other son, aged eleven years, is free from it. The family of the other

daughter consists of three children, the eldest of whom, aged six years, is, as in the former case, a girl, and free from the disease, whilst the two other children, who are boys, aged respectively three years and one year, have the skin very decidedly affected. It is to be noted that the disease in these grandchildren has in each case appeared within a few months after birth. There are two other important facts to which I would call attention before passing on; one is the non-development of the disease in the second generation, and its reappearance in the third, which is an instance of *atavism* for which no satisfactory reason can [?] be assigned; the other is the sexual limitation of the disease, which in this case is complete in a double sense; for whilst the females in the family have alone transmitted the disease, its appearance has been restricted to the males." Dr. Elliotson * reports a case of the same disease, coming under his observation, by which two brothers were affected, and one brother and sister were free from it.

In the well-known Lambert or porcupine family,† this same disease was transmitted to four successive generations, and always limited to the male sex. Two brothers, descended from the original porcupine man, had seven sisters, who were all free from the disease.

Mr. Sedgwick calls attention to the fact of the limitation of the disease in the above cases to the males alone, and says, "it is not to be supposed that there is any peculiar inaptitude in the fair sex to this unsightly affection of the skin, for at one of the meetings of the Med.-Chir. Soc. in 1818, the case of Mrs. Holden ‡ was brought forward, in which the disease was limited to the female sex, in the person of her daughter, aged three years, in whom the disease had appeared when about three months old, the same age as that at which it had occurred in her mother; and this case is the more remarkable from the fact that whilst the child inherited the disease of her mother, she inherited the features of her father."

The same gentleman cites from various authorities several cases of individuals having the rose-colored eyes of albinoes, as having "been observed to be often hereditarily connected with one sex." M. de Saussure § mentions two well-known albinoes who were brothers, whose sisters did not possess this abnormality. Dr. Trail ‖ reports the case of three albino brothers, who had two sisters (the first and fifth children) who were not albinoes, and two twin brothers, one of whom was an albino. Thomas Jefferson ¶ mentions the case of two albino sisters, who gave birth, the one to an infant who was an albino like herself, the other to a very black infant like the father. Sedgwick cites the following two cases from Cornaz.** The two grandsons of a family residing at the village of Ferlens, near Oppens (Switzerland), married, and had each of them two daughters, one affected with albinism, and one exempt. These two albinoes, who are the great-granddaughters of the family referred to, and from whom the inheritance is derived, married: the one had no children; the other became the wife of an agriculturist with black hair and brown eyes, is mother of an infant who is an imperfect albino.

The other case is that of a Swiss girl whose parentage unites her with seven other albinoes. Her great-grandfather had two children, a son and a daughter. This girl, first mentioned, is the only one of the descendants of the son affected with albinism. Among the descendants of the second child (daughter), there have been seven albinoes. This daughter, last named, had two sons who married two sisters. The eldest had, among other children, three albinoes—namely, one son and two daughters. The other brother had seven sons, none of whom were albinoes. Five of these seven sons married, but only one of these five had albino children, and he had four albino daughters out of a family of three sons and nine daughters. Mr. Sedgwick suggests in explanation of the fact of the appearance of albinism in the fourth generation in the one case, and in the fifth generation in the other, that, in the latter, albinism did not appear till the fifth generation, owing, it would seem, to the fact that Charles Rey had seven sons, but no daughters; the defect being transmitted to daughters only. In these cases we see fathers transmitting their abnormalities to their daughters in six instances out of seven.

"Mr. Wardrop has recorded a case in which five brothers, afflicted with the hemorrhagic diathesis, had three sisters free from it; but each of the sisters had, besides other children, two sons similarly affected, whilst no female in the family shared in the disease." (Sedgwick.)

Mr. Sedgwick mentions a case of hereditary pityriasis versicolor which was limited to the males for several generations, "whilst the females of the family, although not suffering from it themselves, have transmitted it to their male children." *

Dr. Henry Stewart records the two following cases of sebaceous tumors of the scalp, which were hereditarily limited to the female sex, in one case for ten, and in the second case for five generations. He observes that "some of the females derived the inheritance from their paternal grandmother by atavic descent, which affords additional proof of the influence of sex, for except when a male thus intervened to arrest the appearance of the disease, the inheritance was direct from parent to child." †

Alibert ‡ states that plica polonica, a disease of the hair in Poland, "is observed not unfrequently to attack the father and the grandson, whilst the son is spared, a character which is common to it with other maladies, particularly with gout."

"Giron relates the case of a man, descended from a family in which the special use of the left hand was hereditary; although not himself left-handed, he has a daughter who is so, and all of whose children are left-handed; he has, moreover, a son married, who is not left-handed, but who is the father of a daughter so completely left-handed from her cradle, that it has been necessary to tie up the left hand, so as to force her to serve herself with the right hand." §

Sedgwick saw a case of supernumerary finger on the left hand of a girl whose two brothers were not so deformed, but whose father, paternal grandmother, and paternal aunt, all had precisely the same defect.

Giron ‖ relates a case in which a *rarer* form of atavism is exhibited, of a defect transmitted through a *male to a female*. "A woman who was club-footed, had three male children all well formed; the eldest of these married, and had, at first, six sons well formed, and afterwards four daughters, one of whom was club-footed like her paternal grandmother." ¶

Maisonneuve * relates a case of epilepsy in a man inherited from his mother's father. Insanity and other peculiarities in the case of George III. were transmitted to the males through the females by atavic descent for eight generations. †

Esquirol ‡ states that insanity is more often transmitted by the mothers than by the fathers." M. Baillarger § is of the same opinion, and declares that "it is more to be feared when it is on the mother's than on the father's side, not only because it is more often hereditary, but also because it is transmitted to a greater number of children." He gives the following statistics with regard to sex:

"Of 346 children who had inherited the disease from the mother, I have found—197 girls and 149 boys. The difference is 48 or a fourth.

"Of 215 children to whom the disease had been transmitted by the father, I have found—128 boys and 87 girls. The difference is 41 or a third.

"The madness of the mother is transmitted, then, more often to the daughters than to the sons, in the proportion of a fourth: the madness of the father, on the contrary, more often to the sons than to the daughters, in the proportion of a third."

"The transmission of the mother's insanity is scarcely more to be feared, as regards the boys, than that of the father; the mother's insanity, on the contrary, is twice as dangerous to the daughters."

Dr. James Webster ‖ says of the hereditary predisposition to mental disease, as it appeared in the 1,798 insane persons comprised in his observations—31.19 per cent. of the males were hereditarily predisposed, whereas of the 1,094 females, 37.47 per cent. were of that description. "This feature becomes more interesting," he observes, "when it is remembered that insanity is a disease more frequently transmitted to offspring by the mother than by the father; whilst mothers also transmit this disease oftener to their female than to their male children."

Sexual preference is not without its influence here, as I have shown in my previous article ¶ that insanity is much more frequently met with in females than in males.

Dr. Morean ** has carried the investigation of this matter still further, and in a direction calculated to assist our inquiries. He was of the opinion "that personal resemblance and cerebral disorder may be transmitted by either parent, but never by the same; that where children resemble the parent of the opposite sex, the following results were obtained: of 22 females suffering from insanity, 17 had inherited it from the mother and five from the father; while of 142 insane males, 95 had inherited it from the father and 47 from the mother; when, on the contrary, the analogy of resemblance was inverted, 47 sons who resembled their father derived their insanity from their mother, and 8 girls, who resembled their mother, derived theirs from the father." Sedgwick, from whom we quote the above, ascribes the peculiarity to atavic descent. He observes that "in the most strongly-marked forms of hereditary disease, uninterrupted descent for several successive generations is the exception rather than the rule."

"In phthisis, for example, the late Dr. Theophilus Thompson,* in a paper read before the Medical Society of London, remarked, 'it is worthy of observation, that the influence (of phthisis) tends peculiarly to extend in the direction of the sex in which it first appeared.' And in 'the first annual report of the Hospital for Consumption and Diseases of the Chest,' it is stated, that of 669 male and 341 female patients suffering from phthisis, and which was ascertained to be hereditary in 18.2 per cent. of the former, and in 36.3 per cent. of the latter (showing that females are twice as liable as males are to inherit the disease from their parents), it is found that whilst the father transmits the disease to his sons in 59.4 per cent., and to his daughters in only 43.5 per cent., the mother transmits it to her sons in 40.6 per cent., but to her daughters in 56.5 per cent." †

Cancer seems to be hereditary in many instances, and, as I have already shown ‡ it to be nearly two and a half times as fatal among females as among males, it is probably due to arrested or defective development, as women have relatively a larger proportion of glandular structure, and are withal less highly developed in their organization than males. The developmental theory of cancer, once established, will corroborate the view here taken of the relative evolutionary developmental condition of the sexes.

In a case of hereditary deformity, consisting of crooked fingers and enlarged joints transmitted five generations, "it was observed by the family that those children who inherited the deformity from the father had it in the more marked degree; those who inherited it from the mother had it in a less marked degree." And what is most curious, two first cousins of the fourth and fifth generations married, one having the deformity in a marked degree, and the other in a less marked degree, yet their two children had perfect hands. §

From this it would appear that "family proclivities to disease are more strikingly manifested in brothers and sisters than between parents and children. The intermingling of opposite tendencies begets, so to speak, in the children a neutralization of the peculiar aptitudes to disease existing in the parents respectively."

"Physiological likeness of the parents induces imperfect progeny, *pro tanto*, just as certainly as intermarriage within forbidden degrees of consanguinity."

In certain animals the young resemble most the parent of the same sex; the young male resembles more the father, and the young female the mother. This phenomenon takes place in the majority of birds, and, following Hausmann, in the equine species. Girou pretends that it is above all true in our domestic animals, in that which concerns the height, the length of hair, the amplitude of the pelvis, in a word, the circumstances of the plastic life, and that this analogy becomes more pronounced by the progress of age than it was in the commencement. The black bulls often produce with red cows heifer-calves which are red at the epoch of their birth, but become black with time; in the inverse circumstance, the young males are from the first black, and red in the adult state. ¶

crook in them, while exactly the same defect is noticeable in the little fingers of her father's mother. The parents of the child, however, are free from any such deformity.

¶ De la Generation, p. 124.

"It appears to be more common, however, that the parents act upon the sex of the product of generation which is opposed to their own.* One of the Colburns † brought into the world three boys and two girls, and propagated her infirmity (supernumerary fingers and toes) to all the boys, but to only one of the girls; the second son of Gratio Kallja ‡ had one son only who was not deformed, but his three daughters all had supernumerary fingers and toes like himself; the daughter only propagated the anomaly to one of her sons, and not at all to her daughters. A man who had the palate malformed, engendered four sons well formed, and three daughters affected with hare-lip and fissure of the soft palate; in like manner the sister of his mother had five daughters well formed, and five sons with hare-lips. § A woman related to a family in which there were several hypospadiacs, brought into the world two sons affected with that deformity. Another woman of weak mind, and of a family several members of which were hard of hearing and idiotic, gave birth to two boys, deaf-mutes, of which one was besides an imbecile; to two daughters well constituted; and finally to a boy who equally enjoyed good health." ‖

A negro in Berlin produced with a white woman seven mulatto daughters and four white sons.¶ Analogous observations have been made on bastard animals. Among the colts of the mare which had previously been fecundated by a Quagga, the females resembled more than the males their mother for the color of their hair. Bastard pups of a dog and female wolf exhibit the same difference of resemblance as regards sex, as the two males resembled the wolf (female) in form, movements, the aversion for men, the defiance of and aversion for dogs; while the female had the head of a dog, did not trot as a wolf, was pleased with dogs, and exhibited less aversion for men.**

Girou assures us that the same phenomena take place in ordinary generation in relation to conformation of the head and other members, to the color and the constitution, as a consequence, in general, to the sensibility and irritability; he makes the remark that mules (females) have a longer mane, the pelvis larger, that they are more headstrong and vicious, that they have more resemblance, as a consequence, to their father than the male mule, and that the latter have much more frequently the same colored hair as their mother.†† He adds that the male dog resembles more his mother, and the female her father; that a smooth mare gave birth to three females provided with hair, and one male smooth like herself; that a cow having white hair with patches of red produced four males that resembled her in color and distribution of spots, and a female similar to the bull; and finally, that the same thing happened in the ewe and in cats. ‡‡

1st Generation.

Gt. Grandfather	Gt. Grandmother	Gt. Grandfather	Gt. Grandmother
2d Generation.			
Grandmother	Grandfather	Grandmother	Grandfather
3d Generation.			
Father	Mother	Father	Mother
4th Generation.			
Daughter	Son	Daughter	Son.

The same writer says,§§ that when in that relation at birth the young resemble their ancestors of the same sex; that, as a consequence, a young male will resemble his mother and his maternal grandfather, as indicated in the foregoing table.

This table is founded on the same law as that of males resembling their mothers, and females their fathers, but extended one generation further. It reads, therefore: 1. the daughter resembles the father; 2, she resembles her father's mother; 3. she resembles her father's mother's father, etc.; or, more properly, her ancestral resemblance has descended in this line more than from a corresponding line in her mother's ancestry.

Osiander had already remarked something analogous.* So therefore, in general, it is that which differs, notwithstanding the affinity, which exercises a stronger influence, and we find in this traces of the law, difference in identity: the daughter resembles her father, because it is to him that she approaches the most in her origin, but she is remote from him by her sexuality; the son resembles his grandfather (maternal) because he approaches to him by his sexuality, and is more remote from him in his origin. If the manner in which we have before explained the discovery made by Chamisso is exact, this relationship is removed beyond possibility in the *Biphores*, in which the mode of generation varies following the generations, and in which the young are never procreated as their parents, but as their grandparents. †

M. Girou de Buzareignues ‡ cites the case of a girl who inherited from her father the habit of sleeping on her back, with her right leg crossed over her left.

Darwin § mentions the case of a *boy* who had the habit of rapidly moving his fingers parallel to each other and raising both hands to a level with the eyes, when excited by any pleasurable emotion. This habit continued with him even when an old man. "He had eight children. Of these, a *girl*, when pleased, (at the age of four and a half years), moved her fingers in exactly the same way," and when much excited raised her hands, all in exact imitation of the habit in her father.

Prof. Bock ‖ reports the case of a father transmitting a congenital absence of the iris to three sons, in a family of eight children; one of the sons transmitted the defect to his two daughters.

Mr. Streatfield ¶ has published the case of a family of ten children, in which the five boys squint, while the five girls do not. Neither the father nor the mother squint, but the mother has a *sister*, whose two children also squint, showing the inheritance from the mother's side. In these cases where but one eye was affected, it was always the left.

Concerning color-blindness, Mr. Sedgwick mentions the case of a boy, aged eleven years, who suffered from this defect, while his four sisters were free from it. The peculiarity of sight was derived from the maternal grandfather, who had a brother similarly affected, while another brother and three sisters were free from it. The second generation consisted of only two daughters, the mother and the aunt of the boy referred to, both of whom were free from this defect of vision. "The essential facts in this case closely correspond with those related in the case of ichthyosis, the hereditary disease being in each case limited to the males of the first and third generations, and transmit-

ted by the females of the second generation, who were themselves unaffected by it." *

Dr. Pliny Earle † states that he inherited this defect of vision from his maternal grandfather, two of whose brothers were similarly affected. The defect prevailed in eight of the families related to this gentleman, being limited to the male sex in all except one family. The total number of persons in the eight families affected was 61 (32 males and 29 females); of the former nine-sixteenths were affected, and of the latter only one-fifteenth. An analysis of upwards of two hundred cases of color-blindness shows that the proportion of males affected is nine-tenths of the whole. ‡

Mr. Miln ‖ inherited his color-blindness from his maternal grandfather, who had two brothers and a second cousin similarly affected. §

Dr. Bronner ‖ records the case of a German having this defect, who had two daughters not so affected. The eldest daughter had three sons, of whom only the second was color-blind; the youngest daughter had three sons, all of whom were color-blind.

M. Cornaz ¶ cites the case of a woman who had two sons, among other children of both sexes, by two different husbands, both of whom were color-blind.

Dr. Osborne ** reports the case of a family of fifteen brothers and five sisters who had eyes resembling in miniature the markings of the back of a tortoise-shell cat. The inheritance was derived from the mother, who, with three sisters and a brother, inherited it from their mother. This peculiarity was transmitted to three successive generations by the females exclusively, though their children, both male and female, inherited the defect.

Mr. Streatfield,†† in his account of the congenital defect known as cleft iris (coloboma iridis), cites the case of three brothers having this deformity, whose mother's father is said to have had the same defect, and, indeed, it had exhibited itself in four successive generations, being limited to the males, though transmitted by the females. Sedgwick, in reviewing the case, says, the chief points of interest are—1st. The transmission of the defect without its being shared in by the mother. 2dly. That whilst two of her three sons had the defect, her three daughters were free from it; and lastly. That the maternal grandfather, the maternal granduncle, the maternal uncle, and the son of the last named, all shared the defect, which shows that the inheritance in this case extended to at least four generations.

Inherited peculiarities show themselves earlier in life in a daughter than in a son, and earlier in the daughter than in her father. The hairy family described by Mr. Crawford,‡‡ produced children during three generations with hairy ears. The hair began to grow on the father at six years of age, and on his daughter at one year.

The famous men of history owe their excellence to their mothers, and the women who have attained celebrity reflect the genius of their fathers. St. Paul wrote to Timothy, saying: "When I call to remembrance the unfeigned faith that is in thee, which dwelt first in thy grandmother Lois, and in thy mother Eunice; and I am persuaded that in thee also." (II. Timothy, c. i., 5.) Sarah Castor, the mother of John Milton [Magnum et Venerabile Nomen], was a woman of incomparable virtue and goodness. Letitia Romilini, mother of Napoleon the Great, was noted for the qualities which she imparted to her son. Lord Byron's mother was noted for her spleen, as she was termed the "unhappy tempered mother." The mother of Gengis Khan, the famous Asiatic conqueror, was noted for her warlike courage and daring. Tamerlane, the greatest warrior of the fourteenth century, was descended from Gengis Khan in the female line. "Arete, the most celebrated woman of her time, on account of the extent of her knowledge, was the daughter of the distinguished philosopher Aristippus, disciple of Socrates. The daughter of the Roman Emperor Caligula was as cruel as her father. Marcus Aurelius inherited the virtues of his mother, and Commodus the vices of his. Charlemagne shut his eyes upon the faults of his daughters, because they recalled his own. Cornelia, the mother of the Gracchi, was a daughter of Scipio. Catherine de Medicis was as crafty and deceitful as her father, and more superstitious and cruel. She had two sons worthy of herself, Charles IX., who shot the Protestants, and Henry III., who assassinated the Guises. Her daughter, Margaret of Valois, recalled her father by her gentle manners. Henry VIII., who put two of his wives to death on the scaffold, had two sons [but one legitimate] distinguished for their meekness of character, and two daughters as cruel as himself. Arete, Hypatia, Madame de Staël, and 'George Sand,' all four had philosophers for their fathers. The mother of Tasso had the gift of poetry. Buffon often speaks of the fine imagination of his mother. The poets Burns, 'Rare Ben Jonson,' Goethe, Walter Scott, Byron, and Lamartine, all were born of women remarkable for their vivacity and brilliancy of language." Shakespeare * is not unmindful of this when he makes Cato's daughter say—

> Think you I am no stronger than my sex,
> Being so father'd and so husbanded?

Herodotus,† in speaking of the Lycians, says: "They have a distinction from which they never deviate, which is peculiar to themselves; they take their names from their mothers and not from their fathers. If any one is asked concerning his family, he proceeds immediately to give an account of his descent, numbering the female branches only." Plutarch ‡ tells us that "a law was instituted among the Xanthians (Xanthia being a part of Lycia), that they should derive their names from their mothers and not from their fathers." Another authority § says, that amongst these people the inheritance descends to daughters and not to sons. And to complete the reversion of the usual ordering of things, according to Beloe, ‖ in some parts of the kingdom, youngest sons inherited the parental estate in preference to their elder brothers.

Viewing this peculiarity in a purely physical light, aside from social and political bias and the accepted usage, there is a very philosophical reason, from what we have shown, why sons should take the names of their mothers, and daughters those of their fathers. In Spain, even at the present time, sons retain their mother's name as a sort of suffix to that of their father's, to indicate their descent in the female line. It is possible that the following complex provision may owe its origin to the same cause, viz.:

‡ On the Virtues of Women.
§ Larcher, note in Beloe's Herodotus, p. 219.
‖ Loc. cit., note, p. 219.

"If a man purchase land in fee simple and die without issue; in the first degree the law respects the dignity of sex and not proximity. * * *

"The nearer heir by the grandmother on the part of the father [paternal grandmother] shall have it before the remote heir of the grandfather on the part of the father [paternal grandfather]." *

Darwin† states "that transmission and development, though generally acting conjointly, are distinct powers. . . . . We plainly see this distinction in the many cases in which a grandfather transmits to his grandson, through his daughter, characters which she does not, or cannot possess. Why the development of certain characters, not necessarily in any way connected with the reproductive organs, should be confined to one sex alone—that is, why certain cells in one sex should unite with and cause the development of certain granules, we do not in the least know; but it is the common attribute of most organic beings in which the sexes are separate."

The fact of the frequent resemblance of grandson to grandfather, alluded to by Darwin, and attributed to reversion, we would explain by the resemblance of the daughter to her father, and the son to his mother, for the reasons already given.

The development of secondary sexual characters and others not necessarily in any way connected with the reproductive organs, we would attribute to the difference in the degree of maturation of the ova at the time of fecundation.

"The principle of sexual limitation may be traced in family statistics of mortality from diseases not in themselves hereditary. In a case of measles, affecting the only son of a respectable mechanic, I ascertained that the disease was peculiarly fatal to the females on the father's side, but that the males, when attacked, recovered. The father and his only brother had both recovered from the disease without any unfavorable symptoms, whilst all the five sisters had died from it. The little boy referred to recovered quickly, but his only sister had died the previous year from the disease, which at its commencement was apparently destined, in her case, to prove fatal." ‡

The adherence to the female line in this case cannot be due to greater mortality among females than males, for we find (1845–53) 102 males died of this disease to every 100 females, while in *whooping-cough* § there were only 83 males to every 100 females, which is the only one of the children's diseases in which the proportion of females is in excess. And it is, moreover, one of the most fatal of the diseases peculiar to children, at least a great number die of it. A much larger proportion of females die of whooping-cough than any other disease incident to children.

According to Sedgwick ‖ sexual limitation of hereditary affections and defects is not owing to sexual preference, as the disease or condition is not more easily transmitted to one sex than to the other, but follows a certain law which limits its appearance to that sex in which it first originates.

"On the whole," says Darwin,¶ "as far as I can judge new characters are more apt to appear in the males of our domesticated animals than in the females, and afterwards to be either exclusively or more strongly inherited by the males."

Both the above statements are notably in harmony with the deductions concerning malformations or defects brought out in my last paper,* wherein I showed that a much larger proportion of males than females (161 m. to 100 f.) perish from defective organization or development, and that there are more malformations by defect among males and more malformations by excess among females.

Dr. Smith† says that when the mother and father are equally healthy, and have the same hereditary longevity, the daughters will be longer-lived than the sons; where the mother is as above, and the father is sickly or from short lived stock, the sons will be longer-lived than the daughters.

"It is not true," says Braschet,‡ "that the male children who resemble their mother live longer than those who resemble their father, as Bacon would have it."

Sinclair § contends that it is the mother principally who assures the longevity, and Dr. J. A. Allen is of the opinion that "Longevity of grandparents on the maternal side is to be preferred to that on the paternal side."

I am rather inclined to coincide with the views of Lord Bacon and Dr. Smith, as they are in harmony with the law on the subject; believing, as I do, that males who resemble their father most are effeminate, and females who resemble their mother more than their father are masculine, and being exceptional, and in a certain degree abnormal, entail upon their possessors a weaker constitution than they would have had, had they been properly constituted. Effeminacy and masculinity are too often looked upon as being caused by the easy and affluent circumstances under which a child is reared, but this is only a concomitant, and not the proximate cause,—it is constitutional, arising from too early fecundation of the ovule in the first instance, and too late in the last. Individuals so constituted are consequently worthy of more sympathy than usually falls to their lot.

(To be continued.)

AN ANALYSIS OF THREE HUNDRED AND TWELVE REJECTIONS.

The following is a condensed analysis of all the rejections made by a life-insurance company in this city during a period of twelve months, from Sept. 1st 1872 to Sept. 1st 1873. If in some instances the cause of rejection appears trivial, it should be remembered that in many of these cases there were concomitant circumstances of an unfavorable nature to influence the decision arrived at. All such minor points, however, have been here omitted, in order that a classification might be made of these rejections.

Light Weight.—24 rejected. Average height, 5 ft. 9 in.; average weight, 126 lbs.

Excessive Weight.—Of the entire number 7 were rejected on account of excessive weight. Average height, 5 ft. 7½ in.; average weight, 216 lbs.

Intemperance.—34 rejected.

Heart Trouble.—31 rejected. A little over one-third of these were rejected because of actual organic disease, the remainder on account of persistent func-

§ "Principes d'Hygiene, Extraits du Code de Santé," Genève, 1823.
‖ Op. cit., p. 45.

tional derangement of the heart's action—palpitation, irregularity, or intermission.

Spitting of Blood.—17 rejected.

Occupation.—10 rejected. Nearly all of them were tavern or restaurant keepers, or liquor merchants.

Lung Trouble.—30 rejected on account of incipient phthisis, asthma, or bronchitis.

Unclassified.—73 rejections. One on account of a disordered nervous system; one, subject to diarrhœa; five, frequent attacks of articular rheumatism; one, renal calculus; one, curvature of spine; one, recent dropsy of doubtful origin; six, poor physique; one, still convalescent from diphtheria; one, because of a recent illness, resembling apoplexy; one, habitual cough until recently; one, some obscure brain trouble five years previously; one, very difficult labors; one, tumor of the leg of doubtful nature; one, tumor of the hand; two, knee-joint trouble; one, frequent appearance of ulcers on the legs; five, amputation above the knee-joint; one, dyspepsia and occasional attacks of diarrhœa; one, recent pneumonia and persistent cough since; three, double hernia; one, tumor of the testicle; one, jaundice; one, recently operated upon for cancer; three, bladder trouble; one, an infirm old man, representing himself to be only sixty years of age; one, fistula in ano; three, occasional epileptic attacks; three, syphilis; two, kidney trouble; one, chronic diarrhœa; one, enlarged spleen; one, enlarged cervical glands; one, unhealed wound; one, tumor of the neck; one, persistent headaches from a blow on the head; one, aneurism of the external iliac artery; four, recently married, but never yet safely delivered of a child; two, on account of their youth (15 and 16); one, advanced age (66); two, pregnancy; one, residence in Mississippi; one, color (negro); one, 64 years of age and prematurely old; one, prolapsus uteri; one, never vaccinated.

Family History.—86 were rejected mainly on account of their family history.

In three cases, both parents had died of consumption. The average age of the parents at death was 39, that of the applicants, 40.

Twenty were rejected because a parent and one or more brothers or sisters had died of consumption. Average age of applicants, 34; average age of consumptive parents at death, 48.

Thirty-seven were rejected because one parent only had died of consumption. Average age of applicants, 26. Average age of 27 of the number, 23. Average age of consumptive parents at death, 40.

Seventeen were rejected because two or more of their brothers or sisters had died of consumption, and also, in many instances, because they themselves were not in good physical condition. Average age of applicants, 35. The ages of only 36 of the consumptive brothers and sisters could be ascertained. These averaged, at death, 30 years.

Seven were rejected because a brother or sister had died of consumption, and also because they were at the same time in poor physical condition. Average age of applicants, 25. Average age of consumptive brothers or sisters at death, 35.

Two were rejected because insanity had manifested itself in more than two members of the family.

It would be highly interesting to know to what extent the life-insurance companies have suffered by the terrible epidemic of yellow fever still raging at Memphis and Shreveport. Has the expected mortality been materially increased, or not?

Correspondence.

THE INFLUENCE OF AN EXISTING SKIN DISEASE ON THE RISK OF A LIFE ASSURANCE.

To the Editor of The Medical Record.

Sir:—The extremely interesting and valuable papers publishing in The Medical Record on life assurance have not as yet touched on the subject of skin diseases as affecting a risk. It has occurred to me to offer, with your permission, one or two brief suggestions on this subject.

No doubt very many cutaneous diseases cause little constitutional disturbance, and as long as the individual remains unaffected with any acute inflammatory affection, the existence of an ordinary skin disease will not usually diminish the average chance of longevity. But there are exceptions to this; for instance, furunculi, or "boils," or pruritus of the skin, should make us test the urine for sugar, as these complaints are often the forerunners of diabetes, and are common in that disease. The presence of ulcers, if of long standing or extensive, imply a "drain on the constitution," which, as "age advances and nutrition declines, may prove fatal;" hence these cases ought to be declined. Moreover, according to Dr. Fischer, the long continuance of an ulcer is apt to cause Bright's disease. A common affection of the skin—eczema—when chronic, is often no doubt then a purely local disease, so to speak; but we have the authority of Hebra for stating that females subject to repeated attacks of eczema usually die from cancer. With regard to acne, a frequent complaint in young people, Dr. Tilbury Fox (Manual of Skin Diseases, page 399) states: "It has been my lot to see the subjects of the most severe and obstinate acne I have met with in young people die of phthisis. I cannot but think that lymphatic subjects, and those who are of a phthisical tendency, are most prone to acne." I may apply the same remark to an allied affection—mollusc sebaceum. I have had cases of it at the Belfast Hospital for Skin Diseases. Two I well remember—healthy, intelligent-looking young girls, aged about 18 years, who died of phthisis. Again, I think the presence of pityriasis versicolor, which occurs usually on the chest, should make us be careful, no matter how healthy the individual. There is in these people an acid state of the secretions, especially of the perspiration, and which is common to scrofulous persons. This favors the development of this parasitic disease; and how frequently, at least in this country, do we observe pityriasis versicolor on the chests and backs of consumptive patients? Morphœa and atrophy of the skin show a degradation of tissue, and want of healthy nutrition. Pustular inflammations are a sign of debility, generally assimilative, and always improve with tonics, such as quinine and iron. Moreover, these pustular affections are often connected with a gouty taint. The slightest darkening or *bronzing of the skin* would point to Addison's disease, which is incurable. Trousseau states in his "Clinical Lectures," that old people who are asthmatic, exhibit in their youth eruptions of an eczematous character, and that eczematous eruptions, gout, and rheumatism are complaints which may be replaced by asthma, and replace it in turn. A few other diseases of the skin may be mentioned. Thus erythema, especially of the face, as noted by Dr. Brinton, is important. The form referred to exhibits itself by a peculiar color of the

cheeks in middle-aged people, due to little streaks of distended blood-vessels, which give the part a mottled appearance, and which is often connected with kidney disease. In heart complaints a bluish-red color of the face is often noticed. Idiopathic erysipelas must not be omitted, owing to its liability to return. Xeroderma, or a dry, harsh, somewhat scaly state of the skin, having the appearance of seldom being washed, owing to the absence of perspiration—a disease usually congenital—is incurable, and those affected therewith are subject to congestion of various organs, chiefly the kidneys and lungs. To conclude with merely mentioning a few other diseases, which would render a life unfavorable: Commencing elephantiasis arabum; gutta rosacea, due to assimilative debility, so often brought on by intemperance; herpes zoster, or more correctly the marks of a former attack, as there is in this disease always more or less structural change in the nerves, and often permanent anæsthesia (see a paper by Dr. McCrea, of Belfast, *Brit. Med. Journal*, July). Pityriasis capitis oleosa is always accompanied by more or less anæmia, discoloration of the skin, showing site of former ulcers or wounds. Incurvation of nails point to debility, and is present in phthisis and aneurism. Syphitic eruptions and staining, lupus, leprosy, and scrofuloderma conclude the list.

Apologizing for the length this letter has already extended to, I remain, Yours, &c.

H. S. PURDON, M.D.

5 COLLEGE SQ., EAST, BELFAST, IRELAND.

SAN FRANCISCO, August 29th, 1873.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I have regularly received your Journal since May 15th, which number contained the notice that the . . . . . Life Insurance Co." had directed you to send me the RECORD for one year at their expense. I am very glad to have the RECORD added to my list of Journals, and as I am a great believer in the importance of "life assurance" to society, and am particularly interested in the relations that the medical man occupies to the business of the institution, I am doubly glad to receive the RECORD with its new department of life assurance.

I have therefore great pleasure in tendering my thanks, through you, to the company for so kindly remembering their medical examiner of San Francisco.

At some future time I will, with your permission, have something to say in regard to the grounds taken by some of the writers, in articles that have appeared in the new department. In the mean time allow me to call your attention to an article in *The Insurance Monitor*, of New York, for July 1873. The article is headed "A New Source of Danger to the Health of the American people," and commences as follows: "San Francisco is justly alarmed over a new evil, resulting from Chinese immigration. That loathsome disease of Eastern countries, the leprosy, has appeared in the city, and lepers are constantly to be met with in the streets," etc., etc.

Had this article appeared as a chapter in Mark Twain's *Roughing It*, it would pass for a very good joke on San Francisco; but when the *Monitor* allows itself to be so imposed upon, it certainly becomes some one's duty to enlighten them on the subject.

The facts are these: We are upon the eve of a municipal election, and politicians must discover a bait that voters will take to. No bait is better adapted to catch a certain class of votes than the Chinese question. If a Doctor wishes the Coronership, the more cases of leprosy he discovers and reports, the better his chances are for Coroner with a certain class of voters.

There have been from three to six lepers in this city for the past ten years; one or two cases American, formerly residents of the Sandwich Islands—the others Chinamen. I hardly think that it will be necessary for insurance companies to add an extra percentage to their California risks on account of leprosy, as the disease will rapidly disappear from our streets for a year or two as soon as our election is over.

W. F. MCNUTT, M.D.

Miscellaneous.

RECENT CHANGES IN THE FORM OF THE APPLICATION AND MEDICAL EXAMINER'S REPORT.—Several of the companies have recently adopted new forms of "application and medical examiner's report." Among other new features we notice that the new "John Hancock" application does not contain a single medical question, these being all incorporated into the medical examiner's report, where they properly belong. By this radical change the company will be far more likely to obtain full and precise information in regard to the applicant's past history and present physical condition than by means of the blank forms now generally in use among the companies.

Another important change has been introduced by the "Universal Life-Insurance Co." The question embodying this new feature reads, if we recollect rightly, very nearly as follows: Are you willing that your medical attendant should, in the interest of the Universal Life-Insurance Co., state fully all the facts in his possession relating to your condition of health, past history and habits? The evident object of this question is to release the physician from the obligation of his professional oath and thus enable him to communicate any information that may be of value to the company in forming an estimate of the character of the risk.

SEPARATE MEDICAL EXAMINERS' REPORTS.—At a recent convention of all the principal agents of one of our New York companies, the question was submitted —"whether it would not be for the best interests of the company to have the medical examiners' reports sent directly to the home office, separate from the application?"—The objection raised was that it would in many instances seriously delay the issue of the policy, and accordingly it was unanimously determined that the best (?) interests of the company demanded no change in this particular.

MORTALITY CHARTS.—A series of mortality charts are among the improvements of the last census. The relative mortality from the various diseases in different sections of the country is shown in colored shadings. Perhaps the most remarkable feature about these charts is the system of compensation. Sections having the lightest shade of one color are deepest dyed with another. What consumption is to the North, malaria is to the South. The general result from these interesting charts is, that the healthiest portion of the country is in that central region stretching through West Virginia and Tennessee into Upper Missouri, along with the extreme Northwest on the borders of Lake Superior.—*Insurance Monitor.*

Original Lectures.

A LECTURE

ON THE USE OF PLASTER-OF-PARIS IN THE TREATMENT OF FRACTURES.

DELIVERED IN THE SPRING COURSE OF LECTURES IN THE COLLEGE OF PHYSICIANS AND SURGEONS.

BY JAMES L. LITTLE, M.D.,

LECTURER ON OPERATIVE SURGERY AND SURGICAL DRESSINGS; SURGEON TO ST. LUKE'S HOSPITAL.

GENTLEMEN:—In my last lecture I told you that in the treatment of fractures we have three indications to follow: 1st. To place the fragments of bone as nearly in their normal position as possible; 2d. To retain them in this position; 3d. To attend to the local or constitutional complications which may arise during the course of treatment. The execution of the *first indication* is what we call "setting" a fracture; and I told you that you should set a fractured bone as soon as possible. In the majority of cases there is no difficulty, and the whole operation of "setting" consists merely in moving the limb from a bent to a straight position. In other cases, where there is overlapping of the fragments of the broken bone, you will have some difficulty in reducing them; extension and counter-extension must here be resorted to, and in some cases it will be necessary to etherize your patient before you succeed.

After reduction, you take means to fulfil the *second indication*, namely, to retain the fragments in their normal position. This can be accomplished by apparatus of various kinds: splints of wood, tin, gutta-percha, leather, felt, &c., may be used; or you may apply splints or dressings made of plaster-of-Paris, starch, or silicate of magnesia, or liquid glass, as it is called. The use of plaster-of-Paris has become so general in the treatment of fractures, that it becomes necessary for me to enter into full details of the methods of its application.

The employment of this substance for fracture dressings is not new. It has been used for very many years, and has been applied in various ways. As far back as the close of the last century it was used by the Arabians.

In Europe it was introduced by Hendricks at the hospital of Gröningen in 1814, and since that date has become one of the standard means of treatment in many of the hospitals throughout Europe.

In this city, fractures treated with plaster-of-Paris by "Pirogoff's method" were reported by Drs. Gluck and Weber in 1855 and 1856. A new method of applying the plaster was introduced into the New York Hospital by myself in 1861, and in that year a full description of its use and application was published in the *American Med. Times*. I also wrote a monograph on this subject which was printed and widely circulated by the Sanitary Commission just before the close of the war.

I also read a report on the use of plaster-of-Paris in surgery before the American Medical Association, at the meeting in Cincinnati in 1867, which was published in the report of the association for that year.

In this college its use has been taught yearly since 1861 by Prof. Markoe, and also by myself in the spring course. I mention these facts because several papers have recently been written in regard to its use in Bellevue Hospital, and in which no allusion has been made to the method which I have introduced and practised. Dr. Saml. B. St. John, a graduate of this college, and afterward resident surgeon of Bellevue, in a paper on "Plastic Apparatus in Surgery, with especial Reference to that variety made with Plaster-of-Paris," published in the *American Journal of Med. Science* in July, 1872, in giving the history of the use of plastic apparatus from the time of Hippocrates down to the present day, makes no mention of the important application of plaster-of-Paris in this city. Prof. H. B. Sands, in a paper on the "Use of the Plaster-of-Paris Bandage in the Treatment of Fracture," published in the *New York Med. Jour.*, June 1871, states that he considers the method which he describes "*superior to that advocated by Pirogoff, which found favor at the New York Hospital some years ago.*" Dr. Sands evidently here confounds Pirogoff's method with that of which I have been speaking, Pirogoff's method never having been used in that hospital to my knowledge. The difference between Pirogoff's and my own method is this: Pirogoff, after bandaging and padding the limb with cotton, applies strips of coarse linen saturated with a solution of the plaster, lengthwise to the limb. These are retained in place by crosswise strips similarly prepared, thus making a *permanent* and *immovable dressing*. My method, which I will describe in full, later in this lecture, consists in the formation of plaster splints, which are applied directly against the integument, retained in position by a dry roller bandage, and which may be removed and the limb inspected at pleasure.

Now, gentlemen, if you will give me your attention, I will describe in detail and show you the application and use of, first, the plaster bandage, and afterwards the plaster splint.

THE PLASTER BANDAGE.

This is made by rubbing the dry plaster into the meshes of the muslin of which the bandage is made, and then rolling this up the usual way as an ordinary roller bandage. The plaster bandages thus prepared should be kept from contact with the air, rolled up in tinfoil until they are wanted, so that the plaster will not absorb moisture and thus become unfitted for use. Before applying this dressing, the limb should be carefully and evenly padded with old flannel, or a layer of cotton batting applied with a roller, and then the bandage, which having been previously placed in a basin of water to become saturated, should be applied as you would apply a dry roller bandage. Several plaster bandages should be used, and it is well to sprinkle dry plaster between them, and wet it, in order to give greater solidity to the whole. This is known as Mathiesen's method of applying plaster, and is at present in use at Bellevue. As far as I know, Dr. Robt. F. Weir was the first in this city to apply this form of plaster dressing to fractures. While resident surgeon of the New York Hospital he treated several cases of fracture by this method; but for some unknown reason the treatment fell into disuse until revived again at Bellevue.

Let me now show you in detail how to apply this plaster bandage (the lecturer here enveloped one arm of the manikin in the dressing described). After the application, the limb should be firmly held in position until the plaster "sets," and makes a firm hard splint. The plaster used for this bandage should be the superfine quality.

In order to remove these bandages, a strong pair of cutting pliers is necessary. This instrument which I show you, is one constructed for the purpose by Dr. Henry, of this city.

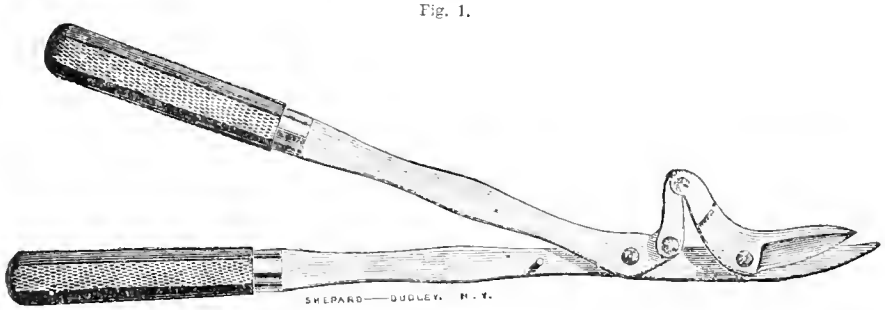
Here is another (Fig. 1) which was introduced by Dr. Victor von Bruns, Prof. of Surgery in Tübingen, made by Shepard & Dudley in this city. It is strong, and of great power, cutting the plaster bandage with ease and rapidity, and is used in St. Luke's, Roosevelt, and Bellevue Hospitals.

The principal disadvantage of this method of treating fractures is, that it conceals the limb entirely after its application.

In applying this method of plaster dressing, we should first cut a paper pattern of the size and shape of the splint required, and from this paper pattern we cut the Canton flannel or muslin. Two or three thicknesses of muslin, or two of thin bleached Canton flannel, make the best splints. A material like mosquito netting is sometimes used, but I have found it makes the splints too brittle, so that in moving them to examine the limb, they are liable to crack, and thus lose their value as splints.

The Canton flannel being cut of the requisite size and shape, and the limb being shaven or oiled to prevent the hairs from adhering to the splint, the plaster

Fig. 1.



At Bellevue it is applied as soon as the fracture enters the hospital, and if put up properly and with care, produces no harm; but if great care is not taken in its application, there is danger of interference with the circulation by the swelling of the limb. This plan of putting up recent fractures in tight immovable dressings, is one which I would not recommend for adoption in private practice unless you have had ample hospital experience. It is better to place the fractured limb in some open dressing, and wait a few days until the swelling has to a certain extent subsided; then you may safely apply this or some other immovable dressing. *Do not, then, put up recent fractures in tight dressings.* To be sure, only one case of gangrene has occurred in Bellevue, and that was an out-patient who failed to report as directed, and who returned after the mischief had been done—so says Dr. St. John; yet, gentlemen, I have seen several cases of severe ulcerations produced by this form of bandage; and in one case where the apparatus was applied in Bellevue, a slough took place over the heel of the patient which took months to heal. My advice, then, to you is, not to apply any dressing to a fracture that is likely to produce harm, even should the patient neglect to follow your advice.

I will now call your attention to the second way of using the plaster, namely,

THE PLASTER SPLINT.

Here you will incur no risk in the application. By this method splints are made of muslin or Canton flannel, saturated with a mixture of plaster-of-Paris and water.

In this way you can construct light but strong splints, fitting the limb with an accuracy unequalled by any other splint, and holding the fragments of bone in perfect apposition, at the same time permitting us to inspect the limb at pleasure.

The application of these plaster splints was first introduced into this city by myself, while resident surgeon of the New York Hospital, and for certain fractures they answer a better purpose, in my opinion, than any form of dressing that we have at the present time.

is then to be mixed with water. Equal parts, by measure, of water and plaster, say one pint of each, make the mixture of the right consistency; it should not be thicker than cream.

Should it be desirable to have it "set" rapidly, a small quantity of common salt (a teaspoonful to the above mixture) should be added while stirring.

If, on the other hand, you wish for any reason to delay the process of "setting," the addition of a small quantity of cream of tartar will effect this result.

The Canton flannel or muslin is now placed in the mixture and thoroughly saturated with it. It must then be removed, placed on a board or table, and smoothed out with the hand; the two pieces being accurately laid on each other, and being neatly pressed, they are applied to the limb directly against the integument, and adapted by the hands to the parts, while a roller bandage is snugly applied. This done, *the limb must be held in position until the plaster becomes hard.* This takes from five to fifteen minutes.

It is better to remove the roller bandage as soon as the plaster sets and apply neatly a dry one, else the one put on the wet plaster will be removed with difficulty when thoroughly dried.

A splint made in this way is light and elastic, and although applied directly against the integument, produces no excoriation; in a word, it combines all the advantages of the plaster bandage, with the additional one of allowing the limb to be inspected when desired. If the limb shrinks, owing to subsidence of the swelling, and becomes loose in the splint, all you have to do is to remove the roller bandage and reapply it tighter than before.

Now, gentlemen, I will bring a case before the class and show you the application of the plaster dressing we are now discussing. Here is a boy four years old, who four days ago fell from a bale of hay and sustained a fracture of both radius and ulna of the right forearm. It was an *incomplete fracture*, or what is called a "green-stick fracture." The forearm was bent near its middle, and on examination no false point of motion or crepitus could be detected. You remember I told you in my last lecture, that both of these symptoms in this kind of fracture were absent

until after you had bent the bones back to their normal position, and then in many cases you would feel a distinct cracking of the bones, and the fracture would be made complete. That occurred in this case, so that we have now a *complete* fracture of both bones of the forearm at about their middle. As a temporary dressing, the forearm was placed on a straight splint, well padded and retained in position by strips of adhesive plaster. Had the case not come to my office in the middle of the day, when I was otherwise engaged, I could have applied, and it would have been better to have done so at once, the plaster splint which I am about to show you. I applied, however, a *provisional* dressing; and here let me say to you, that you should always be ready with some form of temporary dressing for fractures in all parts of the body, so that when called to a case you can at once do something to make your patient comfortable; afterward you can prepare at your leisure a dressing more effective.

Now to return to the dressing of this fracture. I cut out a paper pattern so shaped as to leave the upper or radial border of the forearm uncovered by the splint, and then cut two thicknesses of the Canton flannel of the same shape. I now mix the plaster and water, add a little salt to facilitate the "setting," and saturating the Canton flannel in the mixture, place it on this board, and with my hand smooth out the wrinkles and the excess of plaster. I now apply it under and around the fractured arm, and smooth it well around the limb, while my assistant holds it in position. At the lower end I find the splint a little longer than necessary, and turn it over a half inch, which gives me a rounded and smoother edge.

I will turn back the edge near the elbow also, for the same reason. Now, while my assistant holds the limb straight, I apply a roller bandage two inches in width snugly around the limb. You notice the drops of soft plaster oozing through the bandage as I apply it. Now I take the limb from my assistant, and seizing the forearm just below the elbow with my left hand, and the hand of the patient with my right, I make extension sufficient to keep the limb straight until the plaster sets. In some cases where there is much tendency to displacement, I have my assistant press with two flat wooden splints the palmar and dorsal surface of the limb, while I keep up moderate extension. This shapes the splint so that the muscles are forced in between the bones, following out the same indication formerly fulfilled by interosseous pads.

Now, gentlemen, although not five minutes have elapsed since this splint was applied, it has already become hard, so I remove this wet roller bandage, and there you see a beautiful splint, holding the limb perfectly straight. (Fig. 2.)

A dry roller is now snugly applied, and the patient is in the most comfortable condition possible: the coat-sleeve can be pulled down over the arm, which should simply be suspended in a sling. If this dressing be applied before swelling takes place, the roller can be left off and the splint retained by a couple of strips of muslin loosely tied near the elbow and hand, and lotions can be applied to the swelling.

The after-treatment consists merely in reapplying the roller bandage whenever the limb seems to be loose in the splint. This form of dressing may be used satisfactorily in cases of fractures about the elbow-joint, or in fractures of the forearm and fingers. For fractures of the leg, in my estimation, there is no better dressing. It can be applied at once if desirable, and as the splint does not encircle the limb, there is no danger from undue compression. The patient can go about on crutches at once. I generally prefer, however, to place the limb in a pillow or fracture-box for a few days before applying this dressing.

Fig. 2.

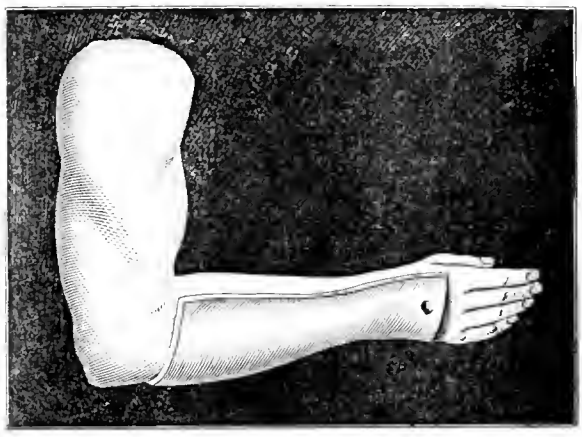


Fig. 3 shows this form of splint applied to the elbow, and Fig. 4 to the leg. Remember, these are retained to the limb by a roller bandage.

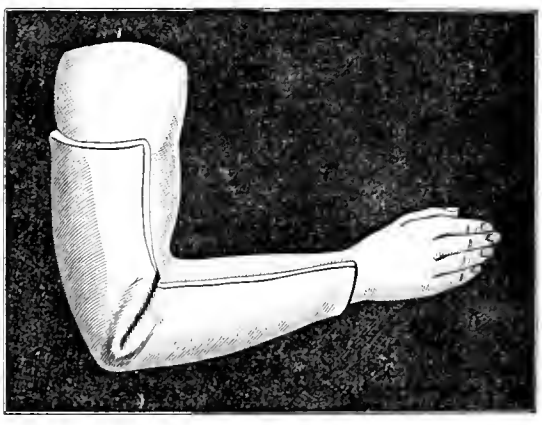
Fig. 3.



In fractures of the humerus, I use coaptation splints and bandages; but if in any case I should want to apply the plaster dressing, I would use the *plaster bandage* as described in the first part of this lecture.

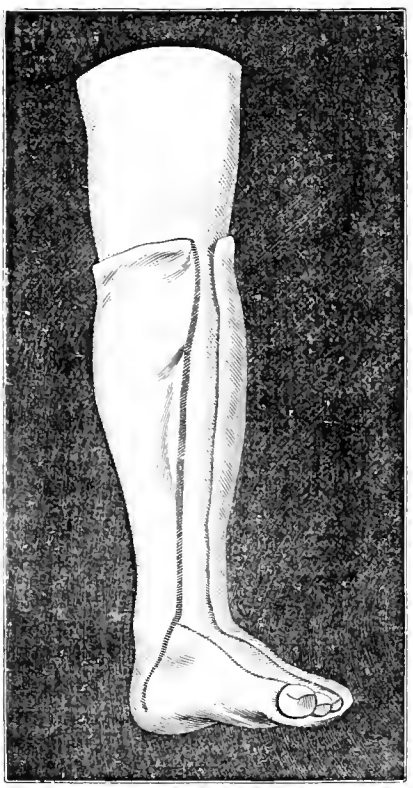
Dr. Buck's extension apparatus, for the treatment of fractures of the thigh in the lower and middle third, and the triple inclined plane, for those seated near the upper third of the shaft, leave little to be desired.

I use both these appliances in the first part of the treatment of such fractures, and after union has become moderately firm, often apply the *plaster bandage* from the toes to as high as possible on the thigh, thus allowing the patient to walk on crutches at a comparatively early date.

The immediate treatment of fractures of the thigh by plaster bandages, as now used in Bellevue Hospital, and described by Drs. Sands and St. John, is one that I think cannot be made practicable outside of a hospital, as it depends for its efficacy on the use of a peculiarly constructed bed, called the stretcher, on which the patient is placed, and while under the influence of ether, and strong extension made with the pulleys, this dressing is applied. The only advantage that I can

see in this form of dressing is, that it allows the patient at once to leave the bed and go about on

Fig. 4.

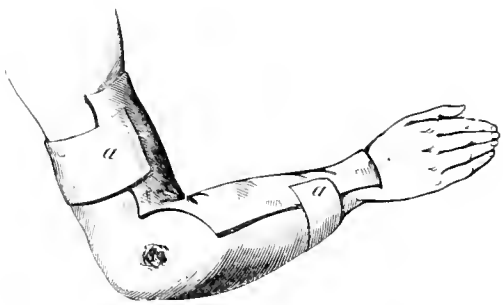


crutches. Dr. Buck's apparatus is simple and can be applied in a few minutes, in any room which will hold a bed; and it is seldom necessary to etherize your patient. To be sure, your patient must keep his bed, but he may sit up, and I seldom find patients complain. After the fourth or fifth week I think we have gained all we can by extension, and then you can apply the *plaster bandage* without resorting to ether and extension with pulley, and then your patient may go about on crutches. In another lecture I will show you how to apply Dr. Buck's apparatus.

I might also state that you can construct plaster splints of any shape for the treatment of diseases of the joints; and after resection of joints, no better form of dressing can be used. I will also call your attention to the use of plaster in the treatment of club-foot. I believe I was the first in this city to use it for this purpose. In young children it is rarely necessary to perform tenotomy, for the deformity can be overcome by gradually stretching the tendons by putting up the foot in plaster dressing, and holding the limb in position while the plaster "sets." I have here a little patient who has talipes-varus of one foot, and I will show you how to apply this dressing. I will use the plaster splint made of two thicknesses of thin bleached Canton flannel, although the plaster bandage would do as well. You see I have cut out the Canton flannel so that it will not completely surround the leg and foot. Now, after saturating it in the plaster I apply it directly against the integument, and apply the roller, while Dr. Maynard holds the foot as straight as possible. Now I take the foot in my own hands and stretch it around to, as nearly as possible, its normal position, and I will hold it so until the splint becomes hard. Now it is getting warm, and I know that when heat is developed the setting is firm. I will take off the outside roller and you see the foot and leg partially enveloped in this fine casing. I advise that this be left on a week and then removed, and another applied, and the position of the foot improved. When the foot can be easily brought to its normal position I resort to the use of some form of club-foot shoe.

In conclusion, I would say that in the treatment of compound fractures, the plaster-of-Paris dressing fulfils a most important indication—namely, *allowing us to dress the wound without disturbing the fractured bone.* It can be applied by either of the methods which I have described, and fenestræ cut out so that the wound can be exposed and dressed as often as desired.

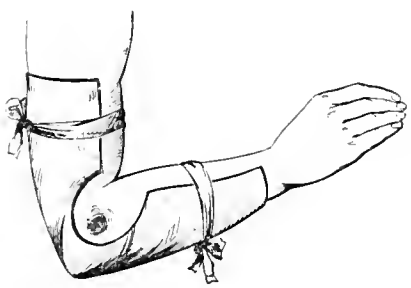
Fig. 5.



In the diagram (Fig. 5) you see a plaster splint applied to the anterior surface of the arm and retained by transverse bands, *a a*. The case was one of a gunshot wound of the elbow. The wound you see could be readily dressed, and the dressing retained by a bandage. In this case the splint was not removed for over one month.

In this picture (Fig. 6) you see a splint applied to

Fig. 6.



the posterior aspect of the elbow and retained by strips of muslin tied around at the upper and lower ends of the splint.

That bell warns me, gentlemen, that the hour is up. I will therefore conclude this lecture by stating that the great advantage of the plaster-of-Paris, in whatever way applied, over all other forms of dressin s for fractures, is: *Its property of hardening rapidly*, allowing us to hold the fractured limb in its normal position until the plaster "sets." No other substance possesses this property in such a degree. Starch takes from 24 to 48 hours before it becomes hard. Liquid glass, which makes a beautiful-looking dressing, also takes some time before it solidifies.

Original Communications.

A CASE OF PENDULOUS TUMOR OF THE FOREHEAD AND TEMPLE.

By GURDON BUCK, M.D.,

VISITING SURGEON TO NEW YORK HOSPITAL AND PRESBYTERIAN HOSPITAL; CONSULTING SURGEON TO ROOSEVELT HOSPITAL AND ST. LUKE'S HOSPITAL, ETC., ETC.

Miss R. R., æt. 35, a resident of New York City, has a pendulous tumor, arising from the right half of the forehead and adjacent temple, and encroaching upward somewhat upon the hairy scalp. It stands out more than one inch from the surface, and in the process of gradually gravitating toward the cheek it has become invested with the upper eyelid, which is spread out on its surface. In its further descent it has also dragged downward the eyeball itself partly out of the orbit. The tarsal margin of the upper lid, which overlaps and conceals the under lid, forms the lower boundary of the tumor, and descends upon the cheek to within a finger's breadth of the edge of the right nostril. The eyebrow is spread out upon the surface of the tumor, and is situated one inch below its natural level.

Fig. 1.

The skin covering the tumor retains its natural color, is very supple, and can be gathered into loose folds between the thumb and fingers. The substance of the tumor itself is of moderately firm consistence and loose texture, and slides freely upon the surface underlying it. When grasped in the hand it has almost the pliability of the scrotum. On separating the lids the eye is found of natural appearance, and possesses good vision. When patient was an infant a few months' old, her mother first noticed a somewhat elevated ridge across the right half of the forehead, which increased very gradually, and spread out to its present dimensions. Its growth became more accelerated, her mother thinks, after her recovery from a dangerous illness in childhood, for the treatment of which she was profusely salivated. When eleven years old an operation was performed, and a portion of skin of the size of a silver quarter of a dollar excised, but without any benefit. Other growths, varying in size from a small pea to a cranberry, are scattered upon the limbs and body. One of these growths of a pendulous form, near the fold of the right elbow, patient allowed to be removed for microscopic examination prior to the performance of an operation on the face. Unfortunately, a memorandum of the result of the examination was lost. It was, however, ascertained that there were no cancerous elements in its structure. Patient's general health being favorable, the first operation was performed 13th January, 1869.

FIRST OPERATION.

A transverse incision, commencing above the left eyebrow, was carried across the tumor along the middle of the forehead to the right temple; a second incision, commencing above the right temple, was carried vertically downward to the upper part of the cheek, joining the first incision at its terminus on the temple, the two incisions forming a letter T laid upon its side. The angular flaps of skin thus formed were dissected up from the surface of the tumor to its margin above and below. The tumor itself was then raised at its circumference from the underlying surface, and a prolongation of it, extending into the orbit under its roof, was dissected out. No large vessels were encountered, nor was the hemorrhage from small vessels considerable. Ligatures were applied to all vessels requiring it. After the removal of the tumor the redundant skin was pared away, so as to permit a good adjustment of the flaps to each other. Numerous thread sutures were then inserted to secure the adjustment. A good result followed, with primary union at almost all points.

SECOND OPERATION.

April 8th. A flattened portion of the tumor, situated high up on the right temple, not having been included in the previous operation, a second operation, of only limited extent, was performed for its removal, and was followed by prompt healing of the wound.

Fig. 2.

THIRD OPERATION.

Performed 28th April, 1869. The right eyeball was attacked with acute inflammation, which proceeded rapidly to disorganization of its internal structures. The eyeball was therefore extirpated, and at the same time some remaining portions of the morbid growth removed. A good result followed the operation, but the remaining conjunctival cavity unfortunately was not sufficiently capacious to permit the insertion of an artificial eye. Patient's condition was examined as late as 11th September, 1873, and found to be as follows: She enjoys ordinary good health. There has been no reproduction of the morbid growth that was removed from the forehead and temple. The cicatrices left by the incisions are linear and quite indistinct. The right eyelids are habitually closed and flattened. Fig. 2 is from a photograph taken nearly two years ago, and faithfully represents her present condition.

46 WEST 29TH STREET, NEW YORK.

CASES IN PRACTICE.

FROM A PAPER PRESENTED TO THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

By C. A. ROBERTSON, M.D.,

MEMBER OF THE AMERICAN OPHTHALMOLOGICAL SOCIETY, OPHTHALMIC AND AURAL SURGEON AT ST. PETER'S HOSPITAL, ALBANY, AND AT THE TROY HOSPITAL.

CASE I.—The patient was a charming little girl about five years old; but, unfortunately, her beauty was marred by an extensive white spot over the pupil of one eye. Beside this leucomatous opacity of the cornea, the eye was deviated inwards. The strabismus was unquestionably caused by the leucoma.

The mother of the child, herself the daughter of a physician, was in a state of anxiety, her mind having been alarmed by a professed oculist with the strange representation that the safety of the well eye was jeopardized by the condition of the defective eye, and that the latter should be taken out for the security of the other! The cheering compensation was held out, besides, that a glass eye *would look better* than the natural one! She naturally shrank from such heroic measures.

I said to her at once that the child's eye was invaluable, although seriously blemished and defective, and that its usefulness might be measurably restored by an operation for artificial pupil. I told her, likewise, that the squint could be corrected, and the white spot be in a great degree, or entirely, obliterated.

Accepting my views, the mother desired the operation to be done for an artificial pupil. Accordingly the patient was etherized, and a portion of iris was excised on the nasal side, with the result of restoring valuable sight. Further remedial measures were postponed for a while, but in the meantime domestic considerations took the parties away for a time, and further interference with the eye is still in abeyance.

The obliteration of a white spot on the cornea by tinting, when it gives no promise of disappearing spontaneously or by artificially caused absorption, is indicated not merely in order to get rid of a blemish, but also as a means of improving vision. The diffused light which it produces within the eyeball disturbs vision like a glare of excessive light in front of the eye, while at the same time the image of the opacity cast upon the retina is projected as a cloud between the eye and any object looked at. In cases of slight nebulæ on the cornea, which might escape the observation of an expert even, unless oblique illumination were employed, the dimness of sight which exists is the result of such projected cloud. The benefit obtained by coloring the white spot on an eye with dark pigment is exemplified by the following case:

CASE II.—A blacksmith, about forty years of age, called on me at the Eye and Ear clinique at the Troy Hospital. He presented an opacity upon each cornea, perfectly white at the centre and shading off into a nebulous periphery. On the right eye the spot was more extensive than on the other. He had undergone an iridectomy, performed by my former distinguished preceptor, Sir William R. Wild, of Dublin. The artificial pupil made by this skilful operator gave him useful vision in the left eye, but the sight of the right eye was not equally improved.

The patient represented that the appearance of his eyes, with a conspicuous white spot on each, operated as a hindrance to him in securing employment at full wages, for a doubt of his ability to see as well as he really could, arose wherever he applied for work.

In order to relieve him from this embarrassment a process of tattooing was commenced on the white spot of the right cornea. It was repeated twice a week for several successive weeks, until the white opacity was finally supplanted by a dark indelible stain. The personal appearance of the patient was greatly improved by the change, but, more than this, he remarked that his sight had been benefited by the operation, and he desired that the same process of tattooing the eye should be practised on the smaller white spot of the left eye.

The operation is a little tedious if judiciously done, for, in the opinion of the writer, too many points of puncture for pigmentation may be made at a sitting, and provoke so much irritation as to jeopardize the safety of the eye from consequent inflammatory reaction. By contenting himself with tinting a little at a time, the writer has avoided any untoward results.

The removal of the eyeball, in the case of the little girl mentioned above, would have radically removed the squint, to be sure! but the folly, as well as heinousness, of such cruel ophthalmic surgery as the proposed extirpation of an eye possessing latent usefulness, because its looks were blemished by a white spot, is demonstrated by the success of the operation for an artificial pupil, and the improvement of appearance obtainable from tinting a white opacity. In the advanced condition of ophthalmic practice to-day, it is remarkable what ignorance or wantonness is sometimes encountered.

Reports of Hospitals.

BELLEVUE HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES IN TREATMENT.

LUXATION AND FRACTURE OF CLAVICLE.

FRACTURE of this bone belongs to a class of injuries which has long taxed the ingenuity of surgeons to invent some apparatus for its treatment, which could be easily worn by the patient, would be simple, and at the same time efficient.

A very elegant, comfortable, and efficient dressing for fracture of the clavicle consists in the use of ad-

hesive plaster according to the method devised by Prof. Sayre. It is equally applicable as a dressing for a luxated clavicle, and consists of adhesive plaster used in a manner described briefly as follows:—

Cut two pieces of adhesive plaster three to four inches in width and of sufficient length to permit one to pass around the arm and around the body, the other to pass from the top of one shoulder obliquely around the body, embracing the olecranon and terminating at the point of beginning. Maw's moleskin plaster is the best, if it can be obtained.

The first strip of plaster is made to surround the arm upon the side of the fracture, just below the axillary border, leaving a space posterior uncovered forming a loop which is fastened with pins or stitches. Then the strip is carried about the body, and brought back to a point at which it may be again fastened to prevent its slipping.

The point insisted upon in the application of the first strip of plaster is this: the arm, after the loop is made around it, is to be drawn downward and backward until the portion of the pectoral muscle attached to the clavicle is sufficiently placed upon the stretch to counteract the action of the sterno-cleido-mastoid muscle. This will bring the clavicle down to its level. Then the strip of plaster is carried around the body and fastened, as indicated above. The second strip of plaster is applied as follows: Commence at a point a little on the front side of the sound shoulder, and carry it obliquely across the back to the elbow of the injured side. At that point a slit should be made for the reception of the olecranon process. Now, passing over the olecranon, and at the same time pressing the elbow firmly forward and inward, carry the plaster over the forearm, which is made to lie obliquely across the chest in the direction of the breast opposite the injured side, and cross the shoulder at the point of beginning, where it may again be fastened, if necessary, with pins or stitches.

This makes a cheap and efficient apparatus. A difficulty attending its adoption is the difficulty of obtaining serviceable adhesive plaster.

CHRONIC SUPPURATIVE DISEASE OF THE KNEE-JOINT.

An interesting class of cases met with in this hospital is what is commonly called "white swelling," or chronic suppurative disease of the knee-joint. There is scarcely a practitioner, who has been engaged at all in general practice, who has not met one or more of these cases. The general appearance of these joints is too well known to require any special description. The case which we are now specially regarding was in a little girl about eleven years of age, who had once been operated upon. During the early progress of the disease in her case, no extension and counter-extension were employed, and the result was that the limb became so flexed that the heel was nearly in contact with the nates. The joint was freely opened, free discharge ensued, tendons divided, and the limb placed in a straight position.

The case formed no exception to the general rule that "white swelling" in all cases is dependent upon some constitutional trouble. The discharge from the joint has been free, and consisted almost entirely of broken-down material. There had been extensive burrowing of pus among the muscles and fasciæ of the thigh, until sinuses were formed, extending up nearly to the trochanter major. After the first operation the extension was removed a little too soon, and the limb again began to flex slightly.

This is an important point in the after-management of these cases. After the limb has been placed in a straight position, or in a *proper* position, if anchylosis is to result, it is important to keep up extension until the parts have got ENTIRELY WELL.

Another important point in connection with this case, and one not infrequently met with in this class of cases, chronic suppuration, connected with diseases of the bones, consists in the fact that this patient became the subject of general anasarca, and the urine contained waxy casts and albumen. In such cases the question arises, should an operation be performed or not, in view of the existence of renal disease? One way of regarding this class of cases is this, that the renal disease is dependent upon the existence and progress of the chronic suppurative disease of the joint, which is doubtless true. If now the discharge from the joint can be arrested, there is a chance for an improvement in the general health, and with that, an improvement in the condition of the kidneys. The present case proves the tenableness of this view, and is an illustrative case. It does not, as experience proves, absolutely and essentially make it a fatal case, because there are waxy casts and albumen in the urine; but, on the contrary, it may be expected in some cases, at least, to get relief from the renal disease by means of the operation. Of course constitutional treatment in these cases is all-important, but we are addressing ourselves more particularly to the surgical considerations.

Another practical point, suggested by the handling of this limb, is that the manipulations give the patient some pain, which is evidence that there is still some motion left in the joint. Sometimes the motion which may be left will be very slight indeed, but it is important to determine whether complete anchylosis has taken place or not. It is sometimes difficult to decide this point, and in the preliminary examination preparatory for the operation, it is well that it should be done without the use of an anæsthetic, for oftentimes the surgeon may be able to tell whether there is motion or not in the joint by the sensibilities of the patient. The patients are able at times to detect by their feeling the existence of motion which the surgeon will be unable to recognize by his manipulation, and the decision of the patients upon this point can generally be relied upon, for they become extremely interested in whatever is intended for their benefit. The after-treatment of these cases consists in complete rest in bed, extension and counter-extension, application of ice or cold cloths, latterly compression of the joint, and, embraced in the primary dressing, partial compression of the femoral artery, leaving just enough circulation to vitalize the parts.

The extension and counter-extension is, at first, kept up by means of the perineal band and adhesive plaster applied to the leg, to which weights are attached over the foot of the bed.

After all acute inflammatory action has subsided, or the time has passed for its accession, the limb may be placed in a Sayre's splint, and then extension can be regulated in the most perfect manner, and the patient may soon be moving about. In the application of this splint there is no adhesive plaster that will scarcely in any degree prove satisfactory except Maw's moleskin plaster, manufactured in London. In applying the first dressing after the operation it is well to pad the ankle with cotton most perfectly, also the popliteal space, for the dressing may not be removed for some time, even for months.

It is regarded as an important point in the dressing to partially close the femoral artery, and this is best accomplished by means of a piece of soft sponge two or three inches in length, and perhaps as thick as two fingers, placed immediately over the artery in its lower

third, and engaged in the bandage as it passes up the limb.

In breaking up the adhesions and restoring motion to the joint, it is regarded as important to break them up most thoroughly at once. Do not hesitate to restore to the joint all the motion you may expect it will have after it has got well, when the tendons are first cut and the limb placed in a straight position. Then keep it perfectly still, past the time at which the inflammation is apt to occur.

The wound is usually dressed at first with a carbolic dressing of some kind; salve, oil, or lint wet in a solution. The first dressing is not usually removed within a week or ten days. The wound must heal from the bottom. When the limb is placed in the splint, compression should be applied to the joint by means of adhesive plaster, applied in strips, uniformly and smoothly, after the manner of strapping. This is done for the purpose of *promoting* absorption of the infiltration which has taken place into all the tissues about the joint. Extension is employed for the purpose of *preventing* absorption of the articular facets of the bone, which will occur if pressure is not removed.

PLEURO-PNEUMONIA.

The following history will illustrate one of the phases of pleuro-pneumonia. The patient is 32 years of age, laborer, single, and a German. He has been sick two weeks. The first symptom was a chill, which was followed by fever. Upon admission into the hospital the patient was suffering from great dyspnœa. Pulse, 148; resp., 56; temp., 102°. Tr. aconite, ℥i., and carbonate of ammonia, grs. v., were administered every three hours. Diet, nourishing. Next morning after admission, was better. The peculiar feature of this case was that as the *pneumonia subsided the pleurisy accompanying it increased.* This particular turn in pneumonia occurs only rarely, and the evidences of this change are chiefly physical. The patient had had dulness upon percussion, bronchial breathing, broncophony, and the characteristic expectoration, which makes out a clear case of pneumonia. The pain (he says he had stitches in his side) and friction sound make out the pleurisy, and all these signs coexisted, except the characteristic expectoration, which appeared and disappeared as it should. The only exception to the statement that we always have breath-sounds when pneumonia is present, is when there happens to be fibrinous bronchitis present with it. This may occur perhaps once in one or two hundred cases; so that, practically speaking, it can be said there are always breath sounds present in pneumonia. They are always absent in pleurisy, and a pleurisy is almost the only thing which does give complete absence of the breath-sounds. In examining a chest in which pleurisy is present, it is well to bear in mind the fact that the bronchial breathing present in the compressed lung may be communicated, and give the impression that it is present in the lower portion of the chest, while the cavity is filled with fluid. The application of these physical tests was the only means by which it could be determined that the pneumonia had been superseded in prominence by the pleurisy. Pneumonia and pleurisy sometimes approach each other very closely, and it is sometimes a matter of unusual difficulty to make a differential diagnosis. As evidence that the pneumonia is now subsiding, it is found that the bronchial inspiration is more prominent than the bronchial expiration. As a pneumonia resolves, the bronchial expiration ceases first. Whether the recovery in this case is due to the treatment or to the natural powers of recovery is, perhaps, a question which can never be determined. He is now taking quinine grs. v., three times a day. He has been receiving this for several days.

INFLAMMATORY ECZEMA.

Inflammatory eczema in a man 66 years of age. His father died of consumption. One year ago one of his ankles was swollen, and "itched him" very much. Soon after, the other ankle was affected in the same way, but in both instances the disease soon disappeared. When admitted into the hospital his right leg was immensely swollen, and was tense and hard. The points of interest in this case are the simplicity of the treatment and the rapidity of the cure.

His was a bad case of eczema, in a bad constitution, yet received no internal remedies, nothing but ward diet, quiet in bed, the local application of bicarbonate of soda, ʒ i. to the ℥ i. It is highly important in the use of this remedy (soda) that the parts should be kept *constantly* wet with the lotion. A failure to observe this precaution will bring with it a failure to cure.

A STRONG TRIO.

In the female wards was noticed a patient who was suffering from what was thought to be a gastric ulcer, well-marked epilepsy, and had also just been cured of Pott's disease. The disease of the spine had been cured by apparatus used at the hospital for cripples, and all that could be seen remaining was a little knuckle in the dorsal region, about one-fourth of an inch in elevation. The epilepsy has received a variety of treatment, without marked benefit. The chief feature in the case at present is what is supposed to be a gastric ulcer. The patient is being sustained by injections of eggs, beaten up with milk, and beef-tea. She has vomited blood and coffee-ground material, which usually indicates one of two things: either cancer of the pylorus or gastric ulcer situated in that region. With cancer a tumor is almost always present; but the absence of a tumor does not necessarily exclude the presence of cancer. Ulcers in other parts of the stomach do not necessarily produce vomiting. Cancer may or may not produce vomiting, and patients with either cancer or ulcer may occasionally vomit blood without vomiting food. The administration of cream is regarded as a very important element in the treatment of ulcers of mucous membranes. It is believed that it is one of the articles of food which do most towards healing ulcers of mucous membranes. This patient took ʒ iv. of whiskey per day for some time while under treatment for Pott's disease, and this was followed by the use of ale.

ACID DYSPEPSIA.

For the relief of this form of dyspepsia, evidenced by acid eructations after eating, an acid is administered as follows: Nitro-muriatic acid dil., gtts. v., t. i. d. *before* meals.

The *modus operandi* of the remedy administered in this manner, and in connection with this condition in digestion, is said to be this: The reason why acid eructations occur is because there is not sufficient gastric juice secreted to completely digest the food, hence acid is generated as a consequence of the process of fermentation. The administration of the mineral acid *before* meals stimulates the gastric tubules to the secretion of a larger quantity of gastric juice, and in that way secures the complete digestion of the food. A goodly number of cases have yielded to this treatment that have defied all other plans employed. In cases of pyrosis the same remedy is administered; but in that

condition it is to be administered *after* meals. Water-brash consists in the vomiting of pure mucus with an insipid fluid. According to *Frerichs* this fluid is usually *alkaline*, always contains the sulphurets, and treated with an excess of alcohol yields a precipitate which has the power of rapidly converting starch into sugar. Such a fluid cannot be formed in the stomach, and is doubtless the product of the salivary glands. The administration of the mineral acid corrects its alkalinity.

FLUCTUATIONS IN TEMPERATURE.

A case illustrating one phase of fluctuation in temperature was admitted into the hospital with rapid pulse, hot skin, high temperature, considerable nausea, and slight vomiting. Diagnosis reserved. May 3d, 11.30 P.M., her pulse was 88; resp., 28; temp., 98°.

May 4th, 8 A.M., P., 130; R., 36; T., 106½°. 11. 0 A.M., P. 126; R., 36; T., 104⅘°. 6 P.M., P., 76; R., 32; T., 100°, and from this date forward her temperature fluctuated between 98° and 100°. Physical examination at the time of this sudden rise and fall in temperature was negative. Urine, 1026; no casts or albumen. Diagnosis obscure after many days.

"In children," says Wunderlich, "the temperature in disease is extremely mobile and sensitive; its extremes greater. Women resemble children in this respect; their temperature springs up or down without apparent causes, and this mobility is also found in nervous men."

This was doubtless a case illustrating sudden elevation of temperature, which may occur as a purely nervous phenomenon.

SILICATE OF SODA.

This article is now being somewhat used in the treatment of fractures. It is employed in the same manner as plaster-of-Paris, and when associated with the metallic strips, or wire strips, already mentioned, it furnishes an elegant and efficient surgical dressing. One advantage which it possesses over plaster-of-Paris is, that it is very much lighter and equally efficient.

HYPODERMIC INJECTIONS OF WHISKEY.

These injections have been used in this hospital somewhat, particularly in those cases which required the immediate influence of stimulants. Thus far no unpleasant results have been experienced in the way of abscesses or other disagreeable symptoms. Dr. McBride, House-Physician of the New York Dispensary, reports that by the administration of 30 drops of whiskey hypodermically, an effect will be produced equal to about three or four good "drinks." It has been suggested that its administration in this manner would be a matter of economy to the habitual "toddy-drinker." It may prove a valuable suggestion to administer the remedy in this manner in certain conditions.

PTYALISM.

The day of measuring the benefit attending the administration of mercury by the amount of salivary fluid poured out has passed. Salivation is believed to be entirely unnecessary, beyond slightly affecting of the gums necessary in the treatment of syphilis. Still, strange as it may seem, there are doctors at the present day who advise and practise salivation. A patient was in the hospital who had been purposely salivated previous to his admission, and at the time of his admission was in a deplorable condition. Soothing local applications and the administration of iodide of potassium are the means ordinarily employed for the elimination and treatment of local manifestations of the poison.

PHTHISIS.

The symptomatic treatment of pulmonary consumption in many cases, if not a majority, makes up the chief management of these patients. There has been a conviction in the profession that distilled spirits, or beer and ale, was, to a certain extent, a prophylactic in relation to pulmonary consumption. It is proven, however, that the hard drinker is *more* apt to get consumption. This is in accordance with the experience of some of our best observers.

With regard to the use of alcohol as a remedy in the treatment of the disease: if the alcoholic liquors will not prevent the occurrence of the disease, it would be hardly supposed that they could do much towards cure, unless they have some specific purpose to perform. By many eminent observers it is not believed that they have any such specific effect. They are not administered in this hospital as an element of the continued constitutional treatment which all the patients receive.

It is believed to be as well to fight the battle upon the ground of regimen, diet, and perhaps some medication, as upon any yet devised. Frictions to the surface of the body, generous diet, fresh air, moderate exercise, cheerful employment, moderate counter-irritation, supporting constitutional treatment, will save a very fair proportion of the cases, at least one-half, and perhaps two-thirds. Some men, whose experience has been, and continues to be, extensive, rely almost exclusively upon regimen. It has been thought that syphilis occasionally predisposes the system to consumption, especially where the disease has been treated with mercury. That this tendency is due rather to the influence of the mercury than to the syphilis, is proven by the fact that if the mercury is withdrawn in these cases, and the patients are placed upon a proper regimen, many of them get well. In the treatment, therefore, it is always proper, if mercurials are used, that they should be used with an eye to the fact that the patient is in danger of having phthisis developed under their influence.

HÆMOPTYSIS.

Almost always, sooner or later, patients suffering from phthisis spit some blood, and sometimes the hemorrhage is profuse and dangerous. There is an opinion prevailing in the minds of the people, and shared in to some extent by the profession, that hemorrhage from the lungs is an immediately serious and alarming accident. As it occurs in the greater number of cases, however, it is believed that it does no harm, but that it acts rather to relieve some local congestion, and leaves the lungs in a better state than it found them. The average cases of hemorrhage from the lungs do not seem to hasten a fatal result. The patients, perhaps, do not do better on account of the hemorrhage, but they do not do worse. This is a grain of consolation for the patients just at the time of their greatest alarm. Again, it is not absolutely true that every person who has hemorrhage from the lungs has pulmonary consumption. Violent acute bronchitis, cancer of the lung, and mechanical congestion of the lung produced by regurgitation at the mitral valve, may be attended with hæmoptysis. Profuse hemorrhage, however, it is said, does not occur in connection with the congestion dependent upon the heart-disease. But aside from these instances, hemorrhage from the lungs is regarded by some as almost

sure evidence of phthisis. In some cases where the disease affects the central portion of the apices of the lungs, and is surrounded by healthy lung-tissue, it requires close attention in the application of physical signs to recognize the diseased spot, but that it has begun in one form or another is regarded as quite certain.

℔ There was another case in the hospital calling to mind a certain point which at one time was regarded of considerable importance. The patient had had intermittent fever, and the influence which intermittent fever may exert upon phthisis was the question suggested. About forty years ago a French observer expressed the opinion that a patient who had had intermittent fever was, to a certain extent, protected from consumption. This opinion has also received plebeian support and professional sanction, and is not infrequently expressed at the present time. By many "the shakes" are regarded as the best prophylactic remedy which can be taken. But later observations have shown that in countries where intermittent fever prevails extensively (particularly observed in Holland), the people are more liable to phthisis.

Some have regarded the hectic fever of phthisis as being only a milder type of intermittent, but it is now regarded that this opinion has no foundation in fact, although the administration of quinine is the most beneficial plan of treatment. When fever is present in phthisis there is generally increased cough and expectoration.

PAIN IN PHTHISIS.

The lungs are scarcely susceptible of pain. Phthisis is almost sure in its progress to develop chronic pleurisy, which will produce pretty firm adhesions of the lung to the wall of the chest; but this chronic pleurisy is quite apt to be painless. It is thought that it is only in exceptional cases, where the pleuritic complication is more acute than ordinary, that the pleurisy accounts for the pain. In a great majority of cases, as held by some, the pain in the chest, referred to the lungs by the patient, is the result of a certain degree of weakness which develops itself in the muscles. The patients have to exert more than the usual amount of muscular force, and this is apt to be attended by pain. If the pain is pleuritic, moderate counter-irritation is serviceable in the form of flying blisters, tinc. iodine, etc., while for the muscular pains hand-friction, and this may be conjoined with some slightly stimulating and anodyne application, will afford considerable relief.

APHONIA IN PHTHISIS.

Aphonia may be hysterical; it may depend upon chronic laryngitis, and is usually dependent upon laryngitis when it appears in connection with a case of phthisis.

The opinion has been expressed by some observers that the hoarseness and aphonia of phthisis is very apt indeed to be connected with, if not indicative of, fibrinous phthisis. The old supposition that it depended upon the presence of tuberculous deposit in the vocal cords has not borne the test of recent observations, and it is now unsafe to assume that such is the pathological condition. Counter-irritation, the atomizer, and local applications by means of the laryngoscope, are the most efficient means of treating this complication.

GRAFTING.

I will describe the method of setting grafts adopted by Dr. Van Wagenen, of Bellevue Hospital. The Dr. has taken a great interest in this subject, having set over 2,000 grafts. The plan which he now follows, after trying all the plans of which he could find any account, is this: Take up a good thick fold of skin, and from a smooth portion of this fold shave a piece of skin, embracing in its thickness a few cells of the true skin, and somewhat variable in length and breadth. A good size is three-fourths of an inch in length and three-eighths of an inch in breadth.

The ulcerated surface to which they are to be applied must have the shining glue-like appearance removed from the granulations by careful wiping before the grafts are set. The grafts are then set about one inch from the peripheral edge of the ulcer, at intervals of one-half or three-quarters of an inch, forming a complete circle. As soon as set they are dressed with lint smeared with simple cerate, and over this a roller is applied. This dressing is to be removed the *next day* after the grafts are set, and be renewed every day. After the second or third day the ordinary strapping can be resorted to, and where the space between the circle of grafts and the peripheral edge of the ulcer becomes closed, another circle of grafts may be set, and so on until complete cicatrization has been secured. If these rules are strictly adhered to, scarcely a graft is lost, the firmness and rapidity with which they adhere to the granulations sometimes being extremely marked.

SEVERE LACERATED WOUND.

It not infrequently happens that the presence or absence of arterial pulsation in a limb at some point upon the distal side, in cases of severe laceration of the soft parts, is regarded as evidence of the presence or absence of an arterial supply for the limb through the torn portion. If pulsation is present, the limb may possibly not be sacrificed by an operation. If pulsation is absent, the limb, now failing to receive its vascular supply, is nominally a dead member, and amputation should be performed. This is not reliable, for arterial pulsation at a point distant from the point of laceration may be absent for 24, 36, or 48 hours immediately after the receipt of the injury, then be restored, and go on in a normal manner.

This delay in return of pulsation will often occur after general reaction has been established. Absence of pulsation should not, therefore, be received as evidence unequivocal that the avenues for vascular supply are permanently cut off.

CONVULSIONS IN BRIGHT'S DISEASE.

Whether these convulsions are dependent upon uræmia or not is a mooted point.

They are generally known, however, as uræmic convulsions. When they come, hypodermic injections of morphine have been employed of late to control them. One patient died last night who had these convulsions, but they were controlled by this means without detriment.

In puerperal convulsions the same remedy has been used, but in these cases, thus far, it has been used more as supplementary to chloroform than independently. The first onset of the convulsions was checked by the chloroform, and, indeed, the control continued for two or three hours, and then the use of morphine hypodermically served a most satisfactory purpose, and it was thought with much more safety to the mother and child than the further continuance of chloroform. The continuance of chloroform for six, eight, or ten hours, or even longer, is thought almost certainly to prove fatal to the child and jeopardize

the life of the mother. Magendie's solution of morphia is used hypodermically in doses varying from ℥ x. to ℥ xx., and repeated p. r. n.

Progress of Medical Science.

Fracture of the Clavicle treated by placing the Arm behind the Back.—M. Broca recently treated a case of fracture of the left clavicle, in which the fracture was near the middle of the bone; was oblique, from above downwards and from without inwards, the fragments riding one another considerably. After numerous plans of treatment had failed to reduce the fragments, M. Broca adopted a suggestion made last year by Dr. Michel to the Société de Chir., and placed the arm in a semiflexed position behind the back, where it was retained by a bandage for eighteen days, with the effect of completely adjusting the fractured surfaces and producing an excellent cure. For a few days longer a sling was used. The patient, a man of considerable nerve, complained of the inconvenience and pain of the method for only the first twenty-four hours.—*Jour. de Méd.*

Poisoning from Aniline Red containing Arsenic.—Dr. Jäderholm has published the following interesting cases of arsenic poisoning, occurring in a family in Malmö, Sweden:—

The family consisted of the father, mother, and three sons. The attending physician suspected poisoning, from the symptoms, but was at first unable to detect the source. It was finally ascertained that the mother had been dyeing yarn with aniline red in a saucepan, and that, without properly cleansing the vessel, she had used it for cooking potatoes. These potatoes were eaten by the family at supper, though it was noticed that they were quite red. Soon after this meal the symptoms of poisoning showed themselves. Some of the aniline red was analyzed and found to contain 6 per cent. of arsenious acid. Arsenic was also found in the stained potatoes.

Two of the children died within 48 hours, the other on the 6th day. A post-mortem examination was made. In addition to the usual inflammatory appearances of the abdominal organs, the upper surface of the liver was found in all three cases to be marked by numerous light yellow spots of various sizes, extending a short distance into the parenchyma of the organ and indicating fatty degeneration.—*Hygeia*, 6, 1873.

Valvular Diseases of the Heart.—In a paper on "Prognosis of Valvular Diseases of the Heart," published in *Saint Thomas' Hospital Reports*, Vol. 2d, by Thomas B. Peacock, M. D., F. R. C. P., the following observations are made: In reviewing what has been said as to the sources of danger in different forms of valvular disease, it will be seen that incompetency of the valves is regarded as a more serious defect than obstruction; and of the affections of the valves of the left side of the heart, incompetency of the aortic is more dangerous than the similar condition of the mitral valves. Not only does incompetency of the aortic valves occasion great impediment to the circulation, and especially an imperfect supply of blood to the brain, but as the power of the left ventricle becomes rapidly exhausted, there is danger at any moment of death by syncope. In the corresponding condition of the mitral valves, though it seriously obstructs the pulmonic circulation and occasions great visceral congestion, death is brought about more slowly as the result of the imperfect aeration of the blood and its impure condition from the state of the parenchymatous viscera, and by dropsical effusions, as sudden death is less likely to occur. As regards obstructive disease of the two sets of valves, he would reverse the order in which they are regarded as serious, obstructive disease of the mitral being apparently a more important defect than the same affection of the aortic valves. In the former condition the combined power of the left auricle and right ventricle is unable adequately to propel the blood through the left auriculo-ventricular aperture, and hence the lungs and other organs soon become very greatly engorged; while in cases of aortic constriction the left ventricle long resists the impediment, and it is only when the obstruction has become extreme, and the power of the ventricle is impaired, that the more distant organs are involved.

Dipsomania.—The letter of Dr. George Fielding Blandford, Lecturer on Psychological Medicine in St. George's Hospital, London, published in *The Journal of Psychological Medicine* for October, 1872, gives a portion of Dr. Skae's remarks on dipsomania: He would strongly urge the clear and certain diagnosis which exists between the dipsomaniac and the self-indulgent drunkard. In the former case a disease of the nervous system is present, often hereditary and displaying itself in fits of disorder; these paroxysms are preceded by general perturbation of the system. The patient is sleepless, ill at ease; he has a perspiring skin; a quick, soft pulse, and experiences a feeling of nervous prostration so great that he is driven to the use of stimulants for relief from his suffering. In the intervals such a man very frequently abhors the very sight and smell of strong drink; he is, while his disorder is in abeyance, amiable and exemplary in the discharge of his duties, and frequently possessed of mental endowments of a high order. How different is the condition of the sot who drinks for the sake of drinking, and the pleasure he derives from the gratification of his appetite! The habitual drunkard is never exemplary in the discharge of his obligations; he does not drink in insane paroxysms, followed by bitter repentance, but quietly makes up his mind that drunkenness is happiness, and indulges his vice for the pleasure he experiences in doing so. He remarks that, when treated on the "let alone" system, cases of dipsomania invariably grow worse; the constitutional force becomes impaired, and as the bodily health gives way the mental powers deteriorate. On the contrary, when the dipsomaniacal patient is subjected to restraint and proper care, he in many instances entirely recovers from his disease, and is enabled again to take his place in the commonwealth.

Magnesia as a Surgical Dressing.—The interest which attaches to the use of dry earth as a surgical dressing in connection with the recent paper by Addinell Hewson and Conner, on this subject, has induced Dr. Ohlmeyer of Weissenburg to record his experiences in the use of the carbonate of magnesia in somewhat similar cases. He has found it of value—

1. In atonic ulcers.

2. In cases where the epidermis was eroded and the subjacent tissues were the seat of pain, and were prone to subsequent suppuration.

3. In relieving the pain of inflamed wounds.

4. In cases where it was desirous to stimulate the affected surface, prevent the access of air, and limit the formation of pus. He was led, in the first instance, to try this remedy, from its well-known action in those states of the stomach where there is an excessive formation of acids. These latter uniting with the base, magnesia, are neutralized, and carbonic

acid evolved. Accordingly he believes that in exposed surfaces where the process of healing is prevented by fermentative action, this dressing is indicated. The use of it was attended with satisfactory results. The magnesia unites with the acids which form on the surface; it excludes the oxygen, forms an artificial covering, irritates the granulations, and forms a barrier against external and harmful agents.

In preparing the application he selects a fluid that will not readily oxidize. Oil answers this indication, and the kind he employs is the oil of sweet almonds. Adding to this the carbonate, he makes a tolerably fluid paste or salve. This is then spread upon linen and laid over the wound. It is held in place in the ordinary way.

Dr. Ohlmeyer also adds that he has used the carbonate successfully in facial erysipelas, when it was important to protect other patients from infection. In this latter case he used water as a substitute for oil.—*Allg. Med. Central-Zeit.*, 47, 1873.

New Method of Healing Chronic Ulcers.—Nussbaum, of Munich, has just published the results of a new operation which he has now performed in sixty cases of old extensive chronic ulcers that had defied all ordinary treatment. His plan was as follows:—

He narcotized the patient, and then made a deep incision entirely round the ulcer and about one inch from its edge. The depth of the cut, which extended to the fascia, was so great that a copious hemorrhage followed, but was arrested by small strips of lint pressed into the open wound. On the next day the dressings were removed, and the whole covered with lint kept wet in water. This same dressing was continued until the healing was well advanced. He observes that the changes which ensued during the first twenty-four hours were very remarkable. In one case, an ulcer that had furnished daily three or four quarts of a thin, filthy, and offensive discharge, gave only about a teaspoonful of a thick, white, and inodorous pus on the day after the operation. The cut, too, in all cases, began to gape open on the second day, and the circumference of the ulcer was now encroached upon by the liberated tissues, so that an immediate diminution in size of the ulcer was accomplished. With each day the ulcer continued to diminish in size, while the wounds produced by the incision increased. When the process of healing in the old ulcer was complete, the artificial ulcer was broad and hoop-shaped.

The last step in the treatment consisted in applying straps and bandages in the ordinary way.

The *rationale* of his method is simply that the incision severs large numbers of dilated vessels that have furnished the ulcer with nourishment. The only source of supply left is the diminutive vessels which reach the surface from beneath. The material supplied by them is small in amount, and has time to undergo change into formative cells and connective tissue without being cast off at a too early stage by a new layer of exudation pressing it from behind; for wherever we have thick, creamy, and white or laudable pus, there we have new formations going on, accompanied by the development of connective tissues and the formation of young vessels, as in every healthy sore. It is not claimed that this method will insure the patient against a relapse; but that the interval will at any rate be longer, and the time occupied in effecting a cure much shorter, than under the usual plans of treatment.

In cases where the loss of blood attendant on the operation would be a contra-indication, the author transplants skin-flaps. Such ulcers are usually upon the leg, and the affected limb is obviously unable to furnish the material. He therefore binds the legs firmly together, and dissects up from the sound one a sufficient flap for his purpose. This he leaves attached by the edge, and carries it over to the surface of the ulcer, so that a bridge is formed. The edges of the ulcer are then freshened, and the flap sewed on its place. Two difficulties, however, are met with which are a great source of embarrassment.

In the first place, the flap shrinks; and in the second, the ulcer grows larger when the edges are freshened. For example, an ulcer measuring eight inches square, is to be covered in the manner described. If a flap of the same size be removed, it will be found to have shrunk to five inches square; and if the edges of the ulcer be freshened, it will be found to measure twelve inches square. So that instead of the proportion of eight to eight being preserved, we shall have five to twelve. To obviate this serious source of difficulty, Thiersch recommends that the parts to be operated on be prepared in advance by fourteen days' treatment, to make them more self-dependent, stronger, and juicier. His plan is this: He proceeds as if to remove a flap of the required size, but completes only two of the parallel incisions, and leaves the flap attached above and below; he then passes the handle of his scalpel under the centre of the flap and inserts a piece of lint. In this way the nutrition of the part is diminished, but it does not shrink, but on the contrary, becomes hypertrophied. At the moment of operation he severs one of the attachments, and then brings the flap into its proper place. When complete union has taken place, the remaining attachment is severed and the limbs are liberated.

The Effects of Tobacco Smoke.—M. Gustave Lebon, of Paris, has recently issued a treatise upon the Chemical and Pathological Effects of Tobacco Smoke upon the Human System, the author having first constructed a variety of apparatus by which he has been enabled, he states, to collect and show with exactness the various elements of smoke which condense and deposit themselves on the organs of the smoker. One hundred grammes—1.300 grs., English troy—of French tobacco furnish 0.550 grs. of nicotine and 0.490 grs. of ammonia. Tobaccos of the Levant are the least dangerous, some of them possessing but a small trace of nicotine. In small doses, he says, tobacco smoke instantaneously excites cerebral activity and the intellectual forces, and facilitates digestion. In excessive and frequently repeated doses, it produces difficulty of digestion, benumbed intelligence, and clouded memory.

Monads in the Metastatic Abscesses of Living Persons.—A striking case is published by Vogt, of Greifswald, sustaining the views held by Recklinghausen, Waldeyer, Klebs, and others, that the living organisms frequently found in the fluids of persons suffering from infectious diseases are of themselves the excitants of disease. The experiments, with the conclusions drawn, were as follows:—

1. A recent abscess of the wrist-joint in a pyæmic patient was opened, and the putrid matter, when examined microscopically, showed abundance of monads in active motion. Subsequently, both the fluid in the opposite healthy joint, which was apparently healthy, as well as the blood of the patient, were examined, and nothing more than an occasional monad was found in either of them. No bacterias were found, and the author believes, with Orth, that when they occur it is only in disorganized preparations.

2. The same experiment was performed daily until the death of the patient, which occurred five days later, and the results were uniformly the same.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month, by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, November 1, 1873.

THE RATIONAL STUDY OF DISEASE.

THERE is nothing which gives greater evidence of progress in medicine than the results which have grown out of the present method we have of studying disease. Our positive knowledge of the laws which govern disease has been very greatly advanced by experiments in physiology and by discoveries in pathology; but the aids thus afforded have not had that bearing upon the prognosis and treatment which plausible theories and apparently legitimate deductions led us to expect.

We cannot get a better appreciation of our present stand-point than by comparison of the results of the experiences of the past twenty-five or thirty years. It may be claimed that we have not made any marked advances in the therapeutics of disease during this period. This assertion has a foundation in truth, if we assume that the patient's treatment is measured by the amount and variety of medicines taken. We have learned to give very little medicine, but we claim this to be the legitimate result of a more thorough study of the laws of disease, and a better appreciation of the significance of symptoms.

During the period named, the tangible results of progress have been seen in the departments of pathology and diagnosis. If we look at the subject in a somewhat different aspect from what it is generally viewed, we shall find that pathology, with its great claim to positivism, and diagnosis, with its nicely drawn distinctions, while it has advanced us in some directions, has misled us in others. When pathology, with the aid of the microscope, taught its lessons a quarter of a century ago, and when diagnosis, with the stethoscope, the ophthalmoscope, and all the instrumental appliances now so well known to all, laid down rules for every imaginary emergency, it seemed as if the science of medicine would soon become an exact one. Experience has, however, taught us many a lesson since, and proved the futility of pinning our faith to theories. The truth is now apparent that we expected too much of pathology; that our prognosis and treatment, based upon purely pathological notions, was far from being absolutely correct; that we have had to supplement such knowledge with the study of disease *per se*.

When the microscope came into use, and this is within the recollection of very many of us, there were no bounds to the expectations of those who were able to use the instrument. Everything was then examined by the microscope, and nothing was considered complete in the history of the case if a microscopical examination of some sort or other had not been made. The certainty with which cancer could be diagnosticated was a matter particularly dwelt upon, and early in the history of microscopical examination we find the pathognomonic cancer-cell figuring quite conspicuously. We should not like to say how many hundreds of tumors were doomed to extirpation on account of the presence of this cell, and how many unfavorable prognoses were given to the poor patients who during the first furor of microscopical examinations were unfortunate enough to have any extra growths about their bodies.

We knew of one gentleman in this city who was one of the first to use the microscope for pathological research, who found cancer in every growth that was brought him. There was, in fact, either an epidemic of cancer for his especial benefit, or the microscope failed to show him anything else. His aptitude in finding these kind of cells became a standard joke among his friends until they discovered to their chagrin that every piece of meat they could obtain from their butcher's stall was afflicted with the disease. And, after all, the difficulty was not so much due to the poor microscope, as it was to the wrong use of the brains at the end of the cylinder.

We give every credit to the microscope for its research, but its fault has been that from the start it has striven to prove too much, to revolve every theory of disease, every prognostication of a result, upon the centre of some cell, and if, perchance, by a continuance of the investigations in this line the cell split, so much wider field there opened for microscopy.

It is needless to say that very many ludicrous mistakes were made in those days by the best microscopists. Every one who has used the instrument for the past fifteen years can bear us out in the statement, that there are many patients still living who ought to have died long ago with cancer and Bright's kidney. We have made such mistakes, and have done it under the full support of the then accepted law of microscopic pathology, and the physician who has not, either did not have an instrument at that time, or his opinion was never asked, or his solemn verdict never recorded.

The microscope, like every other useful instrument, is beginning to find its place in the study of disease. Instead of being the ultimatum in the diagnosis and prognosis, it is merely an aid. The manner of studying microscopic growths has entirely changed from what it once was. Instead of deciding upon a single cell that was scraped from the surface of a tumor, or contained in the so-called cancer-juice, we make sections of tumors; the significance of cells is lost in the study of the relations which these cells hold to the surrounding tissues, the arrangement of the alveoli, and, more than all, the clinical history of the growth itself. Tumors which were considered cancerous fifteen and twenty years ago have now another name—are divided up into classes more in accordance with their clinical history; and the careful observer is not apt to be so positive as heretofore in regard to the absolute certainty of the return of a particular kind of growth.

What is true of microscopy is true of every other department of investigation which in times gone by was considered positive. Positivism has reacted into conservatism, and conservatism finds it a safer plan in making a prognosis or in settling upon a rational plan of treatment to base an opinion upon the results of the study of disease as a whole. It is in this respect that we have made great progress. We are led to respect every means of investigation, but we are inclined to group the evidence rather than pin our faith upon a single microscopical cell, a particular pitch in the respiratory murmur, or a few casts in the urine. We have discovered that it is necessary to take many other circumstances into account, and, while giving each its relative significant value, to found our opinions upon a general clinical study of a particular case.

The signs of the times are already manifest in the different departments of medicine and surgery. By this study of disease in a general way we are beginning to show an antagonism against some of the positive doctrines of pathology. Take, for instance, Bright's disease of the kidneys. Experience has shown us that patients with casts in their urine live on in spite of us. So striking is this fact to many observers that not a few have boldly asserted that we shall have to unlearn much that we have already learned in regard to the prognosis of these affections. Others, with equal experience, say that we have been placing too much confidence upon urinary examinations in our prognoses; that the real significance of fibrinous casts is not yet appreciated. It will be recollected that in a recent number of THE RECORD a surgeon of this city was bold enough to operate upon a patient with waxy kidney, in the belief that the operation would remove the cause of the renal difficulty, and at last accounts the patient was doing well. Not long ago the existence of a waxy kidney was considered the best reason why no operation should be performed.

How is it in cases of heart disease? We discover that, despite our former notions in regard to the fatality of this affection, very many cases of hypertrophy and valvular lesion live to a good old age and generally die of some other affection. We might go on with the enumeration of similar diseases thought to be absolutely fatal in times gone by, but we imagine we have said enough to prove that the investigation of disease is beginning to take a more rational turn; that disease as such is being more and more studied from a purely clinical point of view. This tendency of study has a very healthful influence upon our therapeutics of disease and our prognosis of results. We are beginning to be more cautious in the expression of our opinions in reference to both of them, at the same time we are stimulated to think and act more as philosophers than as hobbyists.

We were accustomed to smile pityingly when our patients preferred their old doctor because he understood the constitution of their family. Now we are beginning to see that there is more in this than a mere notion. We are appreciating what modification particular constitutions have upon the prognosis and treatment of particular disease; in other words, we find it interesting to study that element in our cases spoken of as an individual tolerance of disease. We were pleased to hear at a recent meeting of the County Society a paper upon this subject by one of the leaders of medical thought in this country, in which due importance was given to the effect which treatment and prognosis should have upon a knowledge of this fact. Many of our readers who attended lectures in this city may recollect the story of the Shaw family, so well told by one of the professors of surgery, and can see its bearing in connection with the subject of family constitution. The narrator stated that he was once called into the country to see a case of severe injury. From the account which he received it appeared that there was no chance for the poor patient—he was seemingly crushed to pieces. On his way thither the surgeon was asked his destination. The answer being given, the inquisitive rustic significantly said, "He is a Shaw! Well, I don't care how bad he's hurt, you can't kill any of them. For you see that family have got the constitution to stand it."

Not only do we pay attention to the modifying influences of family history, but we are studying diseases in still broader relations; we are acquainting ourselves more thoroughly with climatic influences, the laws of communities, social surroundings, meteoric and atmospheric changes; in fact we are developing a taste for the study of disease in all its phases and in all its intricate relations to circumstance and individual.

We can see in this a tendency to liberal ideas of treatment, to a settled antagonism against one-ideaism. The day for the man with one remedy has gone by. If the enthusiast for a particular plan of treatment wishes his advice to be heeded, his opinions respected, he must not insult the judgment of his professional

brethren by ignoring the existence of the grand principles in the management of disease which have now become the accepted canons of the church medical.

We say that the present rational system of studying disease is a healthful sign of progress, and tends to give to each method of investigation its due and relative importance, neglecting nothing and making use of everything which has a tendency to make us discriminating and intelligent practitioners in the widest sense of the term.

THE YELLOW FEVER IN THE SOUTH-WEST.

THE reports from the yellow-fever districts of the South-west are very encouraging. The number of cases are steadily decreasing, and the death-rate is growing less and less, day by day. On the eve of the battle with this dreadful scourge, we might refer to the many heroic and life-sacrificing deeds of the brethren of our profession in those districts, but this is not necessary. Every one expected that such a record would necessarily have to be made, and no one has been disappointed in such expectations. Our greatest pride has always been to relieve needy suffering, and it would be strange indeed if we neglected such golden opportunities for gratifying it. The thanks of humanity are also due to the noble labor of the clergymen, and the Christ-like efforts of the various benevolent associations. "Inasmuch as ye have done it unto the least of these my brethren, ye have done it unto me."

ARTICLES IN OUR EXCHANGES.

ANATOMY AND PHYSIOLOGY.

Relation between the opening of the Eustachian tube and the velum palati. MICHEL. *Berl. Klin. Wochenschr.*, 34, 1873.

Termination of nerves in striated muscular fibres. ARNDT. *Archiv f. Micros. Anat*, ix., 3.

On the pecten of the eye of birds. MIHALKOVICS. *Ibid.*

The glands in the heads of snakes. LEYDIG. *Ibid.*

The glands in the pelvis of the kidney. EGLI. *Ibid.*

On Infusoria. BÜTSCHLI. *Ibid.*, ix., 4.

On the embryology of vertebrates. GÖTTE. *Ibid.*

Emigration of the blood corpuscles from the vessels of the Frog. SCHMUTZIGER. *Ibid.*

On striated muscular fibrillæ. WAGENER. *Ibid.*

The posterior layer of the human iris. GRUENHAGEN. *Ibid.*

On tactile corpuscles and the rete Malpighii. LANGERHAUS. *Ibid.*

The skin of the larvæ of Salamandra maculosa. *Ibid.*

The external coverings of reptiles and amphibians. LEYDIG. *Ibid.*

Schobl's investigations on hair. STIEDA. *Ibid.*

Entire absence of internal generative organs. M. DE F. ALENCAR. *Gaz Med. da Bahia*, 143, 1873.

Double generative organs. C. DE PINEIRO. *El Anfit. Anat.*, 15, 1873.

Double generative organs. PULIDO. *Ibid.*

How are deciduous teeth cast off? CHASE, HENRY S. *Missouri Dental Journal*, May, 1873.

Dental physiology. CHASE, HENRY S. *Ibid.*

Novel case of sneezing. *St. Louis Med. and Surg. Journal*, June, 1873.

First phases of living forms. HOUGH, J. B. *Cincinnati Lancet and Observer*, July, 1873.

Tattooing the cornea. WILLIAMS, H. W. *Boston Med. and Surg. Journal*, July 3.

Notes on the pneumogastric. ADAMS, J. F. *Ibid.*, July 24.

Report on physiology. BOWDITCH, H. P. *Ibid.*

SURGERY.

Contribution to resections. BRYK (conclusion). *Archiv für Klin. Chir.*, xv., 3, 1873.

Anatomy and surgery of tumors. *Ibid.*

1. Two cases of granulomata from bone.

2. Two cases of joint resection for neoplasms. VOLKMANN.

Pathology of pernicious traumatic fever. FALK. *Ibid.*

Extirpation of laryngeal polypi after incising the crico-thyroid membrane. BURROW, Jr. *Ibid.*

Relation between cyclamine and septic phenomena and the appearance of low organisms in the higher orders of animals. VON MOSENGEIL. *Ibid.*

Contribution to macroglossus. GIES. *Ibid.*

Remarks on the question of amputation. WAHL. *Ibid.*

Experimental surgery. *Ibid.*

1. On so-called club-shaped and spiral fractures. KOCH and BIERMAN.

2. The changes which are produced in the parenchyma of the lungs by certain mechanical and chemical irritants. KOCH.

Amputation with subsequent subperiosteal resection of the bony stump. VON MOSENGEIL. *Ibid.*

Large vascular trunks ligated for hemorrhage following gunshot wounds in 1870-71. MÜLLER. *Ibid.*

Resuscitation by the induced current in a case of tracheotomy. MÜLLER. *Ibid.*

Observations on the energy of the temperature during fever from an infected wound. VON MOSENGEIL. *Ibid.*

Cases in which portions of the body have reunited after complete separation. ROSENBERGER. *Berl. Klin. Wochenschr.*, 31, 1873.

Electrolytic treatment of naso-pharyngeal polypi. BRUNS. *Ibid.*, 32, 1873.

A trocar for paracentesis thoracis. VON HEUSS. *Ibid.*, 33, 1873.

Curious injury to the great toe KÜSTER. *Ibid.*, 34, 1873.

Resection of the hip-joint. WOLFF. *Ibid.*, 36, 1873.

From Prof. Podrazki's clinique in Vienna—stricture of the œsophagus—œsophagotomy—death. WEICHSELBAUM. *Wiener Med. Wochenschr.*, 35, 1873.

On staphylorraphy. FRANK. *Med. Corr.-Blatt.*, 30, 1873.

Treatment of frost-bite. BERGMANN. *Dorpat Med. Zeitschr.*, 2, 1873.

Ossifying periosteal sarcoma of the scapula—resection. SANTESSON. *Hygeia*, July, 1873.

Tumors of the mamma—their diagnosis and treatment. SIERRA Y CARBO. *El Anfit. Anat.*, 14, 1873.

The bite of the scorpion. J. GUILLEN. *Ibid.*

Noiret's new apparatus for fracture of the leg. *Ibid.*

A mechanical appliance to restore the features after the excision of an osseous tumor of the superior maxilla. KEITH, H. H. *Missouri Dental Journal*, May, 1873.

Theoretic considerations in relation to the treatment of shock. PRINCE, DAVID. *St. Louis Med. and Surg. Jour.*, June, 1873.

Nævus. POOLEY, J. H. *N. Y. Med. Jour.*, June, 1873.

Gunshot wounds of the head. WOODBURY, H. E. *Phil. Med. Times*, June 21, 1873.

Paracentesis thoracis. LAMBERT, W. *Canada Lancet*, July, 1873.

Skin-grafting. TOLAND, H. H. *Western Lancet*, June, 1873.

Compound fracture of the femur; amputation through the trochanter. Anomalous distribution of arteries. CLARK, H. H. *The Clinic*, July 19.

The growth and reproduction of bone. LINDSLEY, VAN S. *Nashville Jour. Med. and Surgery*, July.

Report on Tennessee surgery. BRIGGS, W. T. *Ibid.*

Arresting hemorrhage from deep cavities. LENTE, FRED. D. *Am. Jour. Med. Sciences*, July.

Compression of the brain. GROSS, S. W. *Ibid.*

Absorption of two inches of the shaft of the femur. PADDOCK, F. A. *Ibid.*

Amputation through the knee-joint. ERICKSON, G. *Ibid.*

Bilateral Dislocation of the fourth cervical vertebra forwards; death in twenty-five and a half hours; *post-mortem* examination. FARQUHARSON, R. J. *Ibid.*

Congenital fracture of clavicle. DE LUNA, A. B. *Ibid.*

Diffused false traumatic aneurism of popliteal artery; ligature of femoral; recovery. MONETTE, GEO. N. *Ibid.*

A case of amputation of the leg without hemorrhage, by reason of thrombosis. SALE, E. P. *Ibid.*

Tracheotomy, with a report of two cases. CUSHING. *Pacific Med. and Surg. Jour.*, June, 1873.

Malignant disease of penis following phagædenic ulcer; amputation; recovery. WYMAN HAL. C. *Med. and Surg. Reporter*, June 7, 1873.

Contributions to the history of the surgery of Tennessee. BAILEY, F. K. *Nashville Med. and Surg. Jour.*, June, 1873.

Fracture of the skull. Meningitis. MCCORMICK, J. N. *Am. Practitioner*, July.

Neurotic tumor of the popliteal nerve; amputation; recovery. MONETTE, GEORGE N. *Ibid.*

Plastic surgery. BRIGHAM, CHAS. B. *Western Lancet*, July.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, September 10, 1873.

DR. T. C. FINNELL, Chairman *pro tem.*

AMYLOID DEGENERATION OF CHOROID WITH INTRA-OCULAR HEMORRHAGE.

DR. H. KNAPP remarked that the specimen of amyloid degeneration of the eye, with intra-ocular hemorrhage, presented at the meeting of the Society last June, had been more carefully examined, as was also the case with the condition of the patient. In consequence of said examination he was ready to substantiate the assertion that the disease in the eye was limited to that organ alone, and further, that the degeneration was confined to the arteries of the choroid. He was not aware that there had been a record of any similar case.

IRIDO-CHOROIDITIS—AN INTERESTING POINT IN DIAGNOSIS.

Dr. K. next presented an eye which he had removed that afternoon, and gave the following history: The patient, aged thirty, had lost his right eye when a child. The organ seemed to have shrunken from the beginning, but kept quiet until three months ago, when

it became inflamed, reflecting irritation to the opposite eye. The latter eye, although found healthy, showed great derangement in its function. The damaged eye proved on examination to be the subject of irido-choroiditis, with ossification of the choroid, hence its removal. In a clinical point of view the specimen was of much interest as proving the certainty of diagnosing ossified choroid by the touch. This was done by simply pressing the moistened finger upon the outer and posterior aspect of the ball and discovering the sharp anterior edge of the bony zone situated just posterior to the ciliary body. This clinical fact was very satisfactorily demonstrated on the specimen as exhibited to the Society.

SPINDLE-CELL SARCOMA OF IRIS.

He exhibited a second specimen, consisting of tumors of the iris, which had been presented at a previous meeting, but which at the time was unaccompanied with a complete microscopical examination. Since that meeting he had had an opportunity of making such an examination, and wished to report the results. The tumors were found to be situated in and upon the anterior layer of the iris, the larger upon the superior portion, the size of a small pea, the others on the inferior portion, the size of millet seeds. The large tumor encroached upon the middle layer of the iris, but all presented the same microscopical characteristics, viz., those which belonged to spindle-celled sarcoma. He remarked that he had only seen another tumor of the sort in that locality on record. The specimens were exhibited under the microscope for the inspection of the members.

CHRONIC INFLAMMATION OF ANKLE-JOINT.

Dr. Sayre presented the lower portion of the leg, with ankle-joint, removed by amputation from a negro two weeks before at Healing Spring, Va. The man was a patient of Dr. Gilmore, of that place. Two years before he had sprained his ankle while porter of the hotel. He was able to do his work during that summer, but the following winter the ankle became very painful, which obliged him to keep quiet. During the greater part of the past year he had been confined to his cabin, an apartment only twelve feet square. When seen by Dr. S. the ankle was enormously swollen, puffy, and contained four or five fistulæ communicating with the joint, and from which unhealthy pus was discharged. His constitution had suffered very much in consequence, so much so that he was considered by his medical attendant almost past recovery. The limb was amputated, giving the patient the "poor man's leg," and at last account the wound had healed kindly, and for the most part by first intention.

On opening the joint the whole surface was denuded of synovial membrane and cartilage, and presented the peculiar red appearance common to chronic inflammatory disease, the result of local injury. At the posterior surface the articulating surface of the astragalus was necrosed, but in other portions of the joint there were evidences in the shape of granulations of the attempt on the part of nature to repair the mischief. The specimens, as had many others which Dr. S. had had the opportunity of exhibiting, proved that these troubles in the joint were of traumatic and not of scrofulous origin. In similar cases, but in those in which patients were surrounded with proper conveniences, he had made it a practice to open the joints, giving exit to the pent-up pus, gouging out the dead bone, and establishing free drainage. The treatment had been followed with such success that he had adopted it to the exclusion of other means.

Stated Meeting, Sept. 24, 1873.

Dr. E. L. Keyes, Vice-President, in the Chair.

STOMACH FILLED WITH FÆCAL FLUID, AND NO SATISFACTORY EXPLANATION.

Dr. R. E. Van Geison presented a stomach, with the following history:—

M., aet. 55, had suffered for years from severe indigestion, abdominal pains, eructations, occasional vomiting, loss of appetite, etc. Last spring symptoms increased, he grew more and more emaciated, when occasional fever and chills set in, which were controlled with full doses of quinine after a few weeks.

Aug. 7th, symptoms of retention of urine and pain in rectum set in, followed by complete retention, which lasted for over a week. Suddenly, after a gush of pus from the bladder, all these local symptoms ceased.

Diagnosis.—Abscess of prostate from low state of system, there being no obstruction of urethra whatever.

After this his digestion improved a little until Sept. 14th, when diarrhœa troubled him. Sept. 17th, he complained of severe pain in right side of chest. Evening of Sept. 18th, stercoraceous vomiting set in, the bowels still acting until death from exhaustion at 4 P.M., Sept. 20th.

Post-mortem.—Held Sept. 21st, 19 hours after death. On opening abdomen nothing could be seen excepting the stomach, and a very small loop of small intestines on the left side. The stomach fills the whole abdomen, and is full of fæcal fluid. It measures more than 15 inches in length. Small intestines found, on raising the stomach, entirely collapsed. Liver and kidneys normal. Intestines near sigmoid flexure thick and congested; near transverse colon, appearance of beginning ulceration in two or three parts. Intestines carefully examined revealed no perforation, as was expected. The prostate gland was normal in size.

LITHOTOMY FOLLOWED BY SLOUGH, PERFORATION OF THE RECTUM, AND URETHRO-ANAL FISTULA.

Dr. C. K. Briddon presented a specimen of stone, with the following remarks: I have here the fragments of a single calculus of unusually large dimensions. The gentleman from whom it was removed was twenty-eight years old; he married at the age of twenty-five, and began to suffer from symptoms of stone three months afterwards. For a period of eighteen months he was under the charge of a man who assured him that he would dissolve his stone by medicines administered by the mouth. He then consulted a regular practitioner, who brought him to my office on the thirtieth day of May. His meatus was too small to admit a small lithotrite, which I regard as the best instrument for making such examinations, inasmuch as it enables you to measure the dimensions at the same time, and I used Sir Henry Thompson's searcher. The stone was readily detected, lying, as large stones usually do, near the neck of the bladder. From the sound on percussion I judged it to be soft, and from the impression made upon my fingers, carrying the instrument over its surface, it was considered to be large.

His urine contained one-twelfth its volume of ropy mucus. Specific gravity 1.019. Reaction acid, no deposit of albumen on application of heat and nitric acid, and on examination by the microscope presented abundance of pus corpuscles, but no casts.

Lateral operation of lithotomy was done on the 14th day of June, in the presence of Professors Chas. A. Budd, Erskine Mason, Drs. Quackenboss, John

Howe, Robt. W. Taylor, and others. The first incision was arrested by annoying expulsive efforts made by the patient to empty the contents of his rectum, which was supposed to have been emptied by a dose of oil administered on the night of the thirteenth, and an enema one hour previous to the time appointed for the operation. As soon as these muscular contractions had quieted down under more profound anæsthesia, an entrance was made into the bladder, and a finger detected a very large single calculus. It could only have been removed entire by an unwarrantable amount of traction, and it fortunately broke under the pressure of the forceps. By the finger I estimated its diameters at two and a half inches by two. It took some time to remove all the fragments by the scoop; but this was thoroughly done, and the bladder was well irrigated with tepid water.

A considerable amount of the calculus was lost in blood clot. The portion I preserved, after drying, weighed twelve drachms and thirty-four grains. Its composition was phosphatic, with uric acid nucleus, and if we recognize the fact that such concretions are very light, we may form a pretty fair estimate of its size. For several days he had considerable abdominal pain, tympanitis, and tenderness, that necessitated a pretty free use of opium; but his pulse never rose above 110, and his temperature never exceeded 100° Fahr.

On the twentieth he complained that the wound smarted and felt more sensitive than it had done. It looked well, but the discharge was offensive and contained some small shreddy sloughs. In the evening I was informed by his nurse that flatus had escaped by the wound, and as it was now the seventh day, and the bowels had not moved, I directed the parts to be inspected during the act of defecation. I supposed that sloughing and perforation of the gut had occurred from the unavoidable bruising of the wound in the extraction of the stone. There certainly was no wound of the rectum during the operation, for no escape took place for the seven days following.

21st, 6 A.M. Was summoned to his bedside and found himself and attendant alarmed by the fact that his bowels had moved, and that a part of the contents had escaped through the wound. After verifying this state of affairs, I introduced my left forefinger into the rectum, and feeling a perforation just above the sphincter, about one-sixth of an inch in diameter, I passed a blunt-pointed curved bistoury through the wound and fistulous opening, and divided the sphincter.

His bladder would now retain four or five ounces of urine, but it all passed through the wound, and being very offensive I introduced a silver catheter and injected it with carbolic acid, half a grain to the ounce.

22d. His condition, local and general, was all that could be desired, but towards evening suffered great pain from the passage of three large solid scybala. They were more like enteroliths than anything else, and I was much surprised that their expulsion was not followed by hemorrhage. To get rid of any that might remain, and to prevent the formation of any more, I directed half a tumbler of Frederickshalle every morning.

23d. It is probable that the fistulous communication between the rectum and the wound was not entirely above the internal sphincter, inasmuch as he has entire control over his evacuations.

From the last date until the fourth of July, he continued steadily to improve. Two-thirds of the contents of his bladder passed per urethram; he had no trouble with his bowels, and the wound was nearly healed. On the night of the fourth, he sat for some time in a draught between two windows, and on the following morning complained of muscular pains and headache; his temperature was increased, and his pulse was accelerated. For this condition I prescribed five grains of quinine night and morning. Febrile movement passed away, and nothing occurred until the 8th, when he had a pretty severe attack of renal colic, which lasted about two hours and did not recur.

During my absence in Canada he had an attack of retention, followed by expulsion of two small calculi. The largest was smaller than a pea, and their passage excited an attack of epididymitis, which was attended to by Dr. Mason. On my return to the city I found the patient in very good condition, and on the 28th he was attending to his duties as book-keeper in one of our leading hotels. He had complete control over his rectum; perineal wound was all healed; but there still remained a fistulous communication between the membranous urethra and the rectum, or its anal aperture. The exact position of this opening was about the superior border of the internal sphincter, one inch and a quarter from the verge of the anus. There had evidently been considerable loss of tissue. The wall of the extremity of the rectum appeared to be in close apposition with the floor of the urethra, and the length of the fistulous aperture consisted of these two walls, without the interposition of connective tissue, and measuring probably not more than two lines. Its diameter was large enough to permit the escape of at least a fourth part of the urine. The margins of this aperture were touched first with the strong tinct. of canthar. of the Pruss. Pharm., and subsequently with nitrate of silver. It was not a suitable case for the actual or galvanic cautery, which would in all probability have caused still further destruction of the thin walls that surrounded the opening. He was directed to empty his bladder with a Mercier's catheter for a month or longer. Catheterism had to be discontinued on account of the supervention of inflamed testes, which subsequently suppurated, but it is at present being carried out with better prospects of success.

I present a diagram which illustrates the position of the urethro-anal fistula.

SPECIMEN OF CANCER OF THE STOMACH.

DR. BRIDDON presented a second specimen, and said: The gentleman from whom the specimen was removed came under observation in the month of April of the present year. He was sixty-seven years old, married, and the father of a family of healthy children; no disease such as that to which he succumbed had been known in any of his ancestors. He was a man of temperate habits, had always enjoyed good health, and first complained of symptoms, which were referred to his stomach, in the month of October, eighteen hundred and seventy-two. These symptoms were regarded as functional derangements, and, in fact, when I first saw him there was absence of all the characteristics of malignant disease but anorexia and marked progressive emaciation. There was at that time no vomiting and no epigastric tumor, nor did he suffer from pain. Six weeks before his death he was annoyed by eructations and vomiting, and a tumor could be felt in the usual site. Autopsy was made about eighteen hours after death. All the abdominal viscera except the stomach were found in a healthy condition; that organ was found collapsed, and in size and form resembled a large kidney. The whole of its structure appeared to be infiltrated with the morbid deposit, which had also encroached upon the lesser omentum. Around the cardiac orifice the deposit was an inch thick, along the lesser curvature less, and at the pylorus, which was

contracted to about the diameter of the third of an inch, the thickness was about three-quarters of an inch; on the internal surface of the anterior wall was a small fungous growth about the size of a cranberry.

Correspondence.

AMMONIA AND ITS USES:

WITH MORE PARTICULAR REFERENCE TO THE SPIRITUS AMMONIÆ AROM. OF THE PHARMACOPŒIA.

To the Editor of The Medical Record.

SIR:—Ammonia in the form of the aromatic spirit is not now very frequently used, it being more customary to prescribe the carbonate. Related to this fact, and perhaps accounting for it, is another, and one of some importance.

The formula for the preparation of sp. ammon. arom. in the present Pharmacopœia is not the same as the one in former use, as that in the fifth edition for example. In this latter the spirit is directed to be *distilled* agreeably to the following formula:—

℞ Muriate of ammonia, five ounces.
Carbonate of potassa, eight ounces.
Cinnamon and cloves, of each two drachms.
Lemon peel, four ounces.
Alcohol and water, each five pints.

Mix and distil seven pints and a half.

The formula of the present Pharmacopœia is as follows:—

℞ Carbonate of ammonia, one ounce.
Water of ammonia, three fluid ounces.
Oil of lemon, two drachms and a half.
Oil of nutmeg, forty minims.
Oil of lavender, fifteen minims.
Alcohol, a pint and a half.
Water, a sufficient quantity.

Dissolve the oils in the alcohol and add to the solution of ammonias.

The superiority of the old process over the present one is both theoretically and practically certain. It is theoretically certain, because in the one case we have a fixed, determined salt of ammonia in solution; whilst in the other we have not. What we desire to have is a solution of a mono-basic carbonate, and by the old process we obtain this. But by the modern process who shall tell *what* we get?

Carbonate of ammonia is, to be sure, ordered, but this may be, judging by the specimens one sees, either a carbonate (sesquicarbonate) or a bicarbonate—more likely the latter than the former, but probably a mixture of both. Now the bicarbonate is entirely useless, if not worse than useless. Again, as is very truly remarked by the editors of the Dispensatory, "the omission to distil is a defect; for if the *volatile oils* contain impurity the preparation will be colored and turbid." But, more important than this, the medicinal effect will be more unreliable, if not positively harmful. There is still a third objection—the larger percentage of alcohol in the present process. In the old formula the water and alcohol are in equal proportions; in the new there are three parts of alcohol to only one of water.

So much for the *preparation* of the medicine. But few words will suffice in speaking of its medicinal virtues, for they are well known. If we could obtain the spirit of ammonia made according to the old form it might prove to be one of our most valuable remedies in those complaints incident to our hot summers. We are all familiar with the great fatality of cholera infantum, and of the inefficacy of all medication in a great number of cases. This being so, there is perhaps no new remedy that could be suggested, or come to us with better credentials, than the old aromatic spirit of ammonia. It would be well at any rate to give it a trial, especially where the case is passing into a state of collapse. From five to ten drops might be given every half hour in a little water. The dose and times of administration, however, would be varied according to the discretion of the physician. When the more threatening symptoms subside, the remedy would then be discontinued or given at longer intervals. As an external remedy it might also be useful by sprinkling a teaspoonful on a flannel previously wrung out of hot water and applied to the abdomen. In addition to the use of this remedy in the diseases tending to collapse, it is well known to be a valuable antispasmodic, affording relief more quickly and surely than any other.

The great desideratum is to secure the spirit prepared agreeably to the old formula.

Geo. Herring, M.D.

THE DOUCHE IN AFFECTIONS OF THE THROAT.

To the Editor of The Medical Record.

SIR:—I desire through The Record to call the attention of the profession to a means of treating diseases of the throat that I have found useful, and which, I believe, is not generally employed.

The physician that treats largely throat affections is often asked by his patient if he himself cannot do something in the way of treatment to hasten recovery. To prescribe a gargle is usually sufficient to satisfy this desire; but every physician knows that, as usually performed, it is of almost no value, and even when most successfully accomplished its range of utility is limited to a very small field. To supply this deficit, and at the same time to put something useful and practical into the hands of my patient, I have used for several years a throat douche. The plan occurred to me after listening to a paper* read by Dr. Emmet, wherein he referred to the utility of the hot-water douche in certain uterine affections. Though I first contemplated its use only in acute inflammations, I have found its employment in chronic affections very advantageous.

To carry out this plan I have found the fountain syringe a most convenient receptacle and conductor of the fluid to be used. This being filled and placed at a convenient elevation, the patient or an assistant takes the delivery pipe, which is provided with a glass nozzle with one or more perforations, and, the head being bent far forwards, the mouth widely opened, and lungs well filled, carries it far towards the back of the mouth, and allows the fluid to flow against the different walls of the pharynx. Before expiration is permitted, the stream of fluid is shut off by compressing the rubber tubing, when the operation is again repeated, making each séance as long as the nature of the disease requires. Any fluid, medicated or not, which the physician desires to bring in thorough contact with any part of the cavity of the mouth, can be used in this way.

In a recent number† of the *Bull. Gén. de Thér.*, Dr.

* Read before the Med. Library and Journal Ass., March 10th, 1871.
† June 15, 187[illegible].

A. Cousin advocates the treatment of granular pharyngitis by a very similar principle.

In exceptional cases, when, by reflex action, the stomach is easily affected, a stream of fluid impinging against the pharynx will sometimes excite retching, but cautious perseverance will usually overcome this tendency in a very short time.

R. P. LINCOLN, M.D.

22 WEST THIRTY-FIRST STREET, Oct. 1, 1873.]

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from October 5, 1873, *to October* 18, 1873.

GHISELIN, J. T., Surgeon.—Relieved from duty in Dept. of the Columbia, and ordered to Dept. of Texas. S. O. 206, A. G. O., October 15, 1873.

MCKEE, J. C., Surgeon.—Relieved from duty in Dept. of the East, and ordered to Dept. of California. S. O. 197, A. G. O., October 6, 1873.

ALDEN, C. H., Surgeon.—Relieved from duty in Dept. of the Lakes, and ordered to the Dept. of the Columbia. S. O. 197, C. S., A. G. O.

WEBSTER, WARREN, Surgeon.—Relieved from duty in the Dept. of the East, and ordered to the Dept. of California. S. O. 197, C. S., A. G. O.

MCCLELLAN, ELY, Asst. Surgeon.—Assigned to duty at Headquarters, Dept. of the South. S. O. 174, Dept. of the South, October 8, 1873.

WATERS, W. E., Asst. Surgeon.—Granted leave of absence for 20 days. S. O. 154, Dept. of the Missouri, October 1, 1873.

HUBBARD, VAN BUREN, Asst. Surgeon.—Relieved from further duty at these Headquarters, and to join his Station at Mississippi City, Miss. S. O. 158, Dept. of the Gulf, October 4, 1873; and granted leave of absence for 30 days by Dept. Commander.

BREWER, JNO. W., Asst. Surgeon.—Granted leave of absence for 30 days. S. O. 195, Dept. of the East, October 7, 1873; and assigned to duty as Post Surgeon at Fort Independence, Boston Harbor. S. O. 197, Dept. of the East, October 9, 1873.

DE WITT, CALVIN, Asst. Surgeon.—Relieved from duty in Dept. of California, to proceed to Harrisburg, Pa., and report by letter, on arrival, to the Surgeon General. S. O. 197, C. S., A. G. O.

GIRARD, A. C., Asst. Surgeon.—Assigned to duty at McPherson B'ks, Atlanta, Ga. S. O. 174, C. S., Dept. of the South.

KIMBALL, J. P., Asst. Surgeon.—Granted leave of absence for 30 days. S. O. 224, Dept. of Dakota, October 9, 1873.

Medical Items and News.

INTENTIONAL FRACTURE OF FEMUR TO PRODUCE SHORTENING.—Those who have heard of the surgeon of this city who not long since exseeted a portion of femur from the sound thigh of a young man having shortening of the other limb, in consequence of caries of the head of the femur, and who by this means gave him limbs of equal length, will be interested to know that he has a rival in the person of Professor Rizzoli, of Bologna.

From a paper read before the Medical Society of Bologna, we learn that he has recently had a fourth successful case in which he has intentionally fractured the femur in order to produce shortening of the limb. This case was in a girl of thirteen, who had inflammation of the cotyloid cavity when one month old, and resulting dislocation of the head of the femur. At the time of the operation the limb was so short that, when standing, the great toe hardly reached the ground.

Professor Rizzoli fractured the right femur, and caused the fragments to override to an extent sufficient to equalize the length of the two limbs. Union took place in twenty days, and the patient left the bed at the end of five weeks.

HUDSON RIVER STATE HOSPITAL, N. Y.—Under the auspices of Dr. C. R. Agnew and other members of the Executive Committee of the Board of Managers, a number of prominent medical gentlemen from this city made a visit to Poughkeepsie, Saturday, October 11th, by special train, to inspect the Hospital for the Insane at that place. After a bountiful collation, the distinguished company were conducted through the institution and around the spacious grounds by the Medical Superintendent, Dr. J. M. Cleaveland. Every part of the establishment was visited, and much attention was paid to the arrangements for heat, ventilation, and the water supply. Among the distinguished medical gentlemen present, were, Drs. E. L. Beadle of Poughkeepsie, President of the Board; S. Oakley Vanderpoel, Health Officer of the Port of New York; Drs. Gurdon Buck, Abram Dubois, Meredith Clymer, D. Tilden Brown, M.D., of Bloomingdale Asylum; J. L. Vandervoort, Librarian of New York Hospital; C. M. Allin, Surgeon of New York Hospital; Jared Linsly, M.D., S. T. Hubbard, O. White, J. G. Adams, Corresponding Secretary of New York Academy of Medicine; B. W. McCready, Ellsworth Eliot, President Medical Society Co., New York; D. B. St. John Roosa, B. A. Segur, J. H. Hinton, A. L. Carroll, M.D., R. J. O'Sullivan, James M. Minor, E. R. Peaslee, Prof. T. M. Markoe, Dr. R. L. Parsons, A. N. Bell, M.D., editor of *The Sanitarian*, M. H. Macy, Dr. Buttolph of the Trenton Asylum, New Jersey, were also present, with many other gentlemen from the adjoining counties.

At the conclusion of the visit, a meeting was called and organized by the appointment of Dr. Jared Linsly, Chairman, and C. M. Allin, M.D., Secretary.

A Committee of the following named gentlemen was selected to prepare resolutions expressive of the views of those present of the condition of the Institution: B. W. McCready, M.D., Physician to Bellevue Hospital; Gurdon Buck, M.D., Surgeon to the New York and Presbyterian Hospitals; Thos. M. Markoe, M.D., Prof. of Surgery, College of Physicians and Surgeons, New York; Jas. M. Minor, M.D., Surgeon to Brooklyn City Hospital; D. Tilden Brown, M.D., Resident Physician, Bloomingdale Asylum; R. L. Parsons, M.D., Resident Physician, New York City Lunatic Asylum; S. Oakley Vanderpoel, M.D., Health Officer of the Port of New York; Wm. H. Macy, Governor of New York Hospital and Bloomingdale Asylum.

The Committee retired for deliberation, and upon returning, presented the following resolutions, which were unanimously adopted:—

Resolved: 1st. That having made a careful inspection of the building and grounds of the Institution, we believe that the soil and site, on high ground, commanding extensive and beautiful views, is one of the most desirable that could have been selected.

2d. That we have been impressed by the simplicity, solidity, thoroughness, and completeness, of its structure.

3d. That the ample supply of water, and perfect provision for drainage, are everything that can be desired.

4th. That we believe the design of its internal arrangement, the dimensions of its apartments, their general effect for cheerfulness, and convenient and beneficial classification of its patients, are all that the present knowledge in hospital construction and the principles of sanitary architecture can suggest or demand. We also believe that the Institution has been commenced under enlightened views of the requirements of the insane, and that no diminution of the scale of liberal accommodation, or excellence of material, or thoroughness of workmanship, would be wise or expedient.

5th. That the number of patients necessarily crowded into some of the wards, exceeding the accommodations yet provided for them, renders imperative a speedy enlargement of the building.

On motion, it was ordered that properly authenticated copies of these resolutions be addressed to the Executive Officers of the State, and the Executive Committee of the Board of Managers of the Hospital, and be furnished to the *Sanitarian* and MEDICAL RECORD for publication.

Adjourned.

JARED LINSLY, M.D., *Chairman.*

CHAS. M. ALLIN, M.D., *Secretary.*

DILATATION OF THE OS UTERI IN PARTURITION.—Prof. Alexander J. C. Skene, M.D. (*Am. Jour. Obstetrics*), gives the following conditions requiring artificial dilatation:—

1st. When it is necessary to induce premature parturition at any period of pregnancy.

2d. When labor-pain continues for a long time, so as to tire the patient before the os begins to dilate perceptibly.

3d. When the membranes rupture before the os is dilated sufficiently to permit the presenting portion of the child to engage in it.

4th. In cases where the membranes stretch across the os, but do not project into it, either from the condition of the membranes, or of the low position of the child's head.

5th. When the membranes dilate the os sufficiently to admit the head or breech of the child, but, from some cause, the presenting part does not descend to complete dilatation. Artificial dilatation is required in such cases to facilitate the manual or instrumental delivery, which is generally necessary.

6th. When the os is rigid, and does not yield to the natural causes of dilatation.

In such cases artificial dilatation is occasionally difficult. When the parts do not yield readily to the hydrostatic dilator, the os may be incised at several points. For this purpose he uses a knife which he devised for a uterine scarificator. Its shape is like an ordinary uterine sound, divided longitudinally into two equal parts, one of which is probe-pointed and fixed into the handle; the other, a little shorter, is made at the end like a pointed bistoury. The two halves are held together, like the blades of a scissors, by a button, and when the blades are closed, it looks exactly like a uterine sound or probe.

A COTTAGE HOSPITAL.—Miss Trafford Southwell, Honington Hall, England, has given a cottage hospital to the town of Welbach, and endowed the institution with £5,000.

ELECTRO-THERAPEUTICAL SOCIETY OF NEW YORK.—The officers of this Society, for 1873, are: *President*, Meredith Clymer, M.D.; *Secretary*, T. P. Corbally, M.D.; *Executive Committee*, Drs. Geo. M. Beard, W. R. Fisher, and A. D. Rockwell.

THE MEDICAL DEPARTMENT OF DARTMOUTH COLLEGE.—The New Hampshire Legislature has appropriated $5,000 to complete the renovation of the medical building connected with Dartmouth College.

A QUAINT EPITAPH.—The following epitaph was written on Sir Fielding Ould, M.D., an eminent midwifery practitioner in Dublin, in the last century:—

> "Sir Fielding Ould was made a Knight,
> He should have been a Lord by right,
> For then each lady's prayer would be,
> O Lord! good Lord! deliver me."

NEW YORK PHYSICIANS.—The *New York Medical Register* for 1873–74, contains the names of 1,974 regular physicians who are practising in this city and vicinity.

BOYLSTON PRIZE.—The Boylston Prize Committee has awarded a prize of $150 to D. F. Lincoln, M.D., of Boston, for a dissertation on "Electro-therapeutics;" and one of same amount to Wm. C. Dabney, M.D., of Charlottesville, Virginia, for a paper on the "Value of Chemistry to the Medical Practitioner."

NEW JERSEY STATE MEDICAL SOCIETY.—The following officers were elected for the ensuing year: *President*, Dr. T. J. Thomason, of Monmouth; *First Vice-President*, Dr. Geo. H. Larison, of Hunterdon; *Second Vice-President*, Dr. Wm. O'Gorman, of Essex; *Third Vice-President*, Dr. J. V. Schenck, of Camden; *Recording Secretary*, Dr. Wm. Pierson, of Essex; *Corresponding Secretary*, Dr. Wm. Elmer, of Mercer; *Treasurer*, Dr. H. B. Baldwin, of Middlesex. The next Annual Meeting will be held at Long Branch.

JAUNDICE. PNEUMONIA, AND PLEURISY.

A CLINICAL LECTURE DELIVERED AT BELLEVUE HOSPITAL,

BY PROF. A. L. LOOMIS, M.D.

(Phonographically reported for THE MEDICAL RECORD.)

GENTLEMEN:—The first patient I bring before you this afternoon is a young man, nineteen years of age, a drug clerk. Two weeks ago he began to suffer from loss of appetite, every article of food became offensive to him, and about a week afterwards he began to get yellow. The yellow color first made its appearance in the conjunctiva, but he had no yellow vision. His habits have been good.

His skin, as you see, is at the present time of a bright golden yellow, his urine red, looks like port-wine, his stools are clay-colored, and he feels weak.

He never has had chills and fever; has had no pain or vomiting.

We have before us, then, a case of *jaundice*, and in the first place let us notice some of the causes which would give rise to such a jaundice as this. There is unquestionably an obstruction in the bile-ducts which prevents the free flow of bile into the intestinal canal.

This obstruction may be produced, 1st, by a gall-stone, and pain is one of the prominent, if not the most prominent symptom by which we recognize the presence of this obstruction. The pain in jaundice produced from an obstruction caused by the presence of a gall-stone in the bile-ducts, precedes the jaundice usually twenty-four or thirty-six hours. This pain is somewhat peculiar; it originates in the epigastrium, usually in the immediate region of the bile-ducts, and strikes directly through to the back.

To determine the situation of the bile-ducts draw a line from the right nipple to the umbilicus, and the point where this line crosses the free border of the ribs will indicate it very nearly.

This man has had no pain since his sickness began, and it is altogether probable, therefore, that the jaundice is not dependent upon an obstruction produced by a gall-stone.

Another cause which will produce obstruction of the bile-ducts is an acute catarrhal inflammation. This acute inflammation of the mucous membrane lining the bile-ducts is not primary, but is usually propagated from an inflammation in the duodenum. Again, inflammation of the duodenum does not usually occur as a primary inflammation, but is almost always associated with gastric catarrh as the primary disease.

In acute gastric catarrh, vomiting is almost always present, although in many cases it may not be very severe; but you may expect vomiting, some pain, and a burning sensation at the epigastrium. (The patient was then placed upon the table, and prepared for physical examination.) As pressure is made in the epigastric region, there is manifestly considerable tenderness, yet the patient gives us no history of vomiting. Vomiting, however, we would not regard as absolutely essential to determine the existence of acute gastric catarrh, inasmuch as it may not be present, although it almost always is. In very mild cases there may be simply a loss of appetite to indicate the existence of gastric disturbance.

The first thing which this man noticed was a loss of appetite and nausea, and now he has great tenderness over the region of the bile-ducts and epigastrium, and these alone are sufficient to indicate some gastric inflammation. The obstruction of the bile-ducts, in these cases of acute catarrh, comes from the tumefaction or thickening of the mucous membrane, and more or less from the accompanying secretion.

This inflammation may only involve the hepatic duct, and ductus communis, or it may extend far up into the ducts. As a general rule the catarrhal inflammation extends up quite a distance towards the lobules of the liver. When this inflammatory process has produced sufficient thickening of the mucous membrane to obstruct the ducts, the bile is retained and reabsorbed, giving rise to the jaundiced hue of the skin.

There will usually be some fever present in these cases, generally of a simple ephemeral character, if dependent upon the jaundice alone.

The two principal causes of acute jaundice have been named; obstruction from gall-stones, and an obstruction which occurs in connection with acute catarrh of the bile-ducts.

Jaundice may occur under a variety of circumstances. It may occur from intense congestion of the liver. Sometimes in malarial fevers the congestion is sufficient to cause acute jaundice, but the cases are rare. It may come from pressure on the bile-ducts produced in a variety of ways, and from a variety of causes. There may be the development of a tumor in the transverse fissure of the liver, which by its mechanical pressure obstructs the bile-ducts, and in this way gives rise to jaundice. In such a case, however, the appearance and extent of the jaundice would be influenced by the growth of the tumor, and it would as a rule be developed slowly. Almost all cases of acute jaundice are due to one of the two causes first named.

In most cases of acute jaundice we have a slight enlargement of the liver, which is due to distention of the ducts with bile. As we make percussion upon this patient it is seen that the liver is enlarged in all directions. In the median line, the line of hepatic dulness extends fully four inches from above downwards.

This is an ordinary occurrence in jaundice, and usually we also get more or less tenderness over the hepatic region, as you see in this case, the patient shrinking when percussion is made. We have in jaundice not only a turning back of the bile, but there is soon more or less hyperæmia, which may account for the tenderness.

The question is asked, Might not abscess of the liver give rise to acute jaundice? It might, and the first question you would ask, if your suspicion turned in the direction of abscess, would be, Has the patient ever had dysentery? The reason for asking that question is, that dysentery is the most common cause of abscess in the liver, or rather abscess of the liver most frequently occurs with dysentery. It is believed by some that it produces abscess of the liver by embolism, but I am not quite sure about that.

Abscess is very frequently associated with dysentery, but how they are connected with each other I do not know. What the connection is, is not exactly clear. It may be due to embolism, but I am certain that it is not in the great majority of cases, because the embolus cannot be found at the post-mortems, which it should be, if productive of such grave results.

It is simply a clinical fact, and I have never seen a case where the plugging up of the artery has been found.

Abscess would be excluded in this case because the man has had no dysentery, and has no history which would lead us to suspect the presence of pus in

any part of the body. His history is too short for abscess, which, as a rule, has a long history. There is no hectic fever, his pulse is 70, and his temperature not raised. In abscess the pulse will be accelerated and small in character.

Pyæmia sometimes produces jaundice; and it is very common in connection with all diseases which depend on blood-poisons. In these cases the jaundice is probably produced by some peculiar action of the septic poison on the blood, and the jaundice is not the bright golden yellow seen in this case. In the way of treatment, leeches are suggested, and a much worse thing might be done than that. Counter-irritation is one of the means which may be employed to subdue the inflammation, and it may be in the form of dry cups, leeches, or perhaps a blister over the liver, as an attempt to relieve the catarrh.

It is well, however, to recollect one thing, and that is, that catarrhal inflammations are self-limited, unless the stimulus which produced them is kept up. They have a period of dryness, congestion, and secretion; first, an increase of the normal secretion of mucous membranes, and then muco-purulent. After a certain amount of this secretion has been poured out, unless the inflammatory stimulus is kept up, recovery is rapid and complete.

I do not believe that calomel would be of any benefit in such a case as this, and I would not have you go off with the idea that calomel must be given to act in some peculiar way, because there is hepatic disturbance. If you wish to stimulate the glands of the intestine to action, very well; there is no doubt but that calomel acts as a stimulus to the glands, but everything that is necessary in such a case as this can be accomplished just as well by mild saline cathartics as by calomel. I would not give stimulants, because as a general rule acute catarrhal inflammations are not benefited by stimulants, wherever the inflammation may be. The best diet for the patient is such food as will be digested as far as possible in the stomach.

The second case which I present to you is one in which there is some question among the gentlemen who have examined it in regard to diagnosis. It is a case of special importance, for it belongs to a class of cases which you will frequently meet in practice, and your credit may be very much affected should you err in diagnosis and prognosis. This young girl, 22 years of age, has been sick four weeks. She was first taken with a chill, which lasted her for most of the time during one night. Immediately following the chill, or chilly feeling, she says her "chest got sore;" that this soreness extended over the whole of the chest; that there was no more pain upon one side than the other, except when she drew a long breath, and then she felt the most pain in the left side. She had a great deal of fever at the time she was taken, but at no time cough or expectoration. Since her entrance into the hospital, three weeks after she was taken sick, she has had a slight cough, accompanied by a scanty yellow expectoration, and there has been some blood through it. Her chief symptoms, therefore, are difficulty of breathing, following the chill; fever, but accompanied with no cough and expectoration, or pain, except upon a full inspiration. Her pulse is 114, feeble, rapid, easily compressed, and the temperature 99¼. So much for the history of the case.

Physical examination of the chest, for the history directs our attention in that direction, gives us the following:

Palpation.—Vocal fremitus is negative, her voice not being sufficiently strong to give any vibrations to the chest-walls.

Vocal fremitus is a very important sign, because in connection with consolidation of the lung it is increased, and where fluid is present in the pleural cavity it is absent. Hence its importance in making a differential diagnosis between pleurisy with effusion and pneumonia.

Percussion.—There is complete flatness over the posterior portion of the left lung. Over the posterior portion of the right lung the resonance is slightly increased.

Anteriorly, there is dulness in the infra-clavicular space of the left side, but not flatness. Upon the right side the percussion-note is about normal.

Auscultation.—Bronchial respiration is heard all over the left lung posteriorly, being heard distinctly *low down*. There are no râles present except an occasional unimportant mucous râle connected with the bronchial tubes.

Over the right lung, posteriorly, respiration is exaggerated and vesicular in character. *Anteriorly*, upon the left side no râles, and upon the right side purely vesicular respiration, but somewhat exaggerated.

These are the physical signs, and together with the history of the case present some interesting points in connection with pneumonia and pleurisy.

First, with regard to pleurisy. The fever and the pain in the side which the patient had at the commencement of the attack might indicate the presence of pleurisy, yet the pain was not sufficiently severe to warrant the conclusion that the pleurisy was the leading feature of the disease. The existence of pleurisy would not be determined, therefore, by the amount of pain which the patient suffered.

The complete flatness upon percussion over the affected side, and the absence of all respiratory sounds except along the course where the bronchial breathing is present, tells us of the existence of pleurisy. The bronchial breathing is sometimes heard in subacute pleurisy, but it is *high up* and never at the lower portion of the lung, as in this case. This bronchial breathing always means lung consolidation, and in this case being heard over the lower portion of the lung affected, leads us towards pneumonia as the cause of the consolidation. The patient, however, has had no cough and expectoration until three weeks after the accession of the disease. We usually have the characteristic expectoration of pneumonia present within two or three days after the occurrence of the chill; but in this case we have had no expectoration at all in the acute stage. The bronchial respiration, however, over the entire lung, lower as well as upper portion, may lead us safely to conclude that consolidation is present as the result of pneumonia.

There is probably no way of determining this question positively as regards the presence or absence of fluid in the cavity except by the use of the exploring trocar, although we might be led to exclude fluid from the fact of hearing bronchial respiration down to the bottom of the pleural cavity. In this case the patient has been tapped in the way indicated, and no fluid was found.

Our diagnosis, therefore, must be that this is a case of pulmonary consolidation, with a large amount of plastic exudation. The material which has been poured out in this case as the result of the pleurisy is not fluid, but is of a gelatinous character, and it has been poured out in such abundance that it has caused some compression of the lung, which has undergone more or less consolidation.

The case now becomes one of interest with regard to prognosis. In the first place, a pulmonary consolidation which has lasted for four weeks means something.

Bronchial respiration heard over a lung, when there is no fluid in the pleural cavity, unquestionably indicates pulmonary consolidation. The cause of that consolidation is not so clear. The rational history of croupous pneumonia, in many respects, is wanting. Still, I believe that consolidation of a pneumonic character takes place in lungs compressed by extensive plastic exudation without the patient's giving a clear pneumonic history, and that pleuro-pneumonia, under these circumstances, resolves slowly. Always when pleurisy is marked during the course of a pneumonia, the resolution is very slow, and yet as a rule these cases recover entirely without the development of phthisis.

If it were not for the morbid pleuritic element in this case, all the physical signs present would lead one to the diagnosis of pulmonary consolidation alone, and of four weeks' standing; the case then would be much worse than it now is, in a prognostic point of view; for then we might expect purulent infiltration or cheesy degeneration of the consolidated portion. This lung will undoubtedly be crippled for a long time, but resolution will finally be completely accomplished.

The patient must be sustained by good diet, tonic remedies, and the best hygienic influences. If anything depressing occurs to the patient, the pleuritic exudation may become cheesy, and after a time be the nidus of a tubercular development, so that the prognosis, although good, must be qualified.

This, gentlemen, is one of a class of cases you will occasionally meet with, and it is well worthy of your careful study.

ON LARYNGEAL PHTHISIS.

THE ABSTRACT OF A LECTURE DELIVERED

BY DR. MORELL MACKENZIE, M.D., LONDON,

PHYSICIAN TO THE HOSPITAL FOR DISEASES OF THE THROAT, ASSISTANT PHYSICIAN TO THE LONDON HOSPITAL, ETC., AT THE LONDON HOSPITAL.

(Reported for THE MEDICAL RECORD.)

DR. MACKENZIE commenced his lecture by stating how very infrequently phthisical affections are met with in young patients. This is especially true of patients under twelve years of age.

In Dr. Mackenzie's very large practice, both in private and at the Throat Hospital, he only remembers to have encountered laryngeal phthisis three times in children under three years. It must be considered as a disease which attacks almost exclusively persons who have reached the middle age of life.

Amongst the symptoms of laryngeal phthisis, difficulty of swallowing and loss of voice are the most characteristic. In some instances these may become typical.

Aphonia is more commonly met with than dysphagia. The first patient presented to his students complained also of shortness of breath, which became troublesome upon the slightest effort made by him. Here the loss of voice had preceded the embarrassment of the respiration for two months. One month after the patient had completely lost all power over his voice he became unmistakably thinner.

The symptom dysphagia, in the affection under consideration, often leads to the patient taking less food than he otherwise would, and thus of course proper nutrition is materially interfered with.

Dr. Mackenzie here asks, What would be a complete definition of laryngeal phthisis? For him it consists essentially in a chronic thickening, with ulceration, of the mucous membrane of the larynx, always accompanied with loss of voice, and generally with dysphagia. In the majority of instances it follows disease of the lung tissue (five-sixths of cases). A small proportion of cases are found, however, where one is unable to detect morbid pulmonary conditions.

It must be admitted, that in some few of these last-mentioned cases tubercle may be actually present in the lung, although not recognized by the most rigid and careful examination of the chest.

If an individual in a poor state of health catches cold, laryngeal phthisis is the consequence; whereas in another and more healthy person the same cause would produce ordinary simple laryngitis.

In syphilitic affections of the larynx, large ulcerations are frequently seen without any notable previous thickening. In laryngeal phthisis, on the contrary, we always get thickening before ulceration.

The character of the cough is oftentimes typical. It is frequent and irritable. In fact, it occasionally becomes so obstinate in its recurrence that it is beyond the physician's control, and all prescriptions appear equally inefficacious. This cough is not always present, but, when it is, is no doubt to be explained by irritation of the terminal nerves which supply the glottis.

The respiratory symptoms are generally marked. They may usually be expressed by the term shortness of breath.

By the use of the laryngoscope we can diagnose three forms of laryngeal phthisis.

First. The form where pyriform swellings exist on each side of the laryngeal opening.

The narrow portion of these swellings corresponds to the ary-epiglottic folds; the more enlarged parts to the cartilage of Wrisberg and the capitulum Santorini. If this form of tumefaction is perceived, we can be sure that the case is one of laryngeal phthisis, and that it will terminate fatally.

Secondly. The swollen or turban-like appearance of the epiglottis. This form was first described by Rokitansky.

Thirdly. The carious form of laryngeal phthisis.

Here we find small ulcers all over the surface of the larynx, to which may be added a certain amount of chronic thickening.

This last-mentioned division is the slowest form of laryngeal phthisis; sometimes sufferers from it live so long as five years. When we encounter the first form (pyriform swelling), we should not expect life to last more than a year. If the epiglottis is thickened and tumefied, the march is more rapid still; and the patients are, moreover, much annoyed by persistent dysphagia. With regard to the pathology of these cases, we shall merely remark that interstitial deposit is quickly followed by ulceration, and finally the period of necrosis (or rather caries, as it should be called) of the cartilages is reached. In by far the majority of cases, where we find caries of the cartilages we consider it as due to laryngeal phthisis. Those that remain are attributable to syphilis or to the exanthemata.

Here Dr. Mackenzie stated that laryngeal phthisis was more commonly met with in males than females. Occasionally patients accuse spitting of blood amongst their antecedents. In these cases hemoptysis must be accounted for by concomitant lung disease, as it is very rarely met with where laryngeal phthisis exists alone. In some cases the persons who attend at the hospital give good family histories, free from facts

which might lead one to presume the existence of hereditary tuberculosis. These statements are not to be relied on, so badly do poorer patients observe themselves, so imperfectly are they familiar with (in this connection) their real antecedents. The patients frequently speak of having caught cold not long ago. No doubt in these, as in most other cases, the origin of actual trouble in the larynx is to be found in catarrhal affections of the mucous membrane covering the respiratory tract. It is important in this place to observe, there is very little expectoration in diseases of the larynx. Upon this symptom the differential diagnosis with lung affections may be based in part. If there is much expectoration in a given case, we may be positive that the lungs are attacked, whether it be by bronchitis, tubercle, or still some other form of lung trouble. In laryngeal phthisis dysphagia is frequently owing to the fact that the epiglottic valve, in the effort of deglutition, imperfectly closes the laryngeal opening, and food passes into its cavity. The patients, after vain endeavors to accomplish this function, refuse to eat except so far as is rendered imperative by a feeling of intense hunger. Soon the loss of flesh and strength follow.

The way to meet this difficulty is to introduce a tube through the mouth, just below the epiglottis, and administer nutritive substances by means of injections made by the tube. There is no necessity to pass the tube down so far as the stomach. The aliments must not always be the same. They are to be varied constantly, and the diet should not be made up exclusively of finely divided meat and soups. Vegetable food ought also to be given from time to time, and in the form of purl of different kinds.

In all forms of laryngeal phthisis, we may consider it as settled that little really useful can be done outside of local applications. Amongst these Dr. Mackenzie especially recommends the use of the solution of perchloride of iron (in the proportion of a drachm of solid ferri-perchloride to an ounce of water). This solution gives much temporary relief, and is especially serviceable in the form where pyriform tumefaction exists.

In some cases where the iron is no longer to be depended upon for giving even temporary good results, we may resort with considerable advantage to the use of solutions of the chloride of zinc. According to Marcet, scarifications, followed by applications of tincture of iodine, may be relied upon. Mackenzie affirms that he has sometimes found bad consequences to follow this method of treatment, and as we are unable to cure the disease, except in very exceptional cases, it is better and safer to confine our local treatment of laryngeal phthisis to the employment of the astringent palliatives.

THE ALUMNI ASSOCIATION OF BELLEVUE HOSPITAL COLLEGE.—This Association had its first annual dinner at Delmonico's, on the evening of October 30. A large number were present, including some distinguished invited guests. Toasts were responded to by Prof. A. B. Crosby, Rev. E. H. Chapin, Hon. W. W. Phelps, Chancellor Crosby, E. C. Stedman, Rev. Dr. Potter, and Dr. M. H. Henry. The reunion was a success from many points of view and bids fair to become an established yearly proceeding. Prof. William T. Lusk, M.D., is the President.

A CASE OF INVERSION OF UTERUS AFTER DELIVERY—REDUCTION.

BY ALEXANDER N. DOUGHERTY, M.D.,

NEWARK, N. J.

MRS. N——, æt. twenty, primipara, ten months married, was taken in labor in the night of Oct. 11th inst., and at twenty minutes to 9 A.M. of the 12th, was delivered of a male child, well developed, which had presented by the head. She was attended by a physician of long experience, who says he made moderate traction on the cord, when suddenly the placenta came away, followed immediately by inversion of the uterus. He endeavored at once to replace it, and succeeded so far as to return the organ into the vagina, and simultaneously sent for me as counsel.

I arrived about half-past 9, and introducing my right hand, encountered the inverted uterus, which constituted a mass as large as the double fist. The other hand, placed above the os pubis, discovered there a funnel instead of a globe. Partially flexing the fingers and thumb in the vagina, so as with the palm to make a cup, I proceeded to reduce the organ thus: The uterine mass fitted into the hollow of the hand; the ends of the digits were applied to the open angle existing at the point where the inversion had ceased (for the abnormity included but about four-fifths of the organ), and then by a combination of gentle pushing and compression—the left hand being applied above the pubes for counter-pressure—the uterus was little by little returned, the last portion down being the first to go up. The operation did not take more than five minutes.

I saw the patient on the 25th, and made a digital examination. The mouth of the womb was so contracted as not to admit the tip of the finger. There was evidently subinvolution; the organ was tilted backward and was quite voluminous, having a flabby and spongy feel, and was sensitive to pressure posteriorly.

This is the only case of acute inversion I have seen during a practice of twenty-seven years. I may mention, however, a case of chronic inversion, that of a Mrs. D——, living here, who met with the accident twenty-eight years ago, under the care of an old and experienced practitioner. He, however, would appear not to have discovered the nature of the case for some weeks—indeed not until his attention was called by the patient to the presence of a body which, when she sat on the night-chair, came down and interfered with the natural evacuations.

This lady is now about forty-eight years old; she still menstruates, though rather irregularly, the show being brought on at any time from excitement or overexertion.

She is a full habited woman with a rosy complexion, and in the enjoyment of such a measure of health as, with the near prospect of the menopause, disinclines her to have any attempts made at reduction. It seems when the doctor first became aware of the mishap he proposed to try and remedy it, but she positively refused her consent.

NEWARK, N. J., Oct. 27, 1873.

M. COSTE, the illustrious professor of embryology, and the creator and promulgator *par excellence* of pisciculture and ostreaculture, died September 19th, of an intestinal occlusion, aged 66 years.

CAOUTCHOUC ELECTUARY AS A REMEDIAL AGENT.

By THEODORE R. VARICK, M.D.,

JERSEY CITY, N. J.

At the solicitation of several friends I have been induced to call the attention of the profession to the use of caoutchouc as a remedial agent. I have been in the habit for the past fifteen years of prescribing it, in preference to cod-liver oil, in certain cases of pulmonary tuberculosis in every stage, in chronic bronchitis, or the winter coughs of old people, and in chronic rheumatism.

Under its use I have observed a decided improvement in digestion and hæmatosis, as well as general tonic effects. It seems to be adapted to cases in which cod-liver oil is contra-indicated, and especially those in which there is a frequent occurrence of hæmoptysis. It is not claimed to be a remedy which has any specific action, but that it diminishes excessive mucous secretion and suppuration, arrests hæmorrhage and excessive perspiration, and retards emaciation.

Prepared in the following manner, I have usually prescribed it in doses of a teaspoonful three times a day, about two hours *after* meals.

SOLUTION OF CAOUTCHOUC.

℞. Caoutchouc (in thin slices)..... ℥i.
Ol. terebinth..... ℥ij.
M.

Macerate until solution is effected, and strain through coarse muslin.

ELECTUARY OF CAOUTCHOUC.

℞. Solut. caoutchouc..... ℥ij.
Sacch. alb..... ℥iss.
Mellis (strained)..... ℥iiss.
M.

The mixture should be of opaque yellow color, and thick enough to run *very* slowly off a spoon. It contains about two grains of pure caoutchouc to each teaspoonful. A relative comparison of caoutchouc and cod-liver oil as to the amount of carbon and hydrogen in each, shows the following result:

Prof. Faraday's analysis of caoutchouc gives in 100 parts 87.2 carbon, and 12.8 hydrogen (U. S. Disp., pp. 1255).

Besides various acids, butyric, felluric, cholic, etc., and traces of iodine and other metals, De Jongh finds in 100 parts of cod-liver oil 37 carbon, 34 hydrogen.

RESUMÉ.

100 parts caoutchouc contains of carbon, 87.2; hydrogen, 12.8.
100 parts cod-liver oil contains of carbon, 37; hydrogen, 34.

Percentage of carbon in caoutchouc over cod-liver oil, 135 per cent.

Is the caoutchouc itself available as respiratory force?

I append to this article a communication from my friend Dr. J. E. Culver, of this city, in reference to the subject under consideration.

JERSEY CITY, N. J., Oct. 17, 1873.

DEAR DOCTOR:—Several years ago you recommended me to try the caoutchouc confection in a case of phthisis pulmonalis. I have since used it in numerous cases of phthisis and of muco-purulent bronchial catarrh. Its remedial action, as observed in the cases in which I have prescribed it, fully sustains its claim to the medicinal virtues which your prior and wider experience had already demonstrated it to possess.

Its power to diminish suppuration is very remarkable; hence, doubtless, the prompt relief it affords in some purulent catarrhs, and hence too its conservative efficacy in retarding the softening of tubercular deposits. It does not relieve cough otherwise than by lessening the quantity and changing the quality of the matters to be expectorated. In recurring bronchial hemorrhages, whether in the phthisical or non-phthisical, it is a most reliable and satisfactory remedy; for it controls the hæmoptysis not as a hæmostatic merely, but it soon so improves the blood in the quality of its fibrin as effectually to prevent a recurrence.

It is futile to administer the caoutchouc confection in but a single dose, or for a single day, in chronic diseases; its use should be persevered in for weeks—for months in phthisis. Its continued administration develops no unpleasant effect. It will not do, however, to use the caoutchouc in a state of greater concentration. I once directed the confection to be made of double strength, and my patient's stomach rejected it. Yours truly,

J. E. CULVER, M.D.

COMMINUTED FRACTURE OF THE CLAVICLE; COMPRESSION OF THE SUBCLAVIAN VEIN AND SUBJACENT PLEXUS OF NERVES BY A FRAGMENT.

By H. W. BOONE, M.D.,

A. A. SURG. U. S. A., FT. HALL, IDAHO.

CHAS. W., native of U. S., age 28, tavern-keeper, a large, powerfully built man, in robust health. On the 11th of February, while he was driving a pair of horses, they took fright and threw him out; he landed on his right shoulder with great violence, striking against the string-piece of a bridge. When he applied for treatment, three hours afterwards, I found that the clavicle was broken and comminuted about at the middle portion. One fragment, about an inch and a quarter in length, was tilted so as to lay transversely between the two larger ones; there was much deformity.

The arm was cold, and there was considerable swelling of the veins; no sensation in forearm or fingers, while the patient complained of pain at the seat of the fracture. The patient was placed in bed with his head and shoulders low, and his arm was supported by a pillow. Efforts were made to alter the position of the inverted fragment, but proved ineffectual. The arm was secured to the chest by a strip of adhesive plaster round the body; the whole limb was then enveloped in cotton batting and covered with a light blanket, and the room was kept at a warm, even temperature.

On the following day there was considerable swelling about the neck and shoulder, with some extravasation of blood, the arm was much swollen, and there was no sensation in the hand or fingers.

Feb. 13th. The swelling has increased very much; some incisions were made in the upper part of forearm and in the arm; warm-water dressing applied. From this time the case did well, the swelling gradually going down, and after some weeks he returned to his usual occupation. There is some decrease in the width of the right shoulder, and it is lower than the other. He has good use of his arm, however, and it appears to be quite strong. The deformity in the clavicle is quite prominent. A sensation of numbness in his hand and fingers remained for some time, but has ceased to

trouble him. In this kind of fracture the fragments may cause great injury by pressing upon or lacerating the subclavian vein and the brachial plexus, or by wounding the artery. These results appear to be uncommon, although the late Sir Robert Peel is reported to have died from a laceration of the subclavian vein.

It has occurred to me that in a case of this kind it might be good surgery to cut down upon and remove the offending fragment, where there seemed to be any danger of its wounding the artery or vein. This would of course render the fracture a compound one, but with careful dressing no serious trouble need be apprehended, and the greater danger would be removed.

Reports of Hospitals.

BELLEVUE HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES IN TREATMENT.

GOUT.

A CASE of this disease was noticed which possessed some points of interest. It was in a man 34 years old, with a personal history slightly suspicious with regard to temperance.

There were no nodules of the usual deposit in the helix of the ears, but little concretions could be felt in the bursa over the right olecranon. Hereditary tendency in the case doubtful. The man has had several attacks, and all have heretofore been regarded as rheumatic in character showing the occasional difficulty met with in making a correct diagnosis. As a matter of course, Colchicum entered largely into the treatment of the case. The method of administration, however, is somewhat varied. It is thought to be more serviceable in these cases when carried to the point of producing emesis at the commencement of the treatment of a case. It is believed that administered after this manner it renders the attacks less liable to recur.

Lithia, in the form of "Regia Lithia," is another remedy usually administered, for it is supposed to have the power of rendering a chemical combination with the *Uric acid*, which is highly soluble. The carbonate or Citrate of Lithia is employed in 5 gr. doses t. i. d. when the "Regia" is not at hand.

HÆMOPTYSIS.

Our attention was called to a very interesting case of this character, which had been occurring at intervals of about one year for eight years, without presenting any physical evidences of disease of the lungs until the present admission, and these at present are not well marked. It is a point to be considered whether the recurring hæmoptysis has produced the lesion in the lungs, or the lesion has given rise to the hæmoptysis. It was believed, however, to be one of those cases of hemorrhage from the lungs which has *not* been dependent upon the continued existence of lung lesions or the presence of tubercles.

Upon admission his bleeding had been profuse, and he had bled to fainting. Fl. Ext. of Ergot in doses of gtts. xv. was administered every two hours, and Turpentine covered with hot cloths applied to the chest. Hemorrhage soon ceased, and he is now receiving tonic treatment. The Ergot is said to have a peculiar effect upon the vaso-motor nerves of the blood-vessels.

TYPHOID FEVER.

The case noticed was one which presented many of the symptoms of the disease, which rendered the diagnosis undoubted. The treatment which the man was receiving consisted of the administration of quinine in ten-grain doses three times a day, and phosphoric acid drink. Sponging and the use of the wet pack were resorted to for the purpose of reducing his temperature, which ran up to 104½° at evening. The manner of applying the pack consisted in wrapping the patient in a sheet wet in cold water; over this were placed two dry blankets, and the patient placed in bed. Quinine in such doses was administered, with the view of assisting in the reduction of the temperature, and of prolonging the effect of the packing. It is also believed that the patients who receive quinine from the beginning of the disease are in a better condition when convalescence is established than those who do not receive it.

ACUTE BRIGHT'S DISEASE.

Two cases of this disease were seen which were especially interesting with regard to their treatment. Both were under what is known as the "water treatment."

One was a case of the disease following pregnancy; and the other in a man, and following an exposure to cold. Both of these patients were doing exceedingly well. The treatment consists in requiring the patients to drink as much water as possible each twenty-four hours, and also taking their food mostly in a fluid form, such as milk, soup, etc. One of the patients had been drinking from ℥ 70 to ℥ 100 of water daily, and with an improvement in her condition rapid and marked. Water is less apt to offend the stomach than any articles which have been attempted to be substituted for it, such as weak solutions of bitartrate of potassa, etc. No diuretic remedies were administered.

PARALYSIS.

A peculiar case of this kind was seen in the person of an intelligent woman, who, at the eighth month of her pregnancy, began to gradually lose the power of motion in her arms, and after a short time the same loss of motion began to affect her lower extremities, and she is now completely helpless. The rectum and bladder remain intact. Sensation also remains good. Appetite fair. Muscles remain in good condition. Duration about three months. This completes the history of the case. The treatment adopted in this case consists in the administration of $\frac{1}{12}$ of a grain of Sulphate of Strychnia daily and hypodermically, and the use of the galvanic battery.

Improvement is evident but slow.

EMPYEMA.

The patient was admitted to the Hospital in April, 1873, with one pleural cavity filled with fluid. His chest was aspirated three times. Fluid returned.

In June he began to have hectic, and soon after a free incision was made through the chest walls, and a large quantity of pus drawn off. The pus was extremely offensive. The pleural cavity was washed out with Carbolic Acid water of a strength of one part acid and one hundred parts water. The discharge varied from six to ten ounces for several days, then gradually diminished in quantity, and now is discharging only about two ounces of pus daily. The pleural cavity is now being washed out daily, and the general treatment is tonic. The patient is very comfortable, and able to be about his ward with ease. Another case in the same ward was cured by this plan of management. His difficulty, however, has reappeared, and he is again under treatment.

NIGHT SWEATS,

In connection with phthisis, empyema, etc., have been more successfully treated with $\frac{1}{250}$ grain doses of sulphate of atropia at bedtime than by any other-sized dose administered.

The size of the dose was accidental, but the results realized have been most gratifying. It is usually administered in cinnamon water.

PERITONITIS.

The importance of not relying upon pain as a symptom of peritonitis was again illustrated in a patient in whom the disease was not suspected, until post-mortem revealed its presence.

Absence of pain in this disease is of not infrequent occurrence.

PNEUMONIA.

Several cases of pneumonia were in the wards at this writing, and all are doing very well. Quinine, Carbonate of Ammonia for its stimulant effect, and whiskey or brandy, were the remedies chiefly relied upon in the cases seen. Quinine, when given for its apyogenic effect, it is said, must be given in large doses, and the patients receive, accordingly, 25 or 30 grains per day, and when a pneumonia is treated in this way a majority of the patients get well. When given in ordinary doses of five grains three times a day, a majority of the patients get well, and that without the administration of the remedy with any special reference to its apyogenic influence. "Who is who, and which is what?" might be a query with an outside observer.

LAXATIVES.

A new remedy has been introduced as a laxative, which is said to be preferable to many of the salines on account of its agreeable taste. It is the Sulphovinate of Soda in two-drachm doses.

Another very efficient and much-used laxative compound is the following:—

℞. Ext. Colocynth co.....grs. vi.
Ol. Caryophyl.....gtts. ij.
M.
Div. in pilulæ No. ii.

PARALYSIS AGITANS.

A case of this affection has manifested slight improvement under the use of fld. ext. Conium, ℥ vi., t. i. d.

In the use of this remedy it is essential that care should be taken to secure a good article if any effect would be realized, for most of the conium in the shops is worthless.

Squibb's preparation is thought to be reliable, notwithstanding some complaint has been made Concerning his Sulphuric Ether.

CHRONIC BRONCHITIS AND EMPHYSEMA.

An old man, who is the subject of this combination of disease, derives great comfort when suffering from the intense paroxysmal dyspnœa which commonly accompanies it, by taking drachm doses of

℞. Hoffman's anodyne,
M. Sol. Morphia (U. S.) āā

at the commencement of a paroxysm, and repeating it p. r. n.

CARDIAC.

This man has double aortic lesion, with a large amount of hypertrophy and dilatation of the left ventricle, the regurgitation being the more prominent of the valvular lesions. It was the result of acute articular rheumatism. One month ago his feet commenced swelling. Urine became scanty, acid, and s. g. 1014. Albumen very light. No microscopical examination. Now he has double pleuritic effusion, which is a very common occurrence in the progress of secondary Bright's disease. When this double pleuritic effusion occurs without inflammatory action, it is said to almost always mean Bright's disease. The œdema of the legs, the markedly increased difficulty of breathing, and the presence of albumen in the urine, whether there are casts or not, make it pretty certain that the kidneys are affected with what is usually called Bright's disease. In a great majority of these cases the kidneys are found in what has been known as the condition of cyanotic induration, but which is thought to be better expressed by the term chronic congestion. When examined with the naked eye these kidneys are found intensely red; and when cut into, the cut surface is of a more uniform red color than normal. The kidneys are sometimes almost of stony hardness. They are usually of normal size. When examined microscopically there is simply found a textural change of the normal elements of the kidney. The blood-vessels may be found filled with blood, but there does not seem to be any dilatation. The connective tissue is not increased. Epithelium unchanged or changed, according to vigor and continuance of the congestion. Hyaline casts in the tubes of the pyramids is the most constant lesion found.

In the treatment, set some one of the great emunctories at work to eliminate the fluid collected in the cellular tissue in different parts of the body. The kidneys are the best. It is considered desirable to give diuretics a trial before trying anything else. The standard diuretic for all those cases which demand a vigorous and efficient diurosis, such as the œdema of Bright's, or the effusion of subacute pleurisy, is the infusion of digitalis in half-ounce doses three times a day, combined with acetate, citrate, or bitartrate of potassa in full doses.

STRANGULATED HERNIA.

A case of this kind came into the service of Dr. Bull, House Surgeon of the 1st Surgical Division. The Dr. called the Aspirator to his assistance in the management of the case. The hernial sac was emptied of its contents, and the gut was aspirated, but no fluid was obtained. This, however, did not permit of the reduction of the gut by taxis. The ordinary operation was then performed by Dr. Gouley, the stricture being found at the external ring.

When the operation was performed it was thought that sufficient explanation was found for the failure to reduce by taxis, after the use of the Aspirator, in the fact that new adhesions had already formed about the neck of the sac, which held the parts in sufficiently firm coaptation to resist all efforts in that direction. This was an explanation of the non-success of the Aspirator in this case. If all cases in which the instrument may be used should receive as careful an analysis as this one received, it might soon be determined whether the operation of aspirating the hernial tumor is a valuable one or not in assisting its reduction.

SUBACUTE PLEURISY.

Four months ago this man had pain in his left side, unaccompanied by expectoration, although accompanied by slight cough. Upon admission his urine contained albumen, and had a specific gravity of 1006. The left pleural cavity is now filled with fluid to a level with the angle of the scapula.

This fluid is serous, because there is no history of night sweats or daily fever. But this is not always reliable evidence that the fluid is serous in such cases. The fact that the effusion is beginning to fall under the influence of diuretics and counter-irritation, is additional, if not better evidence, that it is serous. Still better evidence is obtained by exploring the chest with a hypodermic syringe.

It is well to bear in mind the fact that the side is always contracted after pleurisy, and make the statement that perhaps the side will never be as large as it was before the attack.

This man, under the influence of infusion of Digitalis and Acetate of Potash, is passing ℥120 of urine a day. Tincture of Iodine is being applied externally.

SCARLATINA.

Five weeks ago this man was seized with a chill, and that is all he remembers of his history. When admitted to the Hospital his friends could only give a rambling history of the case, embracing the fact that he was discovered first trying to get out of his room with no clothes on. His delirium was of the fiercest variety, endeavoring to bite everybody who came near him. His mouth was covered with a white scum, and he occasionally pointed to his mouth as though he wished a drink of water. There evidently had been some sore throat. Upon admission his skin was in a complete state of desquamation. Temperature during past four weeks has varied from 98⅘ to 99⅘°. This case, from the history, was set down as scarlet fever, although the history is very simple.

It not infrequently happens that in the period of desquamation there is noticed a slight puffiness about the face, a little swelling of the ankles, which may go on to general anasarca; a difficulty in breathing, which indicates that the lungs are participating in the same œdema; albumen is markedly present in the urine; also epithelial and granular casts; and the patient is said to be suffering from an attack of acute Bright's disease, or acute diffuse nephritis.

A very common opinion among the people, and shared in by many practitioners, is that the child—for this is more particularly a disease of children—has taken cold; that all this trouble has been brought on by some exposure.

This is believed to be a mistaken notion. On the other hand, these casts in the urine are to be regarded as one of the phenomena of the disease. Some years it is present in almost every case, while in others it is scarcely seen. It is an analogue to the desquamation of the cuticle, and may take place entirely independent of exposure to cold. The result of this acute desquamation of the epithelium from the tubes of the kidneys is a disturbance of function; hence the general symptoms, such as the œdema, etc. The changes which are found in such kidneys are only such as are readily remedied, and the patient may be restored to perfect health. This is the general rule. The changes consist in a degeneration and desquamation of the epithelium; hence the appearance of epithelial, granular, hyaline, and sometimes blood-casts in the urine and floating epithelial débris; and there is also an accumulation of small round cells between the tubes, most apparent in the cortex, together with a certain amount of fluid.

These kidneys have a succulent appearance, and are usually increased in size. A proper method of treating these cases is, therefore, to call to our assistance diaphoresis, perhaps catharsis; but better, a non-stimulating diuresis to wash out the desquamated material from the tubes, and this, it is said, can be best accomplished by infusion of digitalis again. Patients who have suffered from Scarlet fever should have the skin protected by flannel for some time, for there is probably no doubt but that exposure to cold *may* be a sufficient cause for the appearance of this acute diffuse nephritis or acute desquamative nephritis, or acute Bright's disease. Frerichs expresses the opinion that "anasarca is produced by exposure to cold during the period of desquamation."

A child, however, when well protected, had better receive the beneficial influence of fresh air, than to forego it on account of the danger of exciting this kidney trouble by such exposure. The benefit derived much more than balances the risks taken; for with ordinary care the risks are but trifling, and the benefit is immense. The desquamation from the surface of the body and from the tubes of the kidney are both ordinary phenomena belonging to the natural progress of the disease.

Progress of Medical Science.

Writer's Cramp cured by Massage and Injections of Strychnia.—It is claimed by Rossander that the rational treatment of this disease requires an accurate study of each case, for it will be found that in many cases we can discover the cause. Our principal difficulty thus far has been, that writers on the subject have concealed their ignorance of the true nature of the disease by using terms such as "co-ordinating functional neuroses," etc., which convey no real notion of the *materies morbi*. What we really need to know is, whether the disease is of peripheral or of central origin, and, in the former case, whether it arises from a muscular paresis, or from too great irritability of certain groups of muscles or nerves, and whether there may not be various forms and combinations of these in different cases. Some of the older and more severe cases, when traced to their source, are found to arise from very slight causes that may be easily removed; but which, if allowed to operate unchecked, will give rise to other and more serious complications. When we remember the number of small muscles of the hand that are concerned in writing, we realize the difficulty of detecting which muscle is at fault; and yet the mighty train of symptoms may sometimes be traced back from one or other of the small muscles of the hand to the gray substance of the cord. In some cases, where one set of muscles is too strong for the opposing set, the disease might be compared to muscular asthenopia of the eye.

The following case is introduced, as it shows the characteristics of the disease and the mode adopted for its relief:

A clerk, 32 years of age, of good physique, and in other respects healthy, had noticed the first signs of the cramp about three years previously. At that time he began to notice a difficulty in writing, great fatigue after an hour, and soon total inability to form a letter. The pen could be held as well as ever; perpendicular lines could be drawn; but it was impossible to form letters, or to direct the hand to the ulnar side. At every attempt to do this, the hand was drawn upwards. These movements continued to increase in violence, until at last, at any attempt to write, the hand was forcibly jerked into the air. It occasioned him no pain.

This condition of things lasted two years, during which time he was quite unable to write, and especially if any one were looking at him. At the examination,

the hand and arm were found of normal strength, and the grasp of his hand was unaffected. All other motions were normal. He could hold the pen, and even place it on the paper without difficulty; but any attempt to form letters caused the above-mentioned movements. The treatment consisted of massage twice a day. Energetic friction was applied over all the muscles of the hand, and in addition, a small wooden cylinder was used to beat the muscles of the little finger and thumb, together with those of the forearm, particularly the pronators and flexors, and the flexor carpulnaris. The muscles of the palm contracted at the commencement when they were struck, though not with much force, but the abductor digiti minimi did not react at all. Injections of 10–12 drops of nitrate of strychnia (1 : 100) were then made daily into the forearm. An improvement was noticed after the first week; this gradually increased, and soon the patient commenced to write a little. After four weeks of treatment the cure was complete.—*Hygeia*, Stockholm, July, 1873.

Jaeger's New Incision in the Extraction of Cataract.—Linear incisions are defined by Jaeger as those only which fall throughout their entire length in the planes of one or more ocular meridians. If the surfaces of the wound be so situated as to intersect the planes of several meridians, no one of which traverses its whole length, the result is a flap incision. Again, he divides the linear incisions into complete and partial, according as the wound corresponds to one or more meridional planes, that is, as the canal of the wound is perpendicular or oblique to the surface of the bulb.

The difficulty of making linear incisions according to the above definition with the instruments in use, led Jaeger, in operating for cataract-extraction, to the adoption of the following modifications:

In 1845–6, with a concave-shaped lance eleven millimetres broad, the concave side being directed backwards, he made incisions into the outer segment of the cornea through which cataracts of considerable size could be extracted. However, as this incision did not suffice for the extraction of full-sized senile cataracts, he modified the operation by locating the incision in the sclerotic. He had concave lances constructed of from eight to sixteen mm. radius on the inner concave surface, and of from ten to thirteen millimetres breadth, and bent at an angle from 20° to 30° to the handle. The concave surface was directed backwards, and from the outer and upper border of the cornea an incision was made, parallel with the plane of the iris, into the anterior chamber. The incision fell for the most part in the sclerotic, and had an extent of from nine to eleven millimetres or more. He pursued this method for a considerable time, but in the end, finding that the results thereby obtained were no better than after the old flap extraction, especially when the latter was combined with iridectomy, he abandoned it entirely. From 1865 to 1868 he performed a large number of extractions according to Graefe's method, but his conclusion was that this also had no advantage over the flap extraction with iridectomy.

Quite recently Jaeger has adopted still another method. He has sought to construct a knife whose form should be the best calculated to effect the desired linear incision. The instrument is triangular, resembling in general Beers' knife, but considerably narrower. The length of the blade is 33 to 35 mm., the greatest breadth 5½ to 6½ mm. The back of the blade is blunt, but so thin as to fit exactly in the angle of the wound. The edge is bow-shaped or elliptical. The surface of the blade is curved cylindrically, the axis of the cylinder being parallel to the back of the blade. The front concave surface has a radius of 6 or 7 mm., the posterior convex surface about 5 mm. radius. With this instrument it is claimed that, according as the surface of the blade is inclined to the given meridional plane, a flap incision directed either forwards or backwards, or a perfectly linear incision, can be made as it may be desired. In distinction from other linear incisions, Jaeger has named the one made thus the concave incision (Der Hohlschnitt).

He describes his operation as follows: "The patient is placed either in the sitting or reclining posture; the lids are best kept apart by a simple holder which depresses the lower lid, or, in very restless patients, the double speculum is used; the bulb is fixed by the operator who grasps a fold of the conjunctiva below the lower edge of the cornea with a blunt notched pincette.

"I place the knife already described, with its concavity directed forwards, its edge upwards, parallel with the plane of the iris as to its length, and, as to its surface, inclined at an angle of from 35° to 40° to the same, and pass it, turning it slightly forwards in a direction corresponding to the curve of its blade, or, where possible, keeping it unaltered in a line corresponding to its back through the upper portion of the anterior chamber. Having made the puncture and counter-puncture, the bulb is no longer fixed by the pincette, but in proportion as the bulb tends to roll upwards, counter-pressure is made with the back of the knife. . . . ."

The advantages of this mode of extraction, it is claimed, consist:

1. In the production of the most complete linear wound possible, of a size sufficient for the largest cataract.

2. In the possibility of fixing the bulb as desired during the whole operation.

3. *In the more or less total retention of the aqueous fluid until the completion of the incision.*

4. In the relatively slight increase of the intra-ocular pressure during the accomplishment of the incision.

5. In the relatively easy escape of the cataract.

6. In subjecting the patient to an after-treatment neither very tedious nor exhausting.—*Allg. Wien. Med. Ztg.*, 1873, 27, 28, 29, 30, 31.

Treatment of Scabies.—Dr. Caspari believes that styrax has many advantages over other remedies in the treatment of this disease. In his experience he has found it pretty reliable. It occasions no burning of the skin, and no unpleasant feeling; it has no disagreeable smell, and seems to be more lasting in its effects than anything he has heretofore employed. To obtain the best results, he recommends that liquid styrax should be made up into a liniment with alcohol and oil. Every part of the body should be rubbed with it, the unaffected as well as the affected parts. To insure complete success this treatment should be repeated at least three times. A large quantity will necessarily be used, and if this be an important consideration it may be better to employ carbolic acid, which is far cheaper and effectual, though it requires to be repeated more frequently and for a longer time. A wash may be made of it, in the proportion of one drachm of the acid to a pound of water, or an ointment, of a drachm to the four ounces of lard. The diseased parts should be rubbed vigorously three times a day. In from two to three days the scabies will disappear, and any eczema which remains will yield rapidly to the same treatment. It has an advantage over styrax that it need only be applied at the seat of

the trouble.—*Deutsch. Klin. Allg. Med. Central Ztg.*, 82, 1873.

Neuropathic Origin of Diabetes Insipidus.—So many cases of this form of diabetes have been found to have a distinct causal connection with some nerve lesion, that it is interesting to be able to add three new cases furnished by Mosler. The first was a boy, seven years old, who had survived an attack of epidemic cerebro-spinal meningitis, and developed the symptoms of diabetes insipidus during his convalescence. The disease continued unchecked for years, though he underwent protracted hospital treatment. In the second case the attack followed immediately after a fall upon the head, and at the time of observation the disease had lasted fourteen years. While suffering from diabetes these two cases had no nervous symptoms. The condition of the two patients was materially bettered by the use of acetate of lead and opium, both in large doses.

In the third case the affection seemed to be connected with a syphilitic lesion of the brain, which had occasioned other nervous symptoms, such as convulsions and hemiplegia. This was shown by post-mortem examination, when areas of softening were found in the left hemisphere, medulla, and pons.—*Virchow's Archiv, Berl. Klin. Woch.*, 40, 1873.

Ostitis Deformans.—This name is proposed by Professor Czerny, of Freiburg, for a local affection of the bones which he believes to be exceedingly rare, and has not heretofore been described as a distinct disease by medical writers. Thus far he has personally known of but two cases, of which he gives the following histories: The first was a man, twenty-two years of age, who had served during the late war, and had experienced severe hardships from long marches and exposure to inclement weather. At that time he began to feel occasional pain in his leg, but the symptoms yielded under appropriate treatment. When he first came under observation there was pain and swelling over both malleoli. The foot, too, was less arched than its fellow, and commencing flat-foot was suspected. Rest and moist applications relieved the trouble, and he was discharged after he had been fitted with a supporting shoe (Stromeyer's). He returned, however, in a week, complaining of pain in the tibia at a point higher up. The pain increased, and when he was next seen the lower part of the leg was considerably swollen and painful, and bent somewhat backwards and outwards. A splint of plaster-of-Paris was applied, and tincture of iodine was used locally.

The pain diminished and the patient was discharged again, this time wearing a liquid glass splint. About six months later, when he was seen again, the swelling had entirely subsided, and now it was clear that the leg was permanently bent as before described. There was no pain in the bones, however, and they were quite firm and unyielding. The patient used the limb, depending somewhat upon the use of a stick, as his foot was slightly in the equino-valgus position.

The second case was a woman of pale, anæmic appearance, who had borne three children. She was suffering from periostitis of the ulna, for which she wanted relief. Her left leg showed the same deformity as in the first case described. She suffered no inconvenience from it at that time, but said that from the time she was eight years old, until sixteen she had pain at the point of curvature. At that time it began to bend, and she sought advice. Her trouble continued until her twenty-fourth year, when she was able to walk, and since that time she had not suffered any pain or weakness in the part. A number of somewhat similar cases have been recorded, but they are more properly either cases of senile osteoparesis or rarefying ostitis of the sternum or skull, the latter of which are always fatal. There is also another affection, the rickets of adults, which is simply a postponement of the rickets of children, while in these cases that are presented, the bones that had already received their earthy salts lost them and became soft and flexible, but subsequently regained their usual hardness. In these cases, too, the process was purely local, while in rickets it is general.

In all the cases that Professor Czerny was able to collect, in which the prominent symptoms coincided with his own, the patients recovered after a longer or shorter orthopædic treatment—that is, by rest and position.—*Wien. Med. Woch.*, 39, 1873.

Causes which Induce Cessation of the Menses.—From the statistics which were furnished by the histories of 400 patients, who had passed the climacteric years of life, Dr. Colnstein, of Berlin, has been put in the possession of some important facts, which he has tabulated as follows:

1. The duration of the menstrual function varied between 10 and 44 years; the larger proportion menstruated for a period varying between 28 and 34 years, of which the average, consequently, was 31 years.

2. In 76 per cent. of the cases cessation came on with precursory symptoms; in 24 per cent., or the remainder of the cases, it occurred suddenly. The causes which produced a sudden arrest were such as are usually given, viz.: mental excitement, physical shock, exhausting parturition, abortion, and severe attacks of illness. If the first pregnancy occurred between the 36th and 46th years, it was not uncommon for menstruation to cease, and not recur, even if the labor were normal.

Certain facts are also alluded to by the author which influence the early or late appearance of the menopause.

1. The date of the first menstruation is important, for those who menstruated early (before 14 years of age) continued to menstruate 3 years longer than the average; while, on the other hand, those who began to menstruate later (at 18 years of age and after) ceased menstruating 3 years before the average.

2. The regularity or irregularity of the duration or recurrence of the periods was no indication of an early or late cessation.

3. Marriage exerted a very decided influence. It was found that 15.5 per cent. of the married women continued to menstruate for a period varying between 29 and 34 years, while only 9 per cent. of the unmarried menstruated for an equal number of years.

4. The continuance of uterine activity seemed to depend on the number of births, for those women, whose menstrual functions lasted from 26 to 32 years, had invariably borne more than 3 children.

5. The date of the last delivery was also an important element. If this occurred between the ages of 38 and 42, and was at term, then the menopause occurred between the 24th and 32d year of menstruation; if, however, it fell between the 20th and 38th years, the menopause came between the 25th and 28th year of menstruation. If the last delivery was before term, then cessation often came on without much warning.

6. Lactation was found to be another important factor. In 40 women who had not nursed their children, the average duration of the menses was four years below the mean. From these data it was inferred that the longest continuance of the menses will occur in women who have menstruated early, have

married, have borne more than 3 children, have been delivered at term, between the ages of 38 and 42, and have nursed their children themselves.—*Deutsch Klin., Schmidt's Jahrb.*, 6, 1873.

Changes which the Sympathetic Nerve undergoes in Constitutional Syphilis.—To discover the special lesions of the sympathetic nerve in syphilis, Petrow has made a careful study of twelve cases which came under his own observation. His attention was mainly directed to the cervical, thoracic, and solar plexuses. He sums up the results of his observations as follows:

1. General syphilitic infection of the system manifests itself in the sympathetic system by changes in the nervous elements and in the interstitial connective tissue.

2. The nerve cells, aside from any change in the interstitial tissue, become pigmented and undergo what he calls a colloid degeneration.

3. The excessive production of connective tissue in various organs of the body, which is the peculiar lesion of syphilis, is accompanied by a similar growth in the nerves themselves, and causes atrophy of the nerve fibres and cells.

4. The endothelium surrounding the cells is affected in a similar manner to the cells. At first, the cells increase in size and proliferate, subsequently they undergo a retrogressive fatty metamorphosis.—*Virchow's Archiv, Schmidt's Jahrb.*, 6, 1873.

Treatment of Lupus Vulgaris and Lupus Erythematosus.—Dr. Veiel, of Constatt, has been in the habit of treating these obstinate affections by scarifying the surface, somewhat in the way that Volkmann has recommended, that is, by puncturing the surface of the patches in numerous places, after which he applies a solution containing equal parts of the chloride of zinc and alcohol. The result of this application is, that suppuration takes place at the points of puncture, and then scabs form, which usually fall off after eight or ten days. The same treatment must be repeated until a smooth, shining scar has formed; and then the result is to be regarded as satisfactory. From five to eight applications are usually sufficient. In common lupus the treatment may require a longer time, because the caustic will necessarily produce extensive ulcers that will require a long time to heal. The patients should, at the same time, be put upon the internal use of cod-liver oil and arsenic. Salt-water baths should also be employed. In performing the operation by puncture, Dr. Veiel makes use of six or more lancets, which are so combined together as to constitute a single instrument. In this way less time will be consumed and a great deal of pain will be saved.—*Arch. f. Derm. u. Syph., Schmidt's Jahrb.*, 6, 1873.

Impossibility of making a Differential Diagnosis between Cerebral Embolism and Cerebral Apoplexy.—To illustrate the uncertainty of making a positive diagnosis between these affections, Schmidt mentions two cases which occurred at the clinique in Erlanger. Two women of advanced age were attacked with all the symptoms which are usually ascribed to cerebral apoplexy. The arterial walls were rigid, there was hemiplegia, absence of heart lesions that could be detected, and unconsciousness lasting two days. In one of the cases post-mortem examination showed a slight stenosis of the mitral valve, and embolism of the artery of the right fissure of Sylvius. In the other there was a thrombus in the right carotid, just at the point where it enters the cranium, and sclerosis of the cerebral arteries.—*Deutsch. Arch. f. Klin. Med., Schmidt's Jahrb.*, 6, 1873.

Aphthous Stomatitis from Drinking Cow's Milk.—Dr. C. Van Parys relates a case in which a man who drank some fresh cow's milk was seized shortly after with vertigo, colic, vomiting, and obstinate diarrhœa. Subsequently severe pains in his throat and coughing set in, and he found it difficult to swallow. On examining the cavity of the mouth numerous vesicles and ulcerated points were found along the alveolar border of the lower jaw and on the inner surface of the under lip. The pharynx appeared unchanged. On the right thumb there were blisters, as well as on the inner surface of the left hand, between the fingers and toes, and in the folds of the elbows, and about the perineum, scrotum, and penis. These symptoms were regarded as analogous to the stomatitis aphthosa of cattle. On the morning of the attack the patient had taken freely of fresh unboiled milk from a cow that had the disease. Similar cases are mentioned, and it is stated that in Holland the milk of such cows is strictly prohibited. It was interesting to know that other members of the patient's family drank the milk of the same cow, taking care to have it boiled, and suffered no harm. It is recommended during an epidemic of this kind, to be careful and boil the milk before using it.—*Journ. de Brux., Schmidt's Jahrb.*, 6, 1873.

Metallic Mercury in Obstinate Constipation.—Two cases have recently been reported which revive an old-fashioned notion as to the value of this metal in overcoming obstructions of the bowels. The last case was in the practice of Dr. Kirschstein, who narrates the history as follows: A fisherman of vigorous habits, who had suffered from frequent attacks of abdominal pain, found that he was becoming gradually more and more constipated, until at length his bowels would no longer move, and he was seized with vomiting, tympanitis, and other alarming symptoms. After five days of ineffectual efforts to relieve him, the physicians, who had exhausted the stock of remedies usually relied on in these cases, finally decided to give metallic mercury as a *dernier ressort*. His case was regarded as hopeless, and death was anticipated in a few hours. At eight o'clock in the evening a tablespoonful of the metal was given, and was followed half an hour later by a similar dose. Shortly after the second dose the vomiting ceased, the patient became calm, and towards morning there was a discharge of hardened fæces. No further remedies were given, and the patient was soon able to resume his work. His passages became entirely regular; but for a period of three weeks he passed almost daily larger or smaller quantities of quicksilver.—*Berl. Klin. Woch.*, 37, 1873.

Discovery of a Paleolithic Skeleton.—Mons. Emile Rivière recently discovered in a cavern at Mentone, Italy, a fossil human skeleton of the paleolithic epoch. The attitude was one of repose, as if death had overtaken a man during sleep. It is believed that the stature of the fossil man can be estimated at the lowest at six feet. The skeleton, which no more resembles that of an ape than does a modern skeleton, presents some contradictory characteristics of inferiority and paleolithic antiquity, such as a marked dolicocephalic type, great stature, increased length of the radius relatively to the humerus (10 : 13½ inches), a platycnemic tibia; and, on the other hand, marks of superiority, viz., a forehead neither low, retreating, nor narrow; an absence of prognathism, and a facial angle of nearly 85 degrees.

The skeleton lies in the Anthropological Gallery of the Museum of Natural History, Paris, awaiting the judgment of leading anthropologists as to the significance of the discovery.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month, by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, November 15, 1873.

THE MEDICAL CHARITY QUESTION.

THE medical charity question is still open for discussion, and we are willing that it shall be so long as any new ideas are elicited or new suggestions made. In another column we have letters bearing upon the subject—one in particular referring to the relation of medical charity to the clerical profession—which deserves attention. Our correspondent, who seems to be more than usually favored with ministerial patronage, is inclined to look at the matter in the practical light of a man of business who is seeking some explanation for acts which have been sanctioned by a time-honored custom, and which he in common with others of the profession are expected to perform whenever called upon.

As far as this particular question of gratuitous services is concerned it resolves itself into one of courtesy, of sympathy for a class of gentlemen whose lives are spent in self-sacrifice for the good of others. The custom, doubtless, dates as far back as the time of the Apostles, and is, in the main, a good one; one which does honor to our hearts and consciences. There may be exceptions to the general application of the accepted rule, but these are certainly very few indeed, not enough in themselves to have any particular weight as militating against the general practice.

As a rule, clergymen have small incomes, relatively much smaller than physicians of corresponding standing in their profession. They have a better start in life than physicians, but they are proportionately longer at a standstill when they arrive at a point of barely living.

Again: they do not ask our services for nothing, but that should not relieve us of our self-imposed obligations. If our correspondent finds his clerical charity a burden, he has only himself to blame for forcing himself to do what he believes to be wrong. We are understood now to speak on general principles, and from such a standpoint to sanction the custom. If a physician be very poor, and the clergyman very rich, the case is altered, in a pecuniary sense at least, and charges should be made. We do not think that there would be any objection to paying bills under these circumstances—no more objections than there should be for charging a fee.

Our correspondent has never heard of a clergyman refusing a fee. If a physician refuses a fee when he can get it, he can certainly learn a useful lesson from the minister. We should like to see what would be the result if our correspondent should be offered a fee by one of his five clerical patients. If he should refuse, it would not be because he thought it wrong to do so.

We bestow our charities upon the ministry for two very good reasons, which we cannot conscientiously offset by a merely pecuniary consideration. First, they are gentlemen whose pay, in a general sense, bears no comparison to their work, making them as a class relatively poor. Secondly, we should take a particular gratification in extending professional aid to such active and efficient co-workers in the cause of humanity and suffering.

Another correspondent speaks of the evil of large charges to the poor on the part of the apothecaries. This is one which every one can appreciate. The remedies suggested are good in the main, and for the want of any better which at present occur to us, we commend them to the consideration of all concerned. The class of poor to which particular reference is made by our correspondent is not that which should be treated at our dispensaries, but such as are able and willing to pay the physician a modest fee.

In the interests of charity and in justice to the "struggling practitioner" this class too should have every encouragement to follow out their wishes. We should like to have some suggestions from the pharmacists upon this point.

THE TRANSACTIONS OF THE STATE SOCIETY.

IT will be remembered that the State Legislature refused to make an appropriation for the publication of the Transactions of the State Society for the present year, and that the Medical Society of this county some time ago voted to pay its share towards the expense of the same, provided that the State Society should act independently in the matter. It is high time that the other societies in the county should follow the example of our own, so that some definite plan can be decided upon, and the volume be published before the next annual meeting. The Committee on Publication do not wish to take the responsibility of issuing the volume unless they have the

necessary pecuniary support. This latter is all that is needed, and it is to be hoped that the county societies throughout the State will not be backward in the expression of their opinion upon the subject.

DAMAGES FOR VACCINATION.

A CASE recently came up for adjudication in the courts which has something of a medical interest attached to it.

In July, 1871, when the small-pox prevailed to an unusual extent in this city, and there was fear of it becoming an epidemic, the Board of Health detailed certain surgeons to vaccinate throughout the city all who had not been vaccinated. Dr. Brown, one of such surgeons, vaccinated Alice E. Hallowell, then four years old. It is claimed that through such vaccination she was inoculated with scrofula, and a suit was accordingly brought by the father of the girl against the city to recover $10,000 damages. The testimony for the father showed that he had forbidden his wife to let the child be vaccinated by any public physician, but that Dr. Brown disregarded this injunction and insisted on the vaccination. Several physicians also testified that scrofula, syphilis, and various other diseases might be imparted through the use of improper vaccine matter. At the close of the testimony for the plaintiff, a motion was made by the defence to dismiss the complaint, and the same was argued at considerable length. It was urged that the Doctor exceeded his authority, but the main point insisted upon was, that the city was not liable in the case, inasmuch as the Board of Health under the present laws was distinct from the city government. Judge Van Brunt took this view of the case, and dismissed the complaint.

In times of threatened epidemic, when great numbers are in danger, it is eminently proper to reduce this danger to the minimum, and any interference with the exercise of such duty is reprehensible if not punishable. For the performance of such obligation to a commonwealth the law provides by giving the necessary discretionary powers to Health Boards. In the case before us there seems to have been unusual danger of an epidemic, and the order of the Board to its assistants, to use every means to prevent such an occurrence, was eminently proper. Whether there was any justification on the part of the physician in this particular instance in setting aside the express wishes of the father of the girl is questionable. The parent certainly had a right to choose his own physician to vaccinate his child; all that was necessary on the part of the representative of the Health authorities, was to be satisfied that the said vaccination should be performed in a certain time. By forcing his services upon the family he certainly, under the circumstances, exceeded his authority.

As to the damages from the vaccination, if they were confined to the possibility of proving the inoculation of scrofula, they could not be sustained by any substantiated scientific data. The danger of inoculation of syphilis is, we believe, generally admitted when any of the blood of the infected person is mixed with the vaccine lymph, but beyond this we cannot go.

THE COMMITTEES ON HYGIENE AND THE COUNTY SOCIETIES.

IN our report of the last meeting of the Medical Society of the County of New York, there appears a circular from the Secretary, DR. W. H. BAILEY, directing the attention of the Committees of Hygiene of the several County Societies to certain questions propounded by the Central Committee at Albany. These questions are certainly very important ones, and as such should be discussed by all parties interested.

We should like to see all the necessary information forthcoming, but it strikes us that the proper method has not yet been found to obtain it. There is altogether too much of the elements of self-consciousness and presumption in the suggestions to the small committees, to expect much in the shape of the necessary co-operation—in fact, too much of the committee about it, and too little of the County Societies. We should like to know if any Committee on Hygiene, of any County Society, has a right to communicate directly to a central committee, without the sanction of the County Society. If so, how can the central committee pretend to present in their annual report anything more than the opinions of certain gentlemen who happen to be on these committees? Altogether, the information sought to be collected appears to have for its object the glorification of certain gentlemen who assume to cultivate Hygiene as a business rather than as a strictly scientific study.

Reviews and Notices of Books.

THE CEREBRAL CONVOLUTIONS OF MAN, represented according to Original Observations, especially upon their Development in the Fœtus. Intended for the use of Physicians. By ALEXANDER ECKER, Professor of Anatomy and comparative Anatomy in the University of Freiburg, Baden. Translated by ROBERT T. EDES, M.D. New York: D. Appleton & Co. 1873.

THERE has been an increasing demand of late years to have the descriptive anatomy of the external brain-markings put upon a sound and definite basis. This want has been specially felt by physiologists and pathologists, but thus far they have been unable to unite upon a basis that was acceptable to all, and in consequence the entire subject is involved in the greatest confusion. In this little volume of 87 pages, lying before us, the author has established some sort of order, and he has given us a new map of the fissures, convolutions, and sulci, which is claimed to be both scientific and practical.

In adopting this course he finds himself called upon to make a new nomenclature. His reasons for so do-

ing are, that his classification is a new one, having reference rather to the fœtal development of the brain than to its mature condition in adult life.

He regards the fissures as the most important landmarks, and starts from them in his description. The convolutions are named from their relation in position to the fissures. He mentions three kinds of convolutions: chief, primary, or first; subordinate, or second, and finally, tertiary. The chief or primary he compares to great mountain chains; the second to subordinate ranges, separated by longitudinal valleys; and the third to mountain ridges running off right and left from the greater chains. The fissures are also subdivided into three principal classes.

If we could hope that anatomists in general would be satisfied with this classification, we should certainly have gained a great deal; but it really looks as if the book were only an addition to the confused notions already existing, and the physician will be no better able to find his whereabouts in this most perplexing labyrinth than before. The author concludes the book by giving his method for making a systematic examination of the brain-exterior. This is really useful. The methods he employs for preserving and preparing his specimens are hardly detailed enough for practical use. The translation is smooth and free from Germanisms. The plates are clear and sufficiently numerous.

An Introduction to the Study of Practical Histology. For Beginners in Microscopy. By James Tyson, M.D. Philadelphia: J. B. Lippincott & Co. 12mo, 50 pp. 1873.

This essay is a slightly altered reprint from the *Philadelphia Med. Times*. It is intended to serve as an *introduction* to the study of practical histology. We do not think that the technology of the microscope could be more thoroughly exposed in an equal space than has been done in this little treatise. The methods here given for examining the blood and connective tissue are especially interesting.

A Practical Treatise on the Diseases of the Ear, Including the Anatomy of the Organ. By D. B. St. John Roosa, M.A., M.D., Professor of Diseases of the Eye and Ear in the University of the City of New York, etc., etc. Illustrated by wood engravings and chromo-lithographs. New York: Wm. Wood & Co. 1873. 535 pp. 8vo.

Lectures on Diseases and Injuries of the Ear, Delivered at St. George's Hospital. By W. B. Dalby, F.R.C.S., M.B. Cantab., Aural Surgeon to the Hospital. With twenty-one Illustrations. Philadelphia: Lindsay & Blakiston, 1873. 228 pp. 12mo.

According to the last census there are in the United States sixteen thousand two hundred and five deaf-mutes. Probably in much more than half of these cases the deafness is acquired, and this large percentage is in great measure due to the ignorance which prevails in the profession with regard to otology. Many ears are irreparably damaged by processes of disease which are readily checked by appropriate treatment at their commencement. Many of these diseases are caused by, or associated with, various affections of the general system. This is especially true of the diseases with which young children are affected; such as the exanthemata, pneumonia, coryza, etc. If either of the books above mentioned could receive a few hours' study from every medical man in the land, a great benefit would result to humanity. As Prof. Roosa says in his introductory chapter: "It is to be feared that even now many wise and skilful men do not know that to drop stimulating or even anodyne applications upon a membrane which they have never examined, to probe an ear for wax which they cannot see, are purely empirical practices which every conscientious physician should hold in abhorrence."

This introductory chapter contains a very complete and interesting sketch of the progress of otology from the time of Hippocrates to our own day. The authority of Galen appears to have remained almost absolute for 1,300 years. This want of progress is here very properly ascribed to the absence of scepticism peculiar to those ages. Though light began to dawn in Valsalva's time, it is only within the last few years that this branch of medicine has approached its present high rank.

The anatomy of the ear is in great measure condensed from Henle, and is as explicit as could be expected, considering the space thus occupied. Most of the cuts illustrating this subject are copied from Henle and Rüdinger. In the second chapter, fourteen pages are devoted to the anatomy of the auricle and the external auditory canal. In chapter third, the methods for examining aural patients are given. Among the methods for registering the hearing power, that of Prout is recommended as the best. The distance is usually expressed in inches as a fraction, the numerator being the distance at which the particular sound is heard by the patient, and the denominator that at which it should be heard by a normal ear. Although mention is made of rhinoscopy as an aid to diagnosis, it does not receive the attention which its importance demands, only three pages being devoted to this subject. Prof. Roosa does not lay very much stress on the advantages of the diagnostic tube, although Kramer was of the opinion that the sounds heard are more clear and distinct than those heard with the stethoscope in diagnosing respiratory diseases. The appearances presented by the membrane after the inflation give much more reliable information. As an example of the loosely constructed sentences which now and then occur in this book, we might refer to the one on page 98, where it is stated, in describing Politzer's method, that the surgeon places an air-bag into one of the nostrils. The importance of Politzer's and Valsalva's methods of inflating the ear is acknowledged, and at the same time the evils resulting from the injudicious use of these procedures are also pointed out. Affections of the auricle are, for the most part, relegated to works on general surgery. Othæmatomata are, however, well discussed, though there is not much said about the treatment.

The remainder of the first part of the book—from the fifth to the eighth chapters inclusive—is devoted to the external auditory canal. The injurious effects of improper poulticing, auriculaves, etc., are pointed out, and many useful suggestions for maintaining the health of this part are given. Inasmuch as the external auditory canal is lined by epidermis, and not by mucous membrane, it is improper to speak of a catarrhal inflammation of this part, as is done by some authors. Parasitic otitis is considered not to be a primary disease, but a consequence of diffuse otitis. The formation of a vegetable fungus in the ear is usually preceded by eczema. The histology of aspergillus is illustrated by three original engravings. The cases occurred in Dr. Roosa's practice. Warm water is recommended as the only parasiticide necessary. We think, however, that something stronger will sometimes be found necessary.

Syphilitic affections of the auditory canal are considered to be very rare, though the modifying action of syphilis on other local diseases is not denied. The seventh chapter is occupied with the consideration of inspissated cerumen. This is not so common an affection

as the records of many of our public institutions would lead one to suppose. The cases thus recorded are often only impacted cerumen, or the thickening is due to some other disease of the parts. "A vigorous syringing, or worse still, probing, in order to *see* if the wax be not hardened," is considered a bad practice. Chapter eighth is devoted to foreign bodies in the ear. The employment of instruments for their removal is condemned, at least until syringing has proved unavailing. Even the latter should not be resorted to until the presence of the body has been ascertained with the otoscope.

Part second—comprising chapters nine to seventeen, inclusive—treats of the middle ear, including the membrana tympani. This portion of the ear is affected in a large majority of the aural diseases. Its anatomy is therefore very important. Forty pages are devoted to a very lucid, though condensed account of so much of the anatomy as is indispensable for a correct appreciation of the diseases which occur here. Chapter tenth treats of injuries of the membrana tympani. Independent or primary myringitis probably does not occur, though it is alluded to by some writers. This will be readily appreciated when we consider the anatomical structure of the membrane, two of the three layers of which it is composed being direct continuations of adjacent parts. Its vascular and nervous supplies also show that its inflammations must be of a secondary nature.

The effect of condensed air is ably discussed. Recent engineering enterprise in laying foundations for bridge-piers, has furnished opportunities for collecting valuable information on this subject. Chapter eleventh treats of acute and subacute catarrhal inflammation of the middle ear. There are very few persons who have not suffered from "earache," the popular name for acute catarrh of the middle ear. As it is very rarely treated by physicians, it is often allowed to run on to suppuration of the membrana tympani, myringitis, etc.; indeed many practitioners even encourage suppuration, believing it to be a salutary process. The information contained in this chapter is especially valuable to those who treat diseases of children.

In otitis media hemorrhagica, the inflammation of the lining membrane of the middle ear assumes such a rapid and violent course, that there is not only an exudation through the walls of the vessels, but the walls themselves actually break down, and the cavity becomes so distended with blood that the drum-head almost necessarily bursts. Hemorrhage into the tympanic cavity also occurs in Bright's disease; we should therefore be on our guard for renal disease when treating these hemorrhages.

Chronic non-suppurative inflammation of the middle ear and the affections of the labyrinth are the most intractable of the aural diseases. Nearly half the cases seen in private practice are of the former class. The nasal douche is very properly condemned, and very conclusive evidence is brought forward in support of this opinion. Bougies are not very highly recommended; they can almost always be replaced by the catheter or Politzer's method. The value of electricity for the treatment of aural diseases has probably been overestimated by many. The cases in which it has proved most beneficial are quite as amenable to the catheter, Politzer, and pharyngeal applications. Paracentitis is not considered a dangerous or painful operation. Its chief value is in furnishing a means of treating the lining of the middle ear, and may very properly be performed in cases of chronic proliferous inflammation which still advance in spite of other treatment. Division of the tendon of the tensor tympani and of the adhesions between the membrana tympani and the walls of the cavity, deserve a trial where the symptoms of increased auricular pressure are not otherwise relieved. Angioma is here for the first time classified among the aural polypi, a case having occurred in the practice of Dr. A. H. Buck, of this city. The histology of aural polypi is illustrated by three cuts drawn from microscopic examinations of growths removed from Dr. B.'s patients. Mastoid diseases, and caries and necrosis of the temporal bone, are very thoroughly considered in the seventeenth chapter. Free incisions over the mastoid process are recommended where there are symptoms of inflammation of this part, and the propriety of trephining the process to give free exit to pus is regarded as fully established. This chapter concludes with a table of forty cases "showing the course and symptoms of cases of meningitis, cerebral abscess and pyæmia, resulting from aural disease." This table is well worth the study of those physicians who do not realize the grave importance of the careful consideration of an ulcerated middle ear.

Part third is devoted to the internal ear. Chapter eighteen contains a very good résumé of the anatomy of this part, and the succeeding chapter treats of the diseases which occur here. A short chapter on deaf-mutism and hearing-trumpets, and several exceedingly well-executed chromo-lithographs, illustrating the healthy and diseased membrana tympani, followed by an index of authors and one of subjects, complete the book.

The value of the work is very much increased by the introduction of numerous interesting cases illustrating the various diseases. The literature of the subject is fully presented, and the bibliographical references well arranged. This will be of great assistance to any one desiring to investigate special subjects. The views and experiences of American practitioners, and the results of European researches, are presented with great impartiality and fairness. The general arrangement of the work is excellent; it is very comprehensive and thorough, with a well-elaborated system, and contains answers to all questions in spots easily found. The indications for treatment are so thoroughly stated, and their several advantages so carefully weighed, that no one need hesitate to follow the directions given. We think that all who read this book will agree with us in pronouncing it by far the best treatise which has yet appeared on disease of the ear.

Dr. Dalby has presented us with a very readable little book, which is destined to render much service in the saving of ears. The interesting style in which it is written will make it very popular among general practitioners, and it is therefore fortunate that the information which it contains is so very reliable and safe.

An abstract of these lectures appeared in *The Lancet* during 1872, but they are now presented as originally delivered, with some alterations and additions. The clinical nature of the lectures is preserved by giving an abstract of many of the cases used in illustrating them. Short abstracts of the anatomy of the external, middle, and internal ear precede the discussion of the diseases of the several parts.

AN INTRODUCTION TO PRACTICAL CHEMISTRY, INCLUDING ANALYSIS. By JOHN E. BOWMAN, F.C.S., late Prof. of Practical Chemistry in King's College, London. Edited by Chas. L. Bloxam, F.C.S. Sixth Amer. ed. Phila.: H. C. Lea. 1873.

THIS, which is a sixth American edition, is a reprint of the sixth English edition, which has just appeared.

Compared with former issues the present one has been changed, which enhances its value to the student of chemistry and maintains its reputation as a standard work. The course on qualitative analysis has been revised, especially such of it as has reference to the examination of the precipitate of hydrosulphate of ammonia. Additions have also been made to the examples for practice in quantitative analysis, and more explicit directions given to enable the student to help himself in his studies. The weights and measures for this analysis are given in French and English, giving the learner a very obvious advantage. It is unnecessary to say that the reputation of the work as a standard has long ago been established.

A Treatise on Pneumatic Aspiration of Morbid Fluid. A Medico-chirurgical Method of Diagnosis and Treatment of Cysts, Abscesses of Liver, etc. By Dr. Georges Dieulafoy, gold medallist of Hospitals of Paris. Philadelphia: J. B. Lippincott & Co. 1873.

On the 2d of November, 1869, Professor Gubler presented to the French Academy of Medicine, in the name of Dr. Georges Dieulafoy, an apparatus called an Aspirator, and a paper giving a general view of a method called aspiration. We think that facts warrant the assertion, that no innovation since the introduction of anæsthesia, has produced such a spirit of inquiry in the profession as this same means of diagnosis and treatment. We are fully aware that many have been disappointed at the results obtained by means of an agent with which they were not familiar. In many cases mishaps were occasioned by faulty instruments, and in many more by the injudicious use of good ones, and we would earnestly advise all those intending to avail themselves of the certain advantages which attach to aspiration, to study Dieulafoy's book before selecting an aspirator or using one in the investigation or treatment of disease.

The author has followed up the subject with the true ardor of a Frenchman, and has collected an amazing array of cases, considering the short period that has elapsed since its introduction. The successful as well as the unsuccessful cases are all given in detail, and are commented upon in a very able manner.

Part II.—Aspiration of the Organs—commences with a chapter on the Diagnosis and Treatment of Hydatid Cysts and Abscesses of the Liver, in which the author proves the harmlessness of the puncture where certain precautions are observed. He gives the histories of seven cases of hydatid cysts, some of which were cured by one or two aspirations, and one remarkable and rebellious case, in which three hundred aspirations and several injections were necessary to effect a cure. A remarkable feature which was observed in this case and in others referred to under the head of Aspiration of Thoracic Cavity, was the occurrence of menstruation from the lining membrane of the sac or cyst in amenorrhœal women.

Chapter II. treats of Pneumatic Aspiration in cases of retention of urine. Twenty cases are recorded requiring ninety-eight punctures, and in no case was the relief marred by accident of any kind.

Two cases of spina bifida are given. In both a cure was obtained, in the first by simple aspiration, in the second by aspiration with iodized injections.

Hydrocephalus is illustrated by the histories of five cases, with unfavorable results in all. Twenty-seven cases furnish the elements necessary for forming an opinion as to the innocuousness of aspiration in strangulated hernia; twenty cases that had resisted taxis were reduced by puncture of the intestine; four, in which aspiration failed, were subsequently relieved by kelotomy, and in these last cases it was that the harmlessness of the punctures was demonstrated; in three cases aspiration and kelotomy were followed by death.

Pericardium.—On the 28th of January, 1870, Dr. Pouroy, then dresser to the Hôtel Dieu, performed aspiration, in M. Frémy's ward, on a patient suffering from purulent pericarditis, with the happiest result. Two other cases are recorded in which aspiration afforded relief, but in both of which the patients succumbed to complications of disorders involving the thoracic viscera. We think that it will be found that eventually aspiration will find its greatest field of usefulness in the diagnosis and treatment of collections confined within the sac of the pleura. All but the special practitioners will admit that the diagnosis of such collections is not unfrequently beset with difficulties, and Dieulafoy has shown that by the simple prick of a needle all doubts are at once dispelled. No fear of wounding the lung need deter the physician or surgeon from puncturing the chest, for such wounds have been proved innocent. Successive aspirations have been made in serous, purulent, and hemorrhagic effusions, without untoward results, and injections by the aspirator have been used in a number of cases, all of which are given in detail.

Treatment of hydrarthrosis and effusions into the knee-joint are illustrated by a very large number of cases collected from various sources, and tending to prove that synovial, hematic, and purulent effusions may be removed successfully by aspiration.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Sixty-eighth Annual Meeting, October 27th, 1873.

Dr. Ellsworth Eliot, President, in the Chair.

The President presented to the Society a letter and pamphlets from Prof. Francisco Dechiara, of Palermo, recently elected an honorary member; also copies of *The Sanitarian*, the gift of Dr. A. N. Bell.

The following persons being recommended by the Committia Minora, were admitted to membership:

Garret Cosine, of East 126th street, a Graduate in Medicine at Bellevue Hosp. Med. Col. in 1868; Robert Taylor, 167 West 34th street, a Graduate in Medicine at the Long Island Hospital Col. in 1871; David Webster, 19 East 39th street, a Graduate in Medicine at Bellevue Hosp. Med. Col. in 1868; John A. Weyth, 187 Lexington avenue, a Graduate in Medicine at the University of Louisville, Ky., in 1869, and at Bellevue Hosp. Med. Col. in 1873; Adolph Brandes, 29 Market street, a Graduate in Medicine at the University of Greifswald, Germany, in 1865; Daniel Lewis, a Graduate in Med. at the Col. of Phys. and Surg. Med. Dep. of Columbia Col. in 1871; Eliza Judson, a Graduate in Medicine at the Woman's Med. Col. of Pennsylvania, at Philadelphia, in 1872; and Anna Lukens, a Graduate in Medicine at the same institution in 1870.

The President announced the death of the following members:

Adam Clarke Corson, a Graduate in Medicine at

the College of Phys. and Surg. Med. Dept. of Columbia Col. in 1866, and member of the Society since October 1th, 1869, who died at Hartford, Conn., October 10th, 1873, aged thirty-four years; SAMUEL BLOIS, a Graduate in Medicine of the Med. Dept. of the University of the State of N. Y., and a member of this Society since Oct. 13, 1828, who died on Sunday, Oct. 19, at Irvington, N. Y.

The RECORDING SECRETARY read the minutes of the Commitia Minora for the preceding year, by which it appeared that about eighty physicians had been recommended for membership in the Society.

The TREASURER made his annual report, of which the following is the substance:

	CR.	
Oct. 29, 1872.—By cash in hand		$675 92
" 27, 1873.— " initiation fees		275 00
" " " " annual dues		518 00
		$1,468 92
	DR.	
Oct. 27, 1873.—To expense account		$542 75
Balance on hand		$926 17

THE COMMITTEES ON HYGIENE AND THE CENTRAL COMMITTEE.

The PRESIDENT presented a letter and pamphlets from Dr. Francisco Dechiara, of Palermo, lately elected honorary member of the Society; and the following circular letter from the Secretary of the State Medical Society to the Medical Society of the County of New York:—

"In accordance with the recommendation of the President of the Medical Society of the State of New York, in February last, the following resolutions were adopted:—

"1. That the Standing Committee on Hygiene shall be added to, and hereafter recognized among, the Standing Committees of the Society.

"2. That the Standing Committee shall consist of seven members.

"3. That the Secretary be directed to send a circular to each County Society, urging the formation of Committees on Hygiene, to collect and discuss facts in accordance with the recommendations of the President.

"4. That the Standing Committee on Hygiene place itself in immediate correspondence with the Committees on Hygiene of the County Societies.

"The following were appointed the Standing Committee of the State Society:—

"A. N. Bell, M.D., Chairman, Brooklyn; S. O. Vanderpoel, M.D., Health Officer of the Port of New York; H. D. Didama, M.D., Syracuse; H. W. Dean, M.D., Rochester; John Ordronaux, M.D., Roslyn, L. I.; Stephen Smith, M.D., New York; C. R. Agnew, M.D., New York."

The Committee, through their Chairman, have since communicated the following:—

"After mature deliberation, correspondence, and personal intercourse, as far as practicable—covering a large field of inquiry for the future—the Committee has determined that the work of primary importance through the State is *drainage*. And to the end that as much information may be obtained on this subject as practicable, the following points of inquiry are submitted and commended to all of the County Society Committees:

"1. To what extent are the diseases of your county due to insufficient drainage?

"2. How many acres of marsh lands have you in your county?

"3. Have you intermittent diseases not attributable to marshy deposits, but to soil saturation?

"4. Are there in your county places where intermittent fever has disappeared as a result of systematic drainage of surface saturation?

"5. What system of drainage is necessary to render your county free from malarious diseases?

"The Secretary of every County Society is requested to inform the Chairman of the Standing Committee of the State Society, as soon as practicable, of the appointment of its Committee on Hygiene, and of whom it is constituted. And the Chairman of the Committee on Hygiene is requested to send the report of his Committee to the Chairman of the Standing Committee of the State Society, on or before the first day of January next, that it may be included in the report of the Committee at the annual meeting.

"In forwarding the above circular to the different societies of the State, the Secretary feels it his duty to state that he did not do it at an earlier day, because it was not definitely known whether the Transactions of the Society for 1873 would be published or not; but now, as the State has declined to publish them, and the Publishing Committee do not deem it proper for them to assume the duty, the subject will be referred to the Society at its next session.

(Signed) "WILLIAM H. BAILEY,
"*Secretary.*

"ALBANY, N. Y., *August* 18, 1873."

ELECTION OF OFFICERS.

The Society then proceeded to ballot for officers for the ensuing year, the result being as follows:—

For *President* (Drs. Sands and Thomas having withdrawn): Dr. Ellsworth Eliot; for *Vice-President*: Dr. H. B. Sands; for *Recording Secretary*: Dr. A. E. M. Purdy; for *Corresponding Secretary*: Dr. F. A. Castle; for *Treasurer*: Dr. J. E. Janvrin; for *Censors*: Drs. A. H. Smith, J. C. Peters, G. M. Smith, A. Jacobi, and H. T. Hanks; for *Delegate to the State Society* (for one year to fill a vacancy): Dr. L. De F. Woodruff.

During the counting of the ballot Dr. H. B. Sands showed to the Society a patient on whom he had successfully performed Adams' operation of "subcutaneous osteotom of the cervix femoris" for the cure of bony anchylosis of the hip-joint.

Following the announcement of the ballot the meeting adjourned to meet on the fourth Monday of November, at eight o'clock.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 8, 1873.

DR. ERSKINE MASON, PRESIDENT, in the Chair.

CANCER OF FEMALE BREAST AND ELECTROLYSIS.

DR. CROSBY exhibited a specimen of cancer of the female breast, removed the afternoon of the meeting by him from a lady aged —. She had been for a long time under the electrolytic treatment, but without benefit. The clinical interest in this case was centred in the application of electrolysis to the surface of the wound, in the hope that any remaining germs of disease might be eradicated at the same time that the healing process might be hastened. He had made it a practice in his late operations to make use of the process, and thought that good had come of it.

The tumor had not been examined microscopically, and, at the suggestion of the presenter, was referred to the committee on micro-scopy.

EPISCLERAL MELANOTIC SARCOMA.

DR. H. KNAPP exhibited an eyeball extirpated by him ten days previously. The patient, a man 45 years of age, had first noticed, six years ago, a small blackish elevation on the inner side of the sclerotic, near the cornea of his left eye. During two years it grew slowly to the size of a cherry-stone, when it was removed by the late Dr. Clavitter, of Williamsburg, N. Y. It re-pullulated, increased slowly, and was again removed two years later. A second relapse pursued the same course, and when Dr. Knapp saw the patient for the first time, about a month ago, it had reached the size of a French bean, and extended from a little below the horizontal meridian on the nasal side, upward beyond the vertical meridian, covering the upper inner half of the cornea and a somewhat larger space of the adjacent sclerotic. Its surface was blackish, smooth and lustrous, except in the centre, where it was exulcerated. Pupil, iris, size, and tension of the eyeball were normal. Sight was unimpaired, and the visual field was complete. On ophthalmoscopic examination the whole fundus was found to be in a healthy condition.

The eyeball was enucleated, and immediately after opened by a meridional section passing through the greatest thickness of the pseudoplasm. This growth originated in the superficial layers of the corneo-scleral juncture and the adjacent scleral and corneal tissues. (See accompanying figure).

Its posterior part lay loosely upon the sclerotic, from which it could be readily separated. Its anterior part was intimately connected with the cornea. Its bulk consisted of pigmented, small, spindle-shaped and roundish cells. In some places small, round, unpigmented cells were abundant. The tumor was covered by the conjunctiva, and apparently well encapsulated toward the orbit. Yet a supicious-looking, hardish, unpigmented growth made its appearance on the inner side of the orbit six days after the removal of the eyeball. It increased so rapidly that, this afternoon, the Doctor removed it with the remainder of the orbital tissue. Copious hemorrhage ensued, and was arrested only by tamponing the orbit by means of a large sponge forced into it through the palpebral fissure, while another large sponge and picked lint were pressed upon it with a tight flannel bandage. The orbital tumor consisted of unpigmented, small, round and spindle-shaped cells lying close together. The original tumor sent prolongations, in crooked passages, into the tissue of the cornea. The corneal corpuscles and their offsets were filled with roundish, small, pigmented cells, in the same manner as an intra-ocular melatroma seeks its way outward. The inner structures of the eye were unchanged.

Clinically, the specimen has a good deal of interest. Episcleral melano-sarcomata are of the rarest occurrence in ophthalmo-pathology. The Doctor had never before seen a specimen of it, either living or in anatomical collections. They are, in their nature, as malignant as the intra-ocular sarcomata, but clinically harder to deal with on account of their being less confined, and in greatly more favorable conditions of extending into the neighboring soft tissue. The earliest possible removal of these tumors, and, if there be the slightest suspicion of particles having escaped the knife, the extirpation of the eyeball and orbital tissue, are indicated without reserve, and will not be evaded by a surgeon whose energy is in keeping with the consistency of his principles in pathology.

Correspondence.

THE MEDICAL CHARITY QUESTION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Your remarks upon medical charity and its abuses were of great interest to me. The subject is old enough, and the facts connected with it are sufficiently well established. As discussion helps us to arrive at the truth, I thought it might be relevant to glance at one part of the subject, which as yet does not seem to have been touched, and that is our charitable relations to the clerical profession.

I believe it is generally understood that clergymen are to receive advice and attendance gratis. Why this is so I cannot see unless we, as a profession, desire to respect Christianity.

In regard to this reason it is well enough, but respect for the cloth does not find bread for the physician. On my list I have no less than five clergymen's families to attend, and occasionally ride two or three miles out of my route to visit them when called upon. They represent every denomination, and practically I suppose I may be considered a thorough Christian Samaritan. It must be admitted that a great deal of time is occupied in such attendance, which for professional profit or pecuniary advancement, or rest, are virtually thrown away. When it is considered that many of these gentlemen get more than twice the salary the physician can earn, I for one cannot see why custom should sanction gratuitous services.

There are some ministers who are not able to pay the doctor, but these are comparatively few. Such no one would object to attend any more than any other needy individual, but not because he happens to be a clergyman.

Allow me to ask what we get from the minister in return for the services which custom causes them to expect for nothing. What is fair on one side is fair on the other. Did any one ever hear of a clergyman refusing a fee from a physician? If that person is to be found, I would not mind being the medical attendant of that pastor.

I would not pretend to say that ministers ask for gratuitous medical services, but they can hardly be blamed when we force such services upon them. Is it not time to have this element in discussion of the question of medical charity viewed in its proper light? Our profession should respect Christianity and all those who help to preach the Gospel, but can they not do so in a way common to all ordinary folks? It is not my desire to make any invidious comparison between the medical and clerical professions; but can we not ask if the latter are, after all, so badly off?

A young minister, as soon as he takes a charge, which is generally immediately after he graduates, has a stated salary to live upon, a house is furnished for him, and he has abundance of kind friends. How is it with the young doctor? Well, we all

know. Every young practitioner who starts to make a living by his practice, can endorse the sentiment of one of your correspondents, who says that he used to envy the cartman who was his next-door neighbor.

I am not disposed to be unjust to a very important class of professional gentlemen who do a great deal of good to the world; still, at the same time, there is another class, to which I belong, who can do almost as much good as they, and in their interest I have thought fit to speak. You can use my name, if desirable.

Yours, etc.,

———, M.D.

———, N. Y.

PRESCRIPTIONS FOR THE POOR.

To the Editor of The Medical Record.

Sir:—The charges made by druggists to the poor for their prescriptions are not what they should be, nor what they can be if the right principle is adhered to. The assertions in the last number of the Record are true to the letter. Why could not some plan be devised to show fair play to a patient of moderate means, and a physician who has moderate expectations of his fees. I am in the habit of advising such of my patients to go to particular drug-shops, and it is understood that when I write the letter P in the corner of the paper, that the proprietor shall consider the condition of the patient, and charge a very moderate price. Even then they make a large profit, and are satisfied.

Some physicians have said that their determination is to have the patient pay well for medicine at least, if not for advice. The druggists never object to this, but unless the doctor has an interest in the store he only does himself an injury to benefit the greed of another. I know this principle to be carried out at one of our college clinics. There was an arrangement, implied at least, that the store in the neighborhood of the college should have all the prescriptions, and the freest latitude was taken by the clinical assistants to write prescriptions, and the most exorbitant charges were made for them. This, in my opinion, was victimizing the poor under the cloak of charity.

Now, we know with few exceptions medicines used in prescriptions are not dear, and if any one does not believe this, let him try to find the medicines himself for his patients. I can perhaps speak from experience on this point, when I say that the earlier years of my practice were spent in the country. I had a fair business, that is to say, a large number of patients, supplied the medicines, and yet my drug-bill at no time amounted to a hundred dollars a year. This was not near what it cost me for the wear and tear of my driving establishment. If one would strike an average for each patient he would find that, extra of the price of a visit, there would only be a few cents. Under these circumstances, if we want to do an act of real charity, would it not be as well to give the medicines ourselves as to trust to the cupidity of many of our druggists?

Truly yours,

A. F. D.

Philadelphia, *October* 27, 1873.

A NEW TREATMENT FOR TAPE-WORM.

To the Editor of The Medical Record.

Sir:—I desire to report the following case, involving, I believe, a new treatment for tape-worm.

In March last, J. M—— applied to me to rid him of a tape worm. He had been under treatment previously, had taken Kousso, Malefern, and Pumpkin-seed, without cure. I gave him large doses of turpentine, with no effect save to excite some inflammation of the stomach. In August the man applied to me again, not so much to be rid of the worm, as for relief from the gastric troubles excited by the animal. After these had passed off, I gave with the usual precautions a half-ounce of fluid extract of Malefern, but still without the hope for effect.

The idea then struck me, if small quantities of "carbolic acid" are so pernicious to leeches, is it not probable that the drug might be used against a tape-worm. Accordingly, having purged the patient, I administered six grains of "carbolic acid" in a half-pint of water, four times a day. After two days of this treatment, as only a few joints of the worm had been voided, I changed the vehicle from a liquid to a pill form. Powdered extract of liquorice was used, and each five-grain pill contained two grains of "carbolic acid;" of these the man took one every hour, and a purge of rhubarb and jalap every morning. He soon began to pass large fragments of the worm, and on the third day the head and about four feet of the body of a tænia solium. He had taken thirty-five pills without inconvenience of any kind. He got well quickly, has remained well since, and I am satisfied is cured. I have since thought that the pills would have been improved by a delicate coating of paraffine; the object being, of course, to cause the pill to pass through the stomach unchanged into the intestine, carrying with it the "carbolic acid" in direct contact with the worm.

Davids's Island, New York,
October 15*th*, 1873.

THE PRACTICE AT ST. LUKE'S HOSPITAL, NEW YORK.

To the Editor of The Medical Record.

Sir:—In your publication of June 16th appeared a report of "Practice and Peculiarities of Treatment at St. Luke's Hospital," in which there were some inaccuracies, which you will perhaps permit me to correct here, as I was Resident Physician of St. Luke's at the time, though not at all responsible for the article.

I will take them seriatim. In acute rheumatism, the mode of administration of iodide of potassium and sulphate of quinine, was combining them at the time of administration, and not giving them at intervals, as stated.

In order to do this, a solution was made of ten grains to the drachm of water, of either salt, and a fluid drachm of the first and a fluid drachm and a half of the second were added to a third of a tumbler of water. This was given every four hours, and continued without producing cinchonism, for a week in some more obstinate cases. Usually forty-eight or seventy-two hours ended the malady.

The remedies spoken of as efficacious in night-sweats were used with varying results. In most cases a change from one to another accomplished an abatement for a few nights, and it followed whether the change was in one direction or another.

Ergot acted well, perhaps longer than acid, oxide of zinc, hyoscianus or any of the other various remedies.

Sponging the body at evening was grateful to the patient, and a good prophylactic.

In "reduction of high temperature," ice-water was

repeatedly used and with most gratifying results, whether employed in acute rheumatism, typhoid fever, or other cases. Life was unquestionably saved by its use in a number of cases when the temperature had reached 106° or 107°, and the patients were comatose.

In one instance, ice was applied to affected joints, in acute articular rheumatism, with recovery in thirty-six hours as a result.

In sub-acute pleurisy the treatment was not at all as uniform as stated, and it was claimed (but not conceded) by each advocate that his treatment was the successful one, whether diuretics and blisters, tonics and no blisters, or paracentesis thoracis was practised. One point was established, that in a case with large effusion which did not subside spontaneously, or during the course of other treatment, if a portion of the fluid were removed by trocar or aspirator, the absorption of the remainder was facilitated, and in but one case did death follow tapping, and here the pleural sac was filled for several weeks while other remedies were employed, and when at last resorted to, the patient was quite exhausted, and only a small amount was taken away.

The statement that in "Bright's disease the general principles embrace the administration of tonics and diuretics," is only true of chronic cases.

The treatment of acute nephritis was most gratifying where milk-diet was adhered to, and no medicine used. The custom was to give the patient whatever amount of milk he or she would take at meals, with cracker or oatmeal or other light matter. At the intervals they drank a cup of milk once in two hours, if they wished it. An increased amount of urine of lower specific gravity and subsidence of the œdema followed, with such promptness as to surprise the practitioner new to the use of it.

Among the cases were the following:

Rose McA——, aged 25, was admitted May 10th, having all physical signs accompanying albuminuria. Examination of her urine confirmed diagnosis made from physical signs and history, urine containing casts and albumen in large amount.

She was put at once upon exclusive milk-diet, without medicine, except an occasional laxative, and in three weeks the œdema had disappeared and casts were no longer found in her urine, but a trace of albumen and some granular matter remained. On the seventh of June she was discharged at her own request, having lost all traces of the malady except emaciation and weakness. She was then on improved diet and tonics, but milk was still an important part of her nutriment.

Frank J——, aged 38, was admitted on 16th Oct., 1872, having a history of treatment by a homœopath for "bilious intermittent" during the preceding two months.

His œdema, cachexia, and symptoms generally pointed to renal affection, and examinations of his urine corroborated the opinion; albumen, blood, and granular casts being found. The quantity of urine passed in twenty-four hours was not below the normal amount. He at first was put upon "Bethesda water," with which we were experimenting, and improvement resulted from its use for about a month, and at the end of that time milk-diet was added.

On the twentieth of December, examination for the first time showed a normal condition both under microscope and in quantity—and patient was soon after discharged. He had returned from time to time with specimens of his urine, and examinations have continued to show satisfactory evidence of recovery.

Paul G. A——, aged 57, was admitted Aug. 24, having been under treatment with tr. mur. ferri and inf. digitalis for six weeks at another hospital.

His urine contained 80 per cent. albumen, with granular and hyaline casts. His treatment with iron and digitalis was continued to Oct. 1st, when milk was substituted. He was at that time passing forty ounces of water in 24 hours.

On Oct. 5th, passed one hundred and twenty ounces, and continued to do well with the exception of an attack of rheumatism, during which treatment was changed.

Dec. 1st, water contained no casts, and albumen 30 per cent.

Feb. 9th, discharged at request; still farther improved, but feeble in strength.

GEO. D. BLEYTHING, M.D.

HYGIENE OF TOWNS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—Large cities like New York, Philadelphia, Chicago, are amply provided with splendid sanitary organizations. They have Health Commissioners, Inspectors, Hospitals and money; epidemics are combatted, and even prevented, by every means that science can suggest.

Yet an immense majority of the people of the United States live outside these cities, and they are yearly exposed to epidemics without any efficient plan of protection such as sanitary science in this age ought to furnish.

How many lives might have been saved throughout the country last year, if towns possessed sanitary means for abating small-pox as well adapted to their needs as those of New York are adapted to the needs of that city!

It is to attempt to induce among country physicians some interest in the "hygiene of towns," which I hope may develop into a science in time, that I offer what I believe to be the best plan for checking small-pox in towns of less than 50,000 inhabitants.

After the Chicago fire, I had occasion to make a tour among the physicians of the North-west. Among other matters upon which I asked information was the present subject, and I became acquainted with the various plans adopted in fifty towns to check small-pox, which was then rife. The plan generally adopted was exceedingly inefficient: it consisted in the appointment of physicians to visit all the houses within a certain limit and to vaccinate the inmates. This plan may answer well in metropolitan cities where the people are used to obey ordinances, and where there is a responsible and well-paid force to execute it; yet it did not save Philadelphia in the winter of 1871–2, when in surrounding towns it was common to see upon places of business such placards as the following: "No Philadelphia goods sold here." But the great objection to it in smaller towns is, that many people regard it as an invasion of their premises and refuse to receive the vaccinator, while physicians become tired of their part in the proceedings, shirk the duty, and leave it to the people to get vaccinated or not as they please; then all intelligent people do get vaccinated, but the bottom stratum of society continue to nurse contagion and indifference.

In Chicago the thousands who presented themselves at the relief stations for bread after the fire were compelled to exhibit certificates, or to have their families

vaccinated on the spot by physicians appointed for the purpose, before they could receive aid. This system worked admirably, reaching the class who are always the carriers of contagion; I cite it to indicate this class.

There are many other plans of public vaccination which might be mentioned, but there is only one which, in my opinion, is deserving of consideration; is is sufficiently simple, and consists in appointing physicians to be at certain public places, hotels, or schoolhouses generally, at certain stated hours, during two or three days, to vaccinate free all who may present themselves; this to be thoroughly advertised by posters.

The motives and impulse to which this plan appeals in the people are threefold, viz.: fear, cupidity, imitation; or, to paraphrase it: 1, the desire for safety on the part of families; 2, the universal appreciation for gratuitous services; 3, the enthusiasm of a general movement in which each one feels it a duty to influence the neighbors. To these may perhaps be added that innate sense of justice (to self) which makes a man reluctant to see his taxes publicly expended on vaccine and such things without participating in the benefit himself.

I am convinced that wherever this plan shall be adopted and properly carried out, it will be successful. A very good illustration of its working was seen in Phillipsburg, N. J., three years ago; it was tried when the trade of the town was seriously affected by a small-pox epidemic. After all the private vaccinations carried on during three months of the epidemic, and while it was still increasing in violence, five hundred children were presented at the stations appointed for public vaccination; this in a town whose population was only 7,000. The epidemic was checked instantly, and although it continued unabated in Easton (across the Delaware), where other plans were tried, Phillipsburg remained free from it for nearly two years, when the rapid growth of the town, filling it with strangers unvaccinated, caused the disease to appear again.

In the summer of '72 the epidemic of cerebro-spinal meningitis, which had found in Scranton so congenial a habitat, was followed by an epidemic of small-pox, which promised to do serious injury to the business interests of the city, and was of an unusually fatal type; slight in June, but spreading steadily until September in spite of the efforts of the sanitary police, who had been appointed to isolate the cases: 366 cases of small-pox had occurred in that time within the knowledge of the authorities, with 140 deaths; and doubtless a great many cases were concealed from them.

It now became evident that something must be quickly done to check the spread of the disease and save the business interests of the city; the press clamored for active measures. It was then that the plan detailed above was presented to the mayor and council, and a meeting of physicians called to discuss it; at that meeting many other plans were offered, but were all decided to be inferior to this. It was adopted by the council, and one thousand dollars were appropriated to carry it into effect and to pay the sanitary police. I hold it to be a principle that physicians should be paid for such services, and that their efficiency will be very apt to be in proportion to their pay.

Fifteen hundred children presented themselves for vaccination; this was in the latter part of September; the epidemic ceased immediately, the sanitary police were discharged within a week or two, and the city has remained free from small-pox as an epidemic to this day. I regret to say that in one ward of our city the public vaccination was not efficiently carried out, and that consequently sporadic cases continued to occur there.

In offering this experience to the profession, I would summarize its lessons as follows: 1st. The visiting plan may work well in metropolitan cities, but is too expensive, laborious, and unpopular elsewhere. 2d. A physician should be appointed by the city (or town) authorities for each contemplated vaccinating centre, and be paid to attend to it for two or three hours on one or two consecutive days, and on one day a week later to examine results. 3d. One physician should be designated to inspect the work at the vaccinating stations and to have procured a supply of bovine or other reliable virus, and be responsible for the proper performance of his duty. 4th. Extensive advertisement is necessary.

If these details are faithfully attended to, it will be found that the people will respond promptly, and that small-pox will disappear as surely as there is truth in Jenner's great discovery.

Yours, &c.,

J. E. O'BRIEN, M.D.,

Scranton, Pa.

CAUTERIZATION AND HYDROCHLORIC ACID AS PREVENTIVES OF RABIES.

A LETTER FROM

JOHN. J. CALDWELL, M.D.,

BALTIMORE, MD.

To the Editor of The Medical Record.

SIR:—Concerning the "New Treatment for the Prevention of Hydrophobia after Inoculation," so vividly reported by Paluel De Marmon, M.D., in your number of Sept. 15th, 1873, I beg leave to state, that in the fall of 1860 I was called to see the granddaughter of your estimable citizen, Jno. B. Dunham, Esq., the well-known inventor and manufacturer of the overstrung piano.

She was bitten by a mad dog whilst awaiting her cousin's return from the store and post-office at East Chester, near New York City. The dog had bitten several animals, and coming in contact with her pony, nipped it on the nose, causing the animal to stumble and throw her upon the ground, when she was bitten, the dog's teeth penetrating the pectoral muscles. She was also badly bruised.

I saw her in a few moments after the accident, and immediately cauterized and washed the wound with warm water, and finally applied strong hydrochloric acid to the parts. This, with careful hygiene, was all the treatment.

For aught I know to the contrary, the patient is still living,—at all events she was a few years since. All the bitten animals, including the pony, died of hydrophobia within thirty days.

My only object in mentioning this little incident is to show the prophylactic virtues of other agents in connection with cauterization. There are many persons in and about New York who will, no doubt, remember the above case.

Certainly, Dr. De Marmon deserves great credit for his promptitude and originality.

61 St. Paul Street.

New Instruments.

A NEW INSTRUMENT FOR THE INSUFFLATION OF POWDERS INTO THE LARYNX.

By GEORGE M. LEFFERTS, M.D.,

NEW YORK CITY.

In the treatment of laryngeal diseases by means of the insufflation of powders, the instrument most commonly employed is the ordinary tube of hard rubber or metal, tapering gradually to a pointed end and bent at an angle of about 120°. The powder is introduced through a small opening in its upper surface, closed by a slide, and is propelled through the tube into the larynx by means of a forcible expiration on the part of the operator; connection between his mouth and the instrument in hand being maintained by means of a small flexible rubber tube attached to the extremity of the instrument. The objection to this method is twofold: patients, especially those in private practice, will object to it as inelegant and disagreeable; the propelling force being the breath of the operator, it passes into the throat of the patient, and even if entirely unobjectionable, creates in many cases on his part a sensation of disgust, and even in delicate persons a feeling of nausea difficult to overcome. The surgeon himself, when using the above instrument, is not entirely free from the danger of disagreeable effects. Patients with throats extensively ulcerated by syphilitic or carcinomatous disease, and with the fetid breath which accompanies them, are extremely liable, at the moment that a powder is blown into the larynx, to cough violently or to make a forced expiration, in which case, by no means an exceptional one, as all laryngoscopists to their cost know, the surgeon receives in his mouth more or less of the expired breath of the patient, together with the particles of the powder remaining in the tube.

On account of these objections to it, the above instrument is becoming less and less used by laryngoscopists.

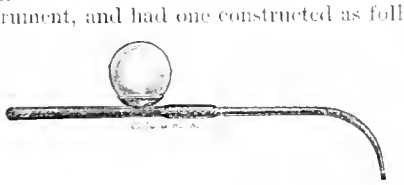
The various modifications which have from time to time been introduced to overcome the above objections are clumsy, and do not answer their purpose; for instance, attaching to the extremity of the india-rubber tube a balloon of rubber, which balloon being placed under the arm, between the knees, or beneath the foot of the operator, is compressed at the moment that the tube is introduced into the larynx. It has the objection of causing too much movement on the part of the operator at the moment of compressing the balloon, thereby disturbing the position of the tube in the larynx and the accurate application of the powder, and further, the air rushing back through the tube, after the balloon has been emptied to fill it, carries with it the powder remaining, so that after a few applications have been made to the throat the balloon becomes partly filled with an admixture of powders rendering it unfitted for further use.

The best substitute for the above tube has been the "Insufflator of Rauchfuss." This consists of a hard rubber tube larger than the preceding, but in other respects similar, terminating at its end in a rubber ball of about two inches in diameter instead of a flexible rubber tube and mouth-piece. The instrument being held between the index and middle fingers, the ball at the right moment is compressed by means of the thumb, and the powder thus expelled from the tube.

The instrument is therefore free from the objections urged against the preceding, but has one peculiar to itself: owing to the awkward position of the hand below the instrument, and steadying it by only three fingers, a careful and accurate introduction of it into the mouth and over the epiglottis is very difficult, and, in patients with irritable throats, next to impossible; and further, at the moment of compressing the ball with the thumb, an impulse forward is given to the instrument impossible to avoid, and which materially alters the position of the point in the larynx and throws the powder wide of its mark.

For a general application to the interior of the larynx, the instrument answers its purpose; but for a special and delicate operation, the placing of a minute quantity of a powder upon a small ulcer of the vocal cord, for instance, it is unsuited.

In order to obviate these defects, I have modified the instrument, and had one constructed as follows:



The hard rubber tube is 8½ inches in its horizontal and 2 inches in vertical length, and is made much lighter and of smaller calibre than that of Rauchfuss.

It is closed at one end, and from thence tapers gradually to its bevelled point. The curve forms the arc of a circle of about 3¾ inches in diameter, and the point indicates a line which makes a right angle with the direction of the shaft. On the upper side of the tube, 4½ inches from its closed end, is placed a rubber ball of 1½ inches diameter; it is set in a small cup-shaped projection from the tube, and communicates with its lumen by a free opening. The instrument, from its closed end up to the ball, is solid, and forms a firm and convenient handle. Immediately in front of the ball is an opening in the tube, closed at will by a slide through which powders are introduced.

The advantages claimed for this instrument are as follows:

1st. It obviates all the objections that can be urged against the first form of apparatus.

2d. It admits of skilful and accurate introduction, and remains steady in the hand during compression of the ball, thereby insuring an accurate application of the powder.

The tube is held by the hand in the position of a writing-pen, the index-finger resting lightly upon the rubber ball. In this position, undoubtedly the true one and safest for a laryngoscopic instrument, it is introduced into the mouth in the same manner and as gently as the laryngoscopic mirror. At the moment that the point of the instrument passes over the epiglottis the operator can allow his third and little fingers to rest upon the cheek of the patient, the instrument being fully steadied by the remaining three fingers which hold it. He thus obtains an additional point of support, and is enabled to carry the point of the instrument slowly and accurately down into the larynx and direct it to any desired point.

At the moment of compressing the ball by means of the index-finger which rests upon it, there is, and can be with care, no sudden movement; a moment's trial will convince that the downward pressure of the index-finger in this situation is much more steady and forcible than the same movement forwards on the part

of the thumb, as with the apparatus of Rauchfuss. The instrument is steadied by the placing of two fingers upon the cheek of the patient, if desired, and a counter support against the vertical pressure on the ball is also given by the hand below the tube, it resting in the hollow between the thumb and index-fingers, and being grasped by the middle finger and thumb after the manner of a pen. A further change may be made in the instrument by those who desire it, by bending the tube in its shaft, thus forming an angle with its concavity looking to the right, after the form of tube used by Prof. Schrotter, of Vienna, and by this means carrying the hand of the operator to the side of the mouth of the patient, out of his line of vision and from interference with the rays of reflected light from his forehead mirror; (when this change is made, the above instrument must be made longer in its hollow shaft).

The straight tube, however, in most hands answers the best purpose, is easier of introduction, and does not have the objections urged against the "double curve" by Prof. Störck of Vienna and others, that the double angle of the tube giving an increased leverage, the slightest movement in the hand of the operator makes a very marked difference in the position of the point of the tube in the larynx; and secondly, that the position of the hand, without having marked advantages, is awkward, and requires that the attention of the operator be divided between the position of his hand and the point of his instrument.

333 West 22d Street.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from October 19, 1873, to November 4, 1873

Knickerbocker, B., Assistant Surgeon.—Assigned to duty at Camp Harney, Oregon. S. O. 146, Department of the Columbia, October 17, 1873.

Girard, Assistant Surgeon.—Assigned to duty at Yorkville, S. C. S. O. 180, Department of the South, October 20, 1873.

Cleary, P. J. A., Assistant Surgeon.—Granted leave of absence for three months. S. O. 210, A. G. O., October 23, 1873.

Matthews, W., Assistant Surgeon.—To report in person at these Headquarters for assignment. S. O. 206, Department of the East, October 22, 1873.

Byrne, C. B., Assistant Surgeon.—Assigned to temporary duty at Willett's Point, N. Y. H. S. O. 210, A. G. O., October 23, 1873.

Medical Items and News.

The Hygiene of Public Schools.—In regard to the necessity for sanitary inspection of our public schools there seems to be no doubt except by members of the Board of Education. The *New York Evening Post*, in a recent article upon the subject, thus speaks of some of the uses of a medical superintendent:

"He is a check upon bad teachers and an aid to good teachers. He is the terror of architects who undertake to build new school buildings. He is a most valuable and necessary public officer, and it is not only disgraceful but dangerous that an attempt should be made in the city of New York to manage the public schools without his assistance."

We entirely agree with this opinion, and believe that the time is not far distant when the profession, as a body, will make its influence felt in this as it will in other matters pertaining to public health.

Sir Henry Holland, Bart., M.D., D.C.L., F.R.S.—The death of this distinguished man occurred in London. He belonged to the generation that was in its prime when Scott, Byron, and Wordsworth still flourished, and was the physician or friend, and in some instances both, of Campbell, Moore, Joanna Baillie, Rogers, Lord Gray, Lord Lansdowne, Lord Brougham, Earl Russell, Macaulay, Sydney Smith, Hallam, and others, whose names will go down to posterity.

Sir Henry was the eldest son of Peter Holland, Esq., and was born at Knutsford, Cheshire, England, October 27, 1788, and had just entered on his eighty-sixth year when he died. He was educated at the University of Edinburgh, where he graduated M.D. in 1811, and soon afterward he made a tour of Greece and the Ionian Islands, of which he published an account in 1815, under the title of *Travels in Albania and Thessaly*. On his return to England he established himself in London, and soon attained a prominent position in the medical profession. He was appointed Physician in Ordinary to the Princess of Wales, afterward Queen Caroline, in 1811, to Prince Albert in 1840, and to Queen Victoria in 1852. He was made a Baronet in 1853. He made eight or nine voyages to this country, the last in 1869.

Dr. Henry Stuart Hewit, N.Y.—At a meeting of the New York Academy of Medicine the following preamble and resolutions were passed:—

Whereas, This Academy has with profound regret learned of the sudden death of a distinguished member, Dr. Henry Stuart Hewit; therefore, be it

Resolved, That in his eminent abilities, high professional attainments, and earnest personal character we recognize the high-toned, conscientious physician whose devotion to the discharge of his duties endeared him to all who knew him, and earned for him the respect of the community in which he lived.

Resolved, That in him we lose a member who in many high and responsible positions deserved well of his country, having served on the medical staff of the United States Army in two great wars—the Mexican and the civil war, and having by sheer force of merit won, during the late conflict, the rank of Medical Inspector.

Resolved, That these resolutions be entered in full on the minutes, and that a duly authenticated copy of the same be transmitted to the family of deceased.

Respectfully submitted,

Richard J. O'Sullivan, M.D.
William H. Thomson, M.D.
John Burke, M.D.

The New York Academy of Medicine.—The Academy will celebrate its *twenty-sixth anniversary* at the *College of Physicians and Surgeons* (23d street) on *Thursday*, 20th inst., at 8 P.M. The oration will be delivered by Prof. J. C. Dalton, M.D. After the oration the Fellows will hold a "Social Gathering" at the *Ashland House* (Fourth avenue), where an entertainment will be provided. Tickets ($2.00 each) may be obtained from the Committee.

THE LAWS OF TRANSMISSION OF RESEMBLANCE FROM PARENTS TO THEIR CHILDREN.

By JOHN STOCKTON-HOUGH, M.D.,

OF PHILADELPHIA.

PART IV.

WHY MALES RESEMBLE THEIR MOTHERS AND FEMALES THEIR FATHERS.

The fact of males resembling their mothers and maternal grandfathers, and females their fathers and paternal grandmothers, was well known to most ancient philosophers and physicians, and many were the reasons given for this condition of resemblances, though none seem to have gone beyond atavism, until in the present day reversion has taken its place. All terms hitherto used as expressive of this condition are without meaning in regard to the proximate cause. The writer will give below what he considers to be the proximate cause, knowing of no other satisfactory explanation as having been given, and offering this as original.

Males are begotten from mature ovules (eggs), and females from immature ovules, hence the *ovule* from which a male is derived is (for a certain length of time, probably from three to seven days) *longer under the sole influence of the mother* than the ovule from which a female is derived, and as the period beginning with fecundation and ending with the extrusion of the ovum from the Graafian follicle is claimed by some as that in which resemblance and hereditary predisposition are impressed, we are led to believe that the sexual differentiation in the resemblance of sons and daughters to their parents is principally due to the difference in the time in which the ovule is under the sole influence of the mother, modified, perhaps, in some degree by the dynamic difference in the ability of the male element to fecundate a mature or an immature ovule, the latter being the more difficult. This, then, appears to be the cause of the law, subject, nevertheless, to differences in nutrition of the embryo, and variations in the condition of the mother during gestation.

CONCLUSIONS.

The author recapitulates the deductions and conclusions arrived at in this paper, at the risk of being tedious, for he believes that every person in writing a philosophical dissertation should state clearly in the beginning what he desires to prove, and finally, in as succinct a manner as possible, the conclusions arrived at. A neglect of this is as culpable as the lack of a complete index to a book. Authors do not deserve to be considered authority on the subject in which they have inflicted on the reader the necessity of perusing the entire text, and, moreover, merit the neglect which they so frequently get.

Recapitulation:—

1. In general, children of both sexes resemble their mother more than their father in physiognomy, habits,* constitution, and temperament.

2. Usually boys resemble their mother more than their father in physiognomy, habits, constitution, and temperament. In the same relationship girls resemble their father more than their mother.

3. As to whether there is any constant relationship between the physiognomical resemblance and a predisposition to the diseases of the person resembled, it is very difficult to decide from the data at hand, but it would appear from the few facts in which any observations were made in this direction, that there was a larger percentage of cases in which inherited diseases were exhibited where there was no resemblance than where there was such physiognomical similitude. In other words, children have resembled one parent in general physiognomy, while they have inherited the constitutional peculiarities and diseases of the other, more frequently than where they have derived both those conditions from (one) the same parent.

This view of the matter is supported by the following cases already recited in this article:—

Mr. Sedgwick's case of ichthyosis, where a girl inherited "the disease from her mother," while "she inherited the features of her father."

Dr. Moreau asserts that personal resemblances and cerebral disorder may be transmitted by either parent, but never by the same.

Dr. James Webster assures us that insanity is more frequently transmitted by mothers to their female offspring than to their male children. And Dr. Theophilus Thompson has shown the same fact to be true of the transmission of pulmonary consumption.

The facts are far too few to warrant us in defining this as a law, yet I know of no facts or theories to the contrary. I am under the impression, however, that physicians have usually regarded a physiognomical resemblance as evidence of greater liability to the hereditary disease of the person resembled, yet it is quite possible I may be mistaken in this view of the matter.*

In general, then, hereditary and acquired diseases and defects are more likely to be transmitted to offspring of the sex in which they originated, and thereafter to be subject to the principle of sexual limitation, either directly from parent to child, or by interrupted or atavic descent, from grandparent to grandchild.

Though sons are usually best able to follow the avocation of their fathers, it is undoubtedly true that men inherit the genius, talent, and intellectual excellence and morality of their mother or their mother's father, while daughters inherit the same qualities from their father or paternal grandmother.

4. *Females more frequently transmit* hereditary diseases and defects than males, though they *less frequently exhibit* them. Males less frequently transmit, and more frequently exhibit, inherited diseases and defects.

I have already, in my last paper,† called attention to, and offered an explanation of, the phenomena stated in the last conclusion (4), and may repeat it here:—

The ovule (egg) from which a male is derived being

---

* Dr. W. B. Carpenter, the distinguished physiologist, has recently written an able article "On the Hereditary Transmission of Acquired Physical Habits," in The Contemporary Review, April and May, 1875.

* Since the above has been in print, I have happened upon the following, which seems to confirm this opinion.

"When only one of the parents is the victim of constitutional disease, the tendency to similar constitutional diseases is most obviously expressed in those children who most resemble that parent in physical conformation and appearance, and it has been observed that, when both parents suffer, the tendency will sometimes be expressed more often in the daughters of the family than in the sons, or more often in the sons than in the daughters."(1) Prof. Gross appears to have given out much the same opinion, in his far-famed work on surgery.(2)

(1) *J. Adams Allen*, M.D., LL.D., Medical Examinations for Life Insurance, Chicago, 1867, p. 46.

(2) Samuel D. Gross, M.D., LL.D., D.C.L. Oxon., A System of Surgery, &c., &c., 2 vols. 8vo, Philadelphia: H. C. Lea, 1859—1872.

† "On the Relative Viability of the Sexes," &c, N.Y. MED. RECORD, June 16, and July 16, 1875, pp. 297–302, 553–4–5.

for a longer time under the sole influence of the mother (before fecundation, and longer in utero-gestation) than the egg from which a female is derived, acquires more of her physical constitution and peculiarities, resembles her more, or inherits more of her physical defects and tendencies, and this ovule is fecundated by a weaker element on the father's part than his female offspring; while the ovule (egg) from which a female is derived is a shorter time under the sole influence of the mother, being impregnated earlier in its course of development (being less mature), and besides this it requires the highest power of the male element to communicate the impregnating influence to it.* Hence we have less hereditary disease *exhibited* in the female, yet she may *transmit* with greater frequency and facility than the male, though it may not have developed in her.

The reason that females do not exhibit hereditary disease as frequently as males, is because of a *higher degree of vitality* in them, which gives them greater power to restrain the appearance of the predisposition, and an *inferior degree of developmental evolution*, retaining in their constitution as germs, what in men become fully developed diseases and defects.

2063 Walnut Street, Philadelphia, July, 1873.

BRIEF REMARKS UPON MEDICAL EXAMINATION FOR LIFE ASSURANCE.†

BY H. S. PURDON, M.D., L.R.C.P.,

PHYSICIAN AND LECTURER ON CLINICAL MEDICINE, BELFAST GENERAL HOSPITAL; PHYSICIAN TO THE HOSPITAL FOR DISEASES OF THE SKIN; LATELY EDITOR OF "THE JOURNAL OF CUTANEOUS MEDICINE."

GENTLEMEN,—In place of the usual clinical lecture this morning, I shall ask your attention to the subject of the medical examination of lives for insurance, which, I need scarcely say, may at some future day be part of your duty. I have gathered my information from every available source, and claim nothing on the score of originality, merely adding thereto such observations of my own as I have put together while for some years acting as Medical Referee to three large insurance offices in this town. Allow me, however, in the first place, to prefatce the following remarks by an extract from Dr. Sutton's introductory lecture at the London Hospital. He says:—"The student of medicine in learning physiology begins with the tissues of the body, but he may also study man in his individual condition by examining his ideas, sensations, movements, and secretions, his organization in action, endeavoring to find out how the vital dynamics of man's system result from elaborate arrangement of tissues and organs." All parts of the body, Dr. Sutton proceeds to say, work independently, but all uniformly and co-relatively. Every viscus and every tissue has its own specific action, each cell its own life, and the sum of these makes up the life of man. Most individuals have certain peculiarities, mentally as well as physically. The shape, features, even the very walk of a child may, and often does, resemble either parent. If this be so as regards outward appearances, we may well reason by analogy that the internal and minute structures of the body are similar. Inherited structures and external conditions are the two factors concerned in the growth and development of every living thing. According to Dr. Brinton, "the tendency to phthisis in offspring is more likely to be transmitted by the mother than by the father thus diseased. But any preponderance is often outweighed by a strong predominant likeness of the offspring to either of these parents. Such an external likeness may well be supposed to be associated with an equal similarity of constitution."

Dr. George Combe, in his "Constitution of Man," remarks that peculiarities, not of body merely, but also of the mind, are for the most part observed to be congenital, and not unfrequently hereditary. Parents often revive in their offsprings, who resemble them not only in countenance and form of body, but in dispositions of mind, in virtues and vices. The imperious Claudian family flourished in Rome, courageous, ferocious, and proud. It produced the pitiless tyrant Tiberius, and at length, in the monstrous Caligula, Claudius Agrippina, and finally Nero, became extinct.

Dr. Carroll, in the New York *Medical Gazette*, November 19th, 1870, states that "diseases themselves are, with the exception of syphilis, seldom, if ever, directly inherited, but a tendency to them is; and whether this tendency is to remain latent during a long lifetime, or to be early developed into fatal action, will depend, to a great extent, upon external circumstances. A person, he says, with a constitutional liability to one form of disease may be capable of resisting influences directed against his stronger organs, as, for instance, the tendency to hepatic derangement will be aggravated by residence in a dry, warm climate, and held in abeyance by a cool moist one, while the scrofulous diathesis may remain dormant in the former condition, but soon succumbs to a bleak, damp atmosphere. The chances in the potential consumptive will be widely different if he lead a sedentary life in a crowded city, or an active one in the pure air of the country. Predisposition to heart disease may be called into activity by business anxiety, or emotional excitement of various kinds, which, under more favorable circumstances, would never have been suspected to exist." Of two flour millers, or bakers, applying to be insured, he whose family history shows a phthisical taint will be the worse risk, the condition of these two occupations being favorable to the development of the disease. The diet and mode of life beneficial to an anæmic or consumptive patient would be injurious to another liable to gout or fatty degeneration. This is to be taken into account in reports on such cases furnished to an insurance office. We must also notice short-lived robustness and comparatively frail longevity. We may find a man in a present condition of perfect vigor, whose family history and personal circumstances may render it doubtful if he will reach old age; or *per contra*, one whose appearance is far less promising may really inherit a type of much greater longevity, irrespective of any tendencies to particular disease in either instance.

It has been observed that men with slender bones, long, flat chests, irritable, feeble hearts, bad digestion, ill-developed muscular systems, whose brain and nerve actions are incapable of prolonged activity, are very liable to die of consumption. They have nervous temperaments, and are liable to disease of mucous tissues.

* This theory of a differential dynamic power of the male reproductive element was first maintained by the writer in "An Inaugural Dissertation, (presented to the Trustees and Faculty of the University of Pennsylvania, March 13, 1868, for the degree of Doctor of Medicine), entitled: Prepotency, Sexual Elective Affinity, Non-congeniality, or the dynamic differentiation of the Elements of Reproduction in the Human Species; the Cause of Relative Sterility. By John Stockton Hough, A.M., M. Chem., of New Jersey."

This theory is further substantiated in the author's paper on "The Effect of the Nationality of Parents on Fecundity and the Proportion of Sexes in Births;" also in his article on "Statistics relating to Births, Marriages, and Deaths, occurring in Philadelphia for the eleven years ending 1871." Penn. Monthly, Philadelphia, September, 1873, pp. 590 to 621.

† Published recently in Belfast, in pamphlet form.—EDITOR.

We therefore observe that with a peculiar build of body there is a particular standard of health and a liability to particular pathological changes. The conformation of body is dependent partly on inheritance, and is largely affected by external conditions. We know that plants or beings developed quickly are apt to die rapidly. Durability and slow growth go together. Vast numbers of children in large towns, the offspring of degenerate parents, shoot up quickly, like ill weeds, to end shortly their delicate and sickly lives. The phenomena of health and disease are the certain results of antecedent conditions.

The intermarriage of blood relations is not judicious. For these close unions have a tendency to intensify in offsprings not only any good quality in the parents, but also the bad—such, for instance, as the hereditary diseases, insanity, phthisis, gout, scrofula, etc.

Dr. Lambert, of New York, believes that in the diagnosis and prognosis of disease, the inherited or internal and absolute condition of the patient are of great consequence, and should be specially noted, so that complete reliance need not be placed upon the uncertain or incomplete statements of the applicant. Mature man, in all his sensations, emotions, intellections, and volitions, so far as they are physical phenomena, is the co-ordinated resultant of all his organs, and of constantly varying external conditions. Amongst the most important antecedent to consider, in valuing an individual life, is the longevity of ancestors. Inherited disease usually appears at about the same age in the inheritor as it did in the person from whom it was inherited. For example, phthisis. In some cases, however, it occurs earlier in the descendants than in the ancestors; but the general rule is that inherited fatal diseases have their issue at about the same age in a subject as that at which a near ancestor died.

The *special* tendency exhibited by some diseases to appear in the offspring of those affected with them may, and frequently does, remain latent for years, or even for the life of the individual. The next generation, however, sometimes suffers from the same class of complaints; consequently, the medical referee must not only look to the parents of the applicant, but to his grandparents, and, indeed, whole family.

The classification of lives adopted by different insurance companies in these countries is much the same for all. The following may be considered an example. It is that adopted by the English and Scottish Law Life Assurance Association:—

CLASSIFICATION OF LIVES.

Class I. Superior lives: having the prospect of more than average duration.

Class II. Average lives: involving no peculiar hazard, or presenting only unfavorable features of so slight a nature as to form no objection to assurance at the ordinary rate of premium.

Class III. Inferior lives: involving increased risk on account either of family history or personal condition, and therefore requiring an equivalent addition to the ordinary rate of premium.

The information to be acquired by the medical examiner may be classed under three heads:—

1st. Present state of health of applicant.

2d. His past history.

3d. The peculiarities of the family.

A minute and searching examination will enable us to answer the first question; but before entering into details regarding the second it would be well to offer a few remarks upon family peculiarities and diseases.

Dr. Steedman, of St. Louis, says:—"Consumption stands at the head of the list of inherited diseases, but it can be acquired independent of any hereditary taint." Niemeyer held the doctrine that phthisis is a frequent result of chronic inflammation, especially of pneumonia, and that a copious spitting of blood in persons predisposed to phthisis frequently does good by relieving congestion. Dr. Steedman holds that when a parent has died of acquired phthisis, free from hereditary taint, those children born before the development of the disease should be considered as comparatively exempt. "Few applicants," he says, "ever admit that a parent or other near relative has ever died of phthisis. It is frequently explained away by some special cause, as exposure to cold, or childbirth. The last excuse is especially calculated to deceive. It should be remembered by the medical examiner that phthisis often stands in abeyance during pregnancy, and as soon as delivery occurs runs a very rapid course." Phthisis occasions in Great Britain about one death in seven, or 15 per cent. of the whole mortality.

When one parent has died of phthisis the applicant should be rejected, unless it was a case of acquired phthisis dating years after his birth, and that the applicant has had very good health, and passed the age of forty-five years. When neither parents have died of phthisis, but two or more brothers or sisters have, he should be rejected, as this indicates a feeble organization or positive inherited liability to phthisis. If the applicant is amongst the last of a large family, the majority of which have died young, he should be rejected, because the evidence is sufficient to show that he or she belongs to a feeble stock. The few years following on puberty Dr. Brinton considers the most liable to phthisis, especially in unmarried females.

Hæmoptysis is a serious item in the calculation, as most of those who have suffered therefrom die of consumption. Niemeyer believes that hæmoptysis may occur, however, without any dependence on tubercle, but it may become a cause of tubercle by the effused blood undergoing caseous degeneration and exciting pneumonic processes. Skoda, of Vienna, holds that blood effused in the air-passages can never do so. Blood, he maintains, is a harmless, bland, unirritating fluid, and is easily absorbed, especially the fluid parts, merely pigment being left. Every person who has had hæmoptysis, unless dating many years back, should be rejected. Spitting of blood by applicants is often said to come from the throat, or to be due to sudden exertion. Dr. Mason remarks, in the Dublin *Medical Journal*:—

"The fact that hæmoptysis is not constantly prior or subsequent to any organic disease of the thoracic viscera has been frequently substantiated. Many people during puberty having suffered from repeated attacks of hæmorrhage from the respiratory organs, still arrive safely at the goal of ripe old age, leaving at their death no appreciable pathological signs of their ever having suffered from it. Though such is sometimes the case, we should still regard every case of hæmoptysis coming under our notice with suspicion, and endeavor to arrive at a knowledge of its direct cause. The more obscure this is, the less we should relax in our attempts to discover its origin. Hæmoptysis through mere ensanguinification, except, of course, such a hemorrhage as would result from a wound or the bursting of an aneurismal sac, is seldom directly dangerous to life. Though it may occur, as above stated, in persons whose lungs during life afforded no physical signs indicative of its origin, or after death exhibited no traces of its ever having taken place, and

though, as several well-authenticated cases prove, it may but supplementalize suppressed menstrual or hemorrhoidal discharges, still it must never be looked upon with unconcern. Hemorrhage from, if we may use the term, healthy lungs, even though it may sometimes relieve nature of a surplus of blood, must, however, have a deleterious effect on the system. In large quantities and frequent recurrence, it tends to produce anæmia, one of the most favorable fields for the development of disease of the chest."

Insanity belongs to the class of hereditary diseases. Where more than one case has occurred in the generation of the applicant he should be rejected, more especially if he either exhibits any marked eccentricity of mental or nervous organization. Insanity usually does not shorten life, but such people are liable to commit suicide.

Cancer and gout belong also to the class of hereditary diseases, but are not so important as those already mentioned. The latter, however, may lead to disease of the kidneys, as described by Dr. Todd.

Hereditary intemperance occurs next to phthisis in importance. No applicant who is intemperate in the use of alcoholic liquors should be accepted. But the great difficulty is to determine who is intemperate. Few men will admit that they are so. If the applicant is an acquaintance, you should make your conclusion from personal knowledge; if a stranger, judge of his habits from general data. Little reliance can be placed on answers to direct questions. Dr. Steedman asserts that habitual intemperance is usually productive of fluid stools in the morning. This fact should be remembered, and your questions applied in that direction. Dr. Brinton thus describes the habitual tippler: —He has a "fiery, unctuous skin, with its secretions reeking with volatile fatty acids; red, ferrety eyes, with tipsy glare rather than gleam; furred tongue, fetid breath, and trembling limbs. These are the chief characteristics of drunkards."

With one class of men alcohol acts only as a stimulus to the nervous system, giving, however, no real power, but finally producing exhaustion. Others are really improved by its moderate use. Digestion is thereby promoted, and the body gains in strength. In this class the habit, if kept in moderation, does not shorten life; but the habit is apt to grow, and will, if persisted in, finally destroy the health. Tavern-keepers have been noted as special instances. The incentive and temptations to intemperance are so great, that few resist it successfully. Every saloon-keeper runs this peril, and the younger the man the more dangerous the risk will be. The reformed drunkard is not a good life for insurance. His constitution is usually destroyed, and he is liable to return to his old habits on the occasion of temptation.

The excessive use of tobacco, it has been remarked, often causes palpitation of the heart, irregularity of pulse, dyspepsia, with obstinate constipation, debility, and nervousness. Any applicant presenting one or more of these symptoms should be rejected, whether due to tobacco or not, since they are certainly aggravated by its use.

The occupation of the person to be examined must also be taken into account, some employments tending towards disease and others unhealthy.

The arm should be examined for the scar left by vaccination. Mr. Marson has shown that the mortality from small-pox after vaccination varies with the number of marks. His observations are based on 15,000 cases. He found in every 100 cases of small-pox, after vaccination, having

1 mark,	8	died	(7.73)
2 "	5	"	(4.7)
3 "	2	"	(1.95)

and in every 200, with 4 or more marks, only one died. Each scar should be distinctly covered all over with little pits like the end of a thimble, and accompanied by loss of substance. Some people are said to have died of old age, when from subsequent investigation it may appear that cerebral hemorrhage, paralysis, or idiopathic gangrene carried them off. The disease occurring in elderly people, called by Dr. Hammond "multiple cerebral sclerosis," is insidious in its approach. It is recognized by tremor, beginning at first in a group of muscles and gradually extending; derangement of sensibility; sometimes hyperæsthesia, pain in the head, characterized by sharp paroxysms and clonic spasm of rectus muscles of eyeball.

Many cutaneous diseases cause little constitutional disturbances, and as long as an individual remains unaffected with any acute inflammatory affection, the existence of an ordinary skin disease will not in any respect diminish the average chance of longevity. Furunculi, or marks of tearing and scratching on the skin due to pruritus, should make us test the urine for sugar, as these complaints are common in diabetes. Indeed in all cases the specific gravity of the urine ought to be taken, and the urine tested, at least, for albumen. In one form of kidney disease,—viz., waxy degeneration,—the patient has a sallow complexion, occasional diarrhœa, and little or no albumen in urine. The use of the microscope is necessary if any suspicion exists. Retinitis is often due to Bright's disease.

In the history of past ailments presented by the applicant the mention of having had an attack of acute rheumatism should make us give particular attention to the heart, which is so liable to suffer in that disease.

Chronic pleurisy manifests itself in two conditions, *with* or *without* retraction of the side. A good many people who offer for insurance have suffered from an attack of pleurisy at some period of their life. After an attack the chest walls may be simply restored to their natural position, or they may sink inwards. These cases require very careful consideration on the part of the medical referee. If taken at all, an additional number of years, equivalent to the increased risk, should be added to life of applicant. Pneumonia, even when ending in recovery, generally leaves some impairment behind in the lung engaged. There are maladies, as has been noted, which are suspicious features in a person's life, from the liability they have to return, as gout, asthma, dropsy, dysentery, gastric ulcer, etc. Asthma is unfavorable, as it may leave its mark in shape of emphysema, finally leading to dilatation of right side of heart. An excessive deposit of fat, polysarchia, or corpulence, is very unfavorable. Moreover, persons thus affected are bad subjects for an acute illness, and liable to Bright's disease, from absorption of fat that surrounds the kidneys. Idiopathic erysipelas is another disease liable to return. Brinton describes a peculiar color of cheeks observed in some middle-aged people, due to little streaks of distended blood-vessels, giving a mottled appearance, and which is often connected with renal disease. Dyspepsia is a symptom of either functional or organic disease of stomach. Its cause requires to be carefully investigated, as Drs. Dobell and Hutchinson have described a form of dyspepsia characterized by dislike for fatty food that is the forerunner of phthisis.

Deformities of the chest. The "pigeon-shaped" chest is not so unfavorable. Rickets in children often

leads to deformity of the pelvis, hence child-bearing is more dangerous in females who have been so attacked.

Hernia is important, as it is apt to become strangulated. A rupture is more dangerous in females than in the opposite sex. Brinton believes that if a good-fitting truss has been constantly worn, the case is not so unfavorable. Amputation of a limb for disease is said to confer increased risk of visceral disease. Here the previous malady should enter into consideration of risk of insurance on life. Amputation for injury or accident is generally followed by a plethoric state, and a tendency to corpulency.

The presence of ulcers, if of long standing or extensive, imply a drain on the constitution, which, as "age advances and nutrition declines, may prove fatal;" hence these cases ought to be declined. Moreover, according to Dr. Fisher, the long continuance of an ulcer is apt to cause Bright's disease of the kidneys.

The force and frequency of the pulse is useful in detecting cardiac disease. Excitement, as in being examined, may quicken it for a time. An abnormal slowness of the pulse points towards cerebral disease.

The condition of the uterine functions must be carefully inquired into.

Residence in certain localities is injurious to health. In some places such diseases as ague, yellow fever, dysentery, liver disease, etc., are endemic; hence, if the applicant intends to proceed to these places, an increased risk is incurred.

The vital capacity of the lungs is a subject of vast importance, as with the spirometer we can often detect the very earliest stage of phthisis, even before physical signs exist, the vital capacity being reduced in first stage of consumption. The following table, after Dr. Davis, exhibits this more clearly:—

Height.	Cubic Inches.
5ft. 0 in. to 5ft. 1 in.	176
5 " 1 " to 5 " 2	177
5 " 2 " to 5 " 3	189
5 " 3 " to 5 " 4	193
5 " 4 " to 5 " 5	201
5 " 5 " to 5 " 6	214
5 " 6 " to 5 " 7	227
5 " 7 " to 5 " 8	228
5 " 8 " to 5 " 9	237
5 " 9 " to 5 " 10	246
5 "10 " to 5 "11	247
5 "11 " to 6 " 0	257

The relation between the weight of the body, the height, and circumference of the chest at nipples is important. The following is Dr. Steedman's table:—

RELATIVE PROPORTION OF THE HEIGHT AND WEIGHT OF THE HUMAN FRAME.

Height.	Weight.	Med. Chest.
4ft. 10 in	105 lbs.	32.56 in.
4 " 11 "	110 "	33.06 "
5 " 0 "	115 "	33.56 "
5 " 1 "	120 "	34.06 "
5 " 2 "	125 "	35.13 "
5 " 3 "	130 "	35.70 "
5 " 4 "	135 "	36.26 "
5 " 5 "	140 "	36.83 "
5 " 6 "	143 "	37.50 "
5 " 7 "	145 "	38.16 "
5 " 8 "	148 "	38.53 "
5 " 9 "	155 "	39.10 "
5 " 10 "	160 "	39.66 "
5 " 11 "	165 "	40.23 "
6 " 0 "	170 "	40.80 "
6 ft. 1 in	175 lbs.	41.30 in.
6 " 2 "	180 "	41.80 "
6 " 3 "	185 "	42.30 "
6 " 4 "	190 "	42.80 "

Example.—A man 6 feet in height should weigh 170 lbs. One-fifth of 170 = 34, which subtracted from 170, leaves 136; hence he would be accepted at the latter figure, all else being favorable.

Of course every one is not expected to weigh and measure exactly these average numbers; but, as a rule, 20 per cent., or one-fifth, is the maximum variation compatible with health.

ABUSE OF POSITION.

BY A MEDICAL DIRECTOR.

Outside of the larger cities the educated physician holds a very influential position among the people to whose physical wants he ministers. His opinion is often asked on matters which are by no means professional in their nature, and it nearly always carries with it great weight. Every individual, for instance, who has himself been relieved of suffering by the doctor's skilful treatment, or has had the satisfaction of seeing his wife or child apparently rescued by the doctor's efforts from the jaws of death, will be very likely afterwards to place the utmost faith in the physician's advice, upon no matter what subject it may be given. A word or a smile from him will often be sufficient to completely undo the hard-earned results obtained by the life insurance agent. Let us be more explicit. The agent, by dint of persistent and oft-repeated efforts, has succeeded, we will suppose, in inducing a young merchant's clerk to take out a policy of $5,000 upon his life for the benefit of his wife. The application is filled out and the young man is brought before the examining physician. In the course of the examination the applicant very naturally asks the doctor if he does not think it a good thing for a young man in circumstances like his to insure his life for a moderate amount. "Well, I don't know," says the doctor; "there is a good deal of humbug about this business of life insurance, and I for one would prefer to put my surplus into the savings bank."

The applicant is a very gamey fish and has to be managed carefully, or he will be lost to the agent. Even after he has been hooked there is no certainty that he will be landed safely in the company's hands, premium and all.

In the case under supposition the applicant places greater confidence in the doctor's few words of advice than in the elaborate and persistent arguments of the agent, and as a result refuses to take the policy when offered to him by the latter.

Under the old régime of appointing medical examiners, complaints of this kind were almost never heard, for the agent would always take the precaution to ascertain whether the examiner were friendly or not to life insurance as an institution, and avoid those who were not. According to the régime at present prevailing among the more careful companies, medical examiners are appointed simply on the ground of professional fitness and moral standing, and no precautions are taken to ascertain whether or not they are friendly to the business of life insurance. In every instance, however, they sign a formal document, accepting the position of examiner to the company which solicits their services. Under these circumstances it seems to us that the physician's duty is very

clear. The company does not ask him to play the part of an agent and sing its praises, but simply to perform faithfully his professional duty of excluding unsound or unworthy risks from the privileges of insurance. It is self-evident, however, that if he consents to receive a fee from the company, he is in honor bound not to injure its interests by word or action. Of course, if the company is in a bad financial condition, and he believes such to be the fact, he should refuse to serve as its examiner, for the very reason that he cannot conscientiously speak well of its soundness. But if he is simply opposed to the institution of life insurance, though believing that this particular company is financially sound and honorable in all its dealings, he should either keep his opinion to himself in the presence of an applicant, or else refuse to serve as an examiner.

We cannot avoid the belief that in the few instances which have been brought to our notice, the examining physician was not conscious of doing any harm by the statements which he made. We are confident, too, that if he had stopped for a moment to consider the possible harm he might do a needy agent, he would have quietly refrained from expressing his opinion.

OCCUPATION AND HEALTH.

That there are healthy and unhealthy occupations is known to all classes in society. What they really are, is, however, not so well understood. It is the duty of life insurance companies to ascertain what are healthy and unhealthy businesses. It is the work of the actuaries to clearly set forth what the rate of mortality in each occupation is, so far as that rate can be properly obtained. Considerable attention has been given to this subject in recent years, and we now know pretty clearly and definitely what occupations are attended with a high rate of mortality.

Perhaps the best paper on the subject, recently published, is one read at the Institute of Actuaries, in London, England, by Francis C. G. Neison, Esq., F.S.S., a leading member of the Institute.

Taking the census returns of Great Britain, giving the various occupations of the whole people, and the death-rate amongst those from 25 to 65 years of age, Mr. Neison has prepared tables of mortality setting forth the average deaths, per 1,000 persons living, in each occupation. Again, taking the returns of Friendly Benefit Societies with which Mr. Neison has been long conversant—he forms a similar table, which varies so little from the other as to be only confirmatory of it. The members of benefit societies are "select lives," examined by a medical officer. This would naturally give a rather lower death-rate than amongst the general community. The difference is, however, scarcely worth notice.

According to the census returns, Mr. Neison finds the mortality in various occupations to be as follows:

MORTALITY PER 1,000 PERSONS LIVING.

	Deaths to the 1,000.
Church of England clergy	10.02
Nonconformist clergy	10.01
Roman Catholic clergy	15.7
Physicians	12.6
Surgeons and Apothecaries	18.7
Barristers-at-law	10.9
Attorneys	16.2
Provision curers	16.8
Butchers	17.4
Poulterers	21.1
Fishmongers	17.4
Iron miners	13.7
Coal miners	14.8
Tin miners	16.1
Lead miners	20.3
Copper miners	24.7
Iron manufacturers	12.7
Paper "	13.0
Tin "	13.1
Nail "	13.2
Brass "	13.8
Glass "	15.8
Copper "	18.5
Lead "	19.3
Earthenware	19.7
Blacksmiths	13.8
Whitesmiths	16.8
Coppersmiths	17.1
Plumbers	18.3
Railway officers	12.8
" laborers	14.2
" porters	15.2
Engine drivers	16.3
Domestic gardeners	7.9
" grooms	9.8
" coachmen	14.7
" general servants	13.6
Beer-sellers	20.6
Wine merchants	23.3
Licensed spirit retailers	23.9
Inn and hotel keepers	26.8

It will thus be seen that the lowest death-rate occurs amongst "Domestic Gardeners," *i.e.*, gardeners who reside in the houses of their employers and are thus well cared for and well fed. The very highest death-rate is amongst hotel-keepers, who, though having little or nothing of any kind of labor to perform—living at their ease and partaking of the best food—yet die off at nearly quadruple the rate of domestic gardeners. Mr. Neison observes on this point: "Though no advocate of teetotalism, the table certainly presents facts of the utmost importance as to the influence of drinks and stimulants upon health. In every one of the different classes of drink-dealers, the mortality, it will be observed, is very high, being lowest for beer-sellers. Innkeepers and hotel-keepers appear as the least healthy. In no other class of results is such a high death-rate presented as amongst the various occupations connected with drinks and stimulants."

Amongst professional gentlemen the lowest death-rate is that prevailing in the ranks of the clergy. The Church of England and all other Protestant ministers die at a very little over 10 per 1,000 of all living at ages varying from 25 to 65 years. The Roman Catholic clergy die at the rate 15.7 per 1,000 of their class. They have in Great Britain the very poorest classes as their flocks. They visit these in every stage of disease and during the severest epidemics. Often they thus catch fever, small-pox, and other diseases, which cut them off. As a rule, too, they are not so comfortably cared for as Protestant ministers. The kindly hand of wife and child in the hour of sickness is more potent in restorative influences than the hands of strangers, be the latter ever so friendly and assiduous in their attentions. These circumstances will fully account for the somewhat high death-rate amongst Catholic clergy.

It is remarkable, too, that in the medical profession, while physicians die at the rate of 12.6 per 1,000, the surgeons and apothecaries die at a rate of 18.7 per 1,000. The two ranks of physicians and surgeons are

kept very distinct in England. The most eminent surgeon is merely styled "Mr."; the title "Dr." being only applied to physician. As a rule surgeons are more exposed to the various causes of death than physicians, and the result is seen in the higher rate of mortality amongst them.

Quite as remarkable is the mortality in the legal profession. The positions of attorney and barrister, like that of physician and surgeon, are quite distinct in the United Kingdom. The attorney does all the preparatory work in a suit, and lays the whole of it before the barrister. The clients in the case see the attorney and impart to him their facts. He prepares these for the barrister, who hardly every consults at all with the party in the suit. The barrister pleads in the open court and does all public work in conducting the case—the attorney sits in silence and supplies his superior with all documents. The heavy plodding, wearying office work, in close rooms often, is thus done by the attorneys: the lighter and more agreeable work by the barristers. The consequence is that barristers die at about the same rate as Protestant clergy, or 10.9 to the 1,000—while the attorneys die at the rate of 16.2 per 1,000; a heavier death-rate than that amongst many of the manufacturing classes.

Amongst all the workers in metals it will be observed that copper miners die off quickest; copper and lead manufacturers faster than those employed in any other manufacture; and coppersmiths somewhat in excess of any other smiths. This is the natural result of the deleterious influences of copper on the health of the human body.

Facts like these have led English Life Insurance Companies to be very cautious about insuring men engaged in certain occupations. There is hardly any respectable company amongst them now that will at all insure the lives of any class of liquor dealers. Some companies accept good, sound lives of hotel-keepers, and others of that class, at $2.50 extra rate per each $500 insured. The liquor traders generally object to pay this extra, so that, practically, no company now insures their lives. They established some years ago, themselves, "The Licensed Victuallers' Life Insurance Company," to meet this want, fancying their lives as good as any others. The death-rate was so great and the claims so many—none but drink-sellers being insured by the company—that in a few years it became bankrupt and had to be "wound up" in the Court of Chancery.

All persons engaged in mining occupations are, of course, charged extra for the risks. We think that, as these results of occupation upon health and longevity come to be more carefully analyzed and tabulated, the various life insurance companies must come to insure the different classes at various rates, corresponding to the mortality. It would, at least, be an interesting work just now for any actuary to engage in the preparation of equitable tables of rates, without profits, insuring all classes of lives according to the rate of mortality known to prevail amongst their ranks, according to occupation.—*Insurance Times.*

NEW MEDICAL EXAMINERS' BLANKS.

In the last number of the Record (October 15) we briefly alluded to the fact that two of the companies had adopted new forms of "application and medical examiner's report." Since then a third company has made a thorough revision of these blanks, and has adopted new forms which in the main resemble those now used by the "John Hancock," in which, as we have already stated, all the questions of a medical nature are printed on the side devoted to the examiner's report.

As many of our readers will be interested to know in what respects the blank intended for the medical examiner to fill out differs from those with which they have hitherto been familiar, we shall mention briefly the changes that have been introduced.

The first part of the medical examiner's report consists of a series of simple medical questions, which he is to put to the applicant, and which the latter, if he be a man of average intelligence, will be able to answer without the assistance of the physician. The two first questions are these: "Are you at the present time in good health?" and, "Do you ordinarily enjoy good health?" The third question reads: "Have you ever been predisposed to or had any of the following diseases or infirmities? (Answer *yes* or *no* opposite each)." Then follows the list of ailments, which in most blanks is incorporated into the application proper. To this list a few new items have been added, as for instance: dizziness, diarrhœa, delirium tremens, frequent desire to urinate, jaundice, lumps or swellings in any part of the body, open sores, pain in back (frequent or severe), swelling of feet or hands, and stricture of urethra. The next two questions are intended to supply any omissions that may exist in the foregoing list. The question relating to accidents is amended so as to read as follows:—"Have you ever met with any accident or personal injury, or undergone any surgical operation?" The questions relating to family history are preceded by a note in fine print, which reads thus:—"In stating the cause of death, avoid such expressions as "general debility," "change of life," "fever," "exposure," or any other indefinite term. If the expression "child-birth" is used, be particular to state how long after the delivery of the child, and also whether there were any symptoms of chest trouble, viz., cough, expectoration, loss of flesh, night-sweats, etc." The question relating to habits is broken up into a number of subordinate questions, as follows: "Have you *ever* used intoxicating liquors?" "If so state whether daily or occasionally, and explicitly to what extent." "Are you *now* in the habit of using intoxicating liquors?" "If so, state whether daily or occasionally, and explicitly to what extent." "Have you ever been intoxicated?" "If so, when last?" "Do you use opium in any form?"

The second portion of the medical examiner's report consists of a series of questions addressed by the company to the physician. They are as follows:—

"Have you carefully questioned the person examined concerning the matters mentioned in the foregoing questions, and are the statements given in reply apparently correct?" "Does he look older than the age stated; if so, how many years older?" (Here follow the data concerning height, weight, etc.) "What is your opinion of the influence of his occupation on the risk?" "What is your opinion in regard to his residence?" "Do you consider him acclimated?" "What is your opinion in regard to any former injury or sickness?" "Is there any indication that he is not now entirely well?" "Has he the appearance of a person addicted to the use of intoxicating liquor?" "Is there anything in his speech, looks, gait, or manner of conducting himself that would lead you to suspect that the party has any disease, organic or functional, of the brain or of any other portion of his nervous system, or any predisposition thereto?" "Has the party paralysis, cramps, tremors, atrophy or rigidity in any portion of his muscular system?" "Is the gait firm and elastic?" These

three last questions, it will be noticed, complete each other; the first one being rather general in character, the last two more specific. The subsequent questions relate to the organs of respiration and circulation, to hernia, to the urinary and other abdominal organs, etc., and differ in nowise from the questions now generally used for the same purposes.

Correspondence.

To the Editor of The Medical Record.

The question of medical examination for Life Insurance has really become so important with the numerical increase of these institutions, that everybody who has any connection with this business ought to contribute his share, so that the public, and especially the managers of those companies, may find out how to improve this most important branch of their business.

As I have been connected with Life Insurance as medical examiner during the past four years, I have taken a more than ordinary interest in the last move of your paper, and I thought that I should give you my view on a few points that have not been mentioned before, and which I think are more important for the solution of these questions than all the others. While the majority of your correspondents enlarge upon the relation between the agents and medical examiner, and give hints how to make the latter more independent of the former, I intend to go a little further into the matter itself, and speak of the making up of the blanks for the medical examiner (which are about the same in all companies). There are questions that ought not to be there, while other and more vital points are omitted. There are questions put in a way to which no answer in a really scientific way could be given, and there is altogether no room left to the examiner to give his opinion of the case as a whole. His simple, short answers to the short questions are sent in to the home office, and applications are accepted, because there was no spot on which the doctor could give a declaration upon some question; and other applications are rejected on the ground that some of these short answers do not tally exactly with the opinion of the medical or other board. I should recommend that a thorough revision of these blanks be made, and that in the new ones there might be questions taken up according to the present standard of medical science; and secondly, that more space and freedom be given to the examiner in sending in his opinion on the acceptability of an application.

To be sure it would then be necessary to be rather more careful in the selection and appointment of the medical examiner; for heretofore, when any medical man was recommended by an agent (because he was his friend or perhaps his partner in business), he was taken, and appointed to this responsible office.

Select from among the profession men of experience in practice, and of undoubted integrity, and so compensate them that they will consider themselves well paid for a hard task, and I am sure they will take the most pains to serve the company honestly without regarding the interest of any agent, and save many a mortification to the life insurance companies.

The second point I am thinking of is, that the medical examiner is often obliged to visit the applicant at a late hour of the night, when he finds him just returned from hard bodily work, worn out, hungry, and sometimes not in the best of humor, and then he expects to get a just and correct opinion of the health and constitution of the applicant. Then it will happen that a man just taken away from his evening meal, half frightened at the sudden visit of the doctor, presents a pulse of 90–100, and perhaps even some undulations of the beats of the heart, which are not natural to him.

No! Let every applicant prepare himself, and go to the office of the examiner, and present himself at a time when he is quiet, not overworked, when his mind is at ease, when he takes his time to be examined—and it will be an easy matter for the right examiner to make up his case correctly.

But who is going to take the initiative to correct all these shortcomings of the old plan? Has any step been taken to arrive at some understanding, in which way to make these reforms? I do not think so. Would it not be right if one of the profession connected with life insurance would issue a call for a meeting of the most prominent amongst these gentlemen, in which all these questions could be discussed and brought to a certain and more profitable condition? I should advise you, Mr. Editor, since you have already taken up this question, to try if you could not act on these suggestions, and bring these matters to an issue.

H. L.

New York, Sept. 20, 1873.

Miscellaneous.

Excessive Weight.—Medical examiners occasionally meet with cases like the following, which occurred during the past month:

The applicant, a stout, healthy-looking man of 62, was brought before the medical examiner by one of the company's regularly appointed agents. The questions in the application had all been answered favorably. He had had no previous sicknesses, had never been rejected by any company, and his family history was good. His pulse was of good volume, 68 to the minute, and perfectly regular. His height was 5 ft. 3 in., and weight 182 lbs., most of it being concentrated about the abdominal region. There was no fulness of the vessels in the region of the neck and face;—in a word, he had every appearance of a man who was temperate in his habits and enjoyed habitual good health. Nevertheless the examiner refused to carry the examination any farther, on the ground that the man's excessive weight was a sufficient cause for rejection. The applicant then inquired why his weight should render him less likely than other men to live out his full expectancy. The reply was, that, other things being equal, excessively heavy men were more liable to die of apoplexy. "Well, I guess you are about right, doctor. Since your mind is made up not to accept my application I might as well tell you that three or four years ago I had a kind of apoplectic attack, followed soon by a second. I at once commenced to live on plain, wholesome food, and ate always in great moderation; and since then I have had no trouble of any kind."

Rules regarding weight and family history often operate unjustly, but that they occasionally save the company a few thousand dollars is rendered highly probable by the instance just related; for it can be safely assumed in this case that the applicant is not at all likely to live five years longer, much less the thirteen expected.

Physical Aspects of Primogeniture.—Dr. J. Stockton-Hough's article on the "Physical Aspects of Primogeniture" will not appear in this number of the Record, as already announced, but in the Dec. 15th number.

Original Communications.

SOME OF THE

THERAPEUTIC USES OF COLD WATER IN THE TREATMENT OF HYPERPYREXIA AND OTHER MORBID STATES.

WITH CONTRA-INDICATIONS GROWING OUT OF INSUFFICIENT HEART-ACTION, ESPECIALLY IN PNEUMONIA.*

By SAMUEL G. ARMOR, M.D.,

OF LONG ISLAND COLLEGE HOSPITAL, BROOKLYN, N. Y.

The use of cold water as a therapeutic agent dates from an early period in the history of medicine. It is an old remedy, and it is therefore difficult to say much about it that is new. Indeed this is not my ambition, as my paper abundantly proves. I rather seek to attract attention to the use of cold baths in *lowering excessive heat of the blood*, and to present some facts bearing upon the general subject of hyperpyrexia.

Before reaching this point, however, I desire to say a word as to the mode of action of the cold bath, or cold douche, on the human organism: for it bears directly upon the varied action of the remedy as a therapeutic agent.

A simple mechanical view of its action has so long occupied the popular mind, that the physician often encounters great and unfounded prejudice in its use. Fear is expressed that it will "drive in the disease," or that the patient will "catch cold" from the sudden shock of water applied to the surface. All these notions are derived from physics, and the laws of dead and inorganic matter, and should find no place in the mind of any intelligent physiologist. For if it be true that the fluids are driven from the surface on one occasion and drawn to it on another, just as if the skin represented two sides of a hydraulic machine, why is it that we use the cold dash, or cold applied in some form, to arrest internal hemorrhage? Anatomically we find no direct vascular connection, for instance, between the skin and the uterine blood-vessels. There intervene skin, cellular tissue, superficial fascia, cellular membrane; again, deep-seated fascia, muscular tissue, peritoneum, etc. How, then, does cold applied to the surface constringe deep-seated blood-vessels? Evidently through an excitant and constringing influence reflected from nerve-centres.

Between the skin and mucous membranes everywhere there is an evident nervous connection. Anatomically and physiologically they are also closely identified; so that an excitant impression upon the skin is directly communicated to mucous membranes. This is sometimes explained by the vague term "sympathy." We rest satisfied with the general statement, that parts having similar anatomical structures have similar functional activities, and that when diseased, they "sympathize" with each other. The true explanation, however, in this case is based on the law of reflex nervous action. An excitant impression made upon the sensory nerves of the skin is communicated, first, to nerve-centres, and from thence reflected to the vaso-motor nerves which so abundantly supply capillary circulation. And this impression is readily communicated to mucous membranes; perhaps for the reason already stated, namely, similar anatomical resemblances; and when we remember that internal hemorrhage usually takes place from mucous membranes, the action of cold as a hemostatic becomes at once apparent. The hemorrhage is arrested by reflex contraction of the capillary blood-vessels.

In this respect cold resembles somewhat electricity and galvanism, and this is especially the case in what is called "transition baths," as practised by the Greeks and Romans of ancient times, and recently revived in our own country. By means of sudden alternations of heat and cold, the extensive network of cutaneous sensory nerves is brought into relation with the vaso-motor, nutritive, and secretory system; passive congestions are dispersed, and nutrition improved. Its action as an anti-congestive remedy is not unlike quinine. Indeed, according to the observations of Dr. L. Fleury, a congested spleen or liver will sometimes rapidly diminish in volume under the use of the cold douche. And Brown-Séquard says that, in a series of carefully conducted experiments made some years since, he found that dipping one hand into water at freezing-point produces in the other considerable contraction of blood-vessels. These experiments led to the alternate use of cold and hot water in the treatment of *spinal affections*. "I have often," he says, "applied with benefit cold and hot water to the spine, with the view of producing contraction of the blood-vessels of the spinal cord." And he speaks also of deriving benefit from alternate applications of ice and hot poultices in the treatment of neuralgia, and expresses the opinion that it operates remedially by "modifying the nutrition of the nerve-centres, and particularly the base of the brain."

The same treatment is advocated by Dr. John Chapman, in *The Medical Times and Gazette*, July, 1863, and in *The Year Book of Sydenham Soc.* He claims to have discovered that "a controlling power over the circulation of the blood in the brain, in the spinal cord, in the ganglia of the sympathetic system, and, through their agency, in all the organs of the body, can be exerted by means of applying ice and hot water to different parts of the back." He speaks with much confidence of this plan of treatment in varied affections of the nervous system, such as *epilepsy and paralysis, disordered menstruation, constipation, coldness of the surface, etc.*

Following the suggestions of Brown-Séquard and Chapman, I have been in the habit, for years, of recommending either the local shower-bath, or the "transition bath" (hot and cold), to the base of the brain and upper part of the spinal column, as a *general nerve tonic*, and I have found it useful in strengthening the body. It is true I have generally advised it in connection with iron, quinine, and other tonics. But as a nerve tonic in cases of general debility, it perhaps more than any single measure lessens morbid sensibility to the impressions of cold, and aids in giving permanent firmness and steadiness to nerve-action generally.

I have alluded to the well-established effects of cold in the arrest of hemorrhage, and to the probable facts as to its mode of action. Indeed, the proofs of the reflex influence of cold water upon blood-vessels at a remote point are among the most valuable recent contributions of physiology to therapeutics, and they furnish, in my estimation, a reasonable explanation of the action of the same remedy in *inflammatory* affections of deep-seated organs. In the more superficial inflammations, where cold can be continuously applied, there can be no doubt of its benefit when resorted to with judgment and discrimination. It is, of course, only applicable to the early stages of inflammation, with marked elevation of temperature, and absence of any sense of chilliness. We should rely

* Read before Kings County Medical Society, Brooklyn, N. Y.

greatly, in its use, upon the *thermometer* and the *sensations of the patient*.

Of late years, belief is gaining ground in the efficacy of cold applications in the treatment of inflammations of *serous tissues*. To every practitioner the practical question presents itself as to whether he shall apply hot or cold applications in the first or forming stages of these inflammations. Some are partial to one, some to the other. As a rule, German practitioners resort to cold applications. "At the commencement of an attack of pleurisy," says Niemeyer, "I cannot sufficiently recommend the use of cold and of local blood-letting." And in acute peritonitis, he says he has seen "the best results, in cases that were amenable to any treatment, from covering the entire abdomen with cold compresses, and renewing them every ten minutes." He regards leeches to the abdomen, the use of cold, and the internal administration of opium, as the most effective treatment.

It must be remembered, however, that, in all cases of peritonitis, the tendency to death is at the heart, and increased feebleness of heart-action, as I shall more fully state in a moment, contra-indicates the use of cold to the surface, without at least giving stimulants at the same time.

Prominence has been recently given to this point in considering the use of the cold bath, or cold applications, in the treatment of *pneumonia*. Its use may, however, be exceptionally dangerous in this disease. What, then, is the danger in pneumonia? And can the objections to the use of the cold bath, as a general antipyretic, be in any way overcome? These are interesting practical points, and can be answered only by a clear comprehension of the natural history of the disease under consideration. This I can state only in brief.

In a somewhat general sense, then, pneumonia presents two main points for our consideration: 1st, *Restriction in lung function*; 2d, *Fever*. There are other points of interest, but these are the ones with which we are chiefly concerned at present. Now, what relation, it may be asked, does the local lesion sustain to the general constitutional condition of the patient—in other words, to the fever? And what relation does the fever sustain to the heart-action?

This whole subject is ably discussed in a recent clinical lecture by Prof. Jürgensen, of Kiel (Prussia). He maintains the position that the immediate cause of death in pneumonia is "insufficiency of heart-action." I cannot give, at length, the ingenious process of reasoning by which he arrives at this conclusion. Briefly stated, it is something like this: The pneumonic exudation affects an increased resistance to the lung circulation, and therefore imposes a greater demand for work upon the right ventricle. This increased resistance to the circulation of blood in the lungs causes correspondingly increased labor of the heart in order to effect a complete exchange of gases. The *high temperature of the blood*, according to Prof. Jürgensen, is an important and dangerous element in pneumonia, as in many other forms of disease. With the rising of bodily heat, rises the frequency of the pulse; the laboring time of the heart is increased, and the time of rest lessened; carbonic acid is increased beyond the normal amount, and must be eliminated quicker than in health. This requires, of course, increase in the force of the heart and the respiratory muscles.

But the fever, we are told, leads to "degeneration of the muscular fibres of the heart," and lessens its power at a time when it is already overtasked by its efforts to overcome the resisting pulmonary exudate. Now this loss of contractile power, growing out of failure of nutrition in all high febrile states, will be the most severely felt in those parts whose expenditures are the greatest, and these are the constantly laboring muscles—the heart and the respiratory muscles. Hence the great danger, in pneumonia, of the heart losing its contractile force. This, according to the views here presented, is the "dead point of danger"—not so much the local disturbance in the lungs; else why, inquires our author, do we find, soon after the natural crisis has set in, say the fifth or seventh day, such marked subsidence of all subjective phenomena, notwithstanding the continued infiltration of lung-substance? "*The fever*," says Jürgensen, "*is the most dangerous enemy of the heart* . . . . *With the cessation of the fever, the power of the disease is broken.*"

How, then, shall we subdue the fever, which is the "dangerous enemy in pneumonia?" Shall we resort to cold applications, as in pleurisy, peritonitis, etc.? In the hospital at Prague we are told that "every acute sthenic pneumonia is treated with cold compresses;" and Smoler says, "it is exceptional for a patient not to feel material relief from this treatment." And Niemeyer has made extensive employment of cold in "croupous" pneumonia, as in pleurisy and peritonitis, and, relying upon a large number of very favorable results, says he can recommend the practice.

Prof. Jürgensen is also partial to cold water as a febrifuge. He states that, to his knowledge, nobody has employed the bath so frequent, so cold, and with such untiring energy, and that he has never had any reason to regret the practice; and yet no one more clearly recognizes than he *à priori* objections that may be raised to the cold bath—that is, if not accompanied by the use of stimulants. What are some of these objections?

In the first place, contraction of the vessels of the periphery, caused by the cold bath, brings on increased resistance to the blood-current, and with it increased labor of the heart, which, we have seen, is already enfeebled by the fever, by increased labor, and by increased resistance in the consolidated lung-tissue.

That during a cold bath, therefore, a fatal collapse may ensue in pneumonia is a clinical fact of great practical importance—one that is to a certain extent exceptional; and hence the prominence I have given to the subject in this connection. Under no circumstances should cold baths be resorted to in pneumonia, in cases of aged people, very fat people, debilitated people, and finally those suffering from heart-disease. And, if none of these considerations forbid its use, the heart-action should always be supported by stimulants at the time of the bath. Of these I will mention alcohol as most rapid in its action; quinine, as the most permanent. If there is any doubt as to the failure of heart-action, quinine is the remedy above all others, for the reason that while it diminishes temperature, it tones and strengthens at the same time the tailing muscles of the heart. As a general febrifuge and cardiac stimulant, digitalis should also be mentioned in this connection as a valuable addition to the quinine. But, with a purely antipyretic method, Liebermeister claims to have brought down the mortality in "croupous" pneumonia from 24.4 per cent. to 8.8 per cent. But the value of this exclusive treatment certainly requires to be confirmed by further experiment before it can be generally received. Moreover, our pneumonias in this country vary so greatly in their type, and in different localities, that all exclusive modes of treatment are out of the question. Indeed, quinine and stimulants are, in many cases, indicated from the first.

I have dwelt mainly upon the uses of the cold bath in the more inflammatory types of pneumonia, because it brings up the question of *excessive blood-heat* upon the body, and especially—for reasons suggested—upon the *heart* and *respiratory muscles*.

It cannot escape the attention of the general professional reader, that growing attention is given to the danger resulting from simple *increase of bodily temperature*. Without discussing the question as to the cause of the fever, we are beginning to discuss its effects upon the organism as a dangerous element of disease *per se*. Trousseau says: "Few persons recover from enteric fever if the temperature exceeds 105°." This may be too dogmatical in its statement, but it is an approximation to the truth. Fever is a dangerous element of itself, and it is beginning to be more and more recognized as such. In typhus, typhoid, and other infectious diseases, "the greatest danger," says Niemeyer, "is from the severity of the fever." This danger he regards as a double one. On the one hand, the increase of the bodily warmth above a certain point—say 108°—"induces paralysis of the heart and renders life impossible;" while, on the other hand, "continued increase of the production of heat, or increased tissue metamorphosis, induces consumption of the body of the patient." The exhaustive effect of the fever is compared to that of excessive bodily fatigue.

In the treatment of these fevers, Niemeyer urgently advises the *abstraction of heat*, and speaks of cold affusion, or the cold bath, as one of our most valuable antipyretic agents. This will be recognized, however, as an old remedy in fevers. It was a favorite with Galen, and still more so with Currie; and, at a later period, with our own countryman, Nathan Smith. At the present time Niemeyer and others urge only what Currie so enthusiastically wrote about during the latter part of the last century. His *Medical Reports on the Effects of Water, Cold and Warm, as a Remedy in Febrile Disease*, are among the most eloquent contributions to the professional literature of his time, and his recommendations have been followed with much success. Armstrong, who wrote so well on fevers at a later period, speaks no less enthusiastically of the febrifuge virtues of water. He adopted, substantially, Currie's mode of using it.

Niemeyer has somewhat modified his mode of using cold water. Formerly, when the bodily temperature had risen to a dangerous height, and there was occasion to lower it, he had his patients "wrapped in cold wet sheets, and the proceeding repeated at intervals of ten to twenty minutes until the desired end was attained." But, observing that there was occasional exhaustion along with the retardation of the pulse, he more recently doubted the propriety of such sudden and persevering abstraction of heat. He raises the question, very properly I think, as to whether it is not possible to exhaust the patient by an "excessive increase of the production of heat," comparing it, as already stated, to the effect of excessive bodily exercise. He now resorts to less sudden and less energetic abstraction of heat than formerly. His plan is substantially that recommended by Ziemssen: "As often as the temperature rises above 104° the patient is placed in a bath whose temperature is about 10° below that of his body, or about 95°." The temperature is gradually reduced to 68°, the patient remaining in till he is slightly chilled. He is then placed quickly in a warm bed. This is repeated at first four or five times a day; subsequently it is reduced to two or three. If quinine is used in two or three grain doses at the same time with the abstraction of heat, he thinks we are not obliged to use the baths so often.

In the inflammatory stage of our autumnal or remittent fevers, in which there is marked elevation of temperature, with dry, hot skin, cold affusion frequently proves to be a valuable sudorific. My experience with it in this class of fevers in the West and South-west has been extensive, and I can speak, therefore, with confidence as to the value of the treatment. In all malarious forms of remittent fever the exacerbations are characterized by very sudden and marked elevation of temperature. It is not unusual to find a temperature of 105° or 107° during the first or second paroxysms of the fever. Now, practically it is found extremely difficult to produce diaphoresis by drugs when there is such excessive heat of skin. A patient rarely sweats at a temperature above 102°. The degree of heat called the "sweating point" is essential, and nothing secures this so well, so speedily, and so surely as affusions of cold water. Shower a patient at 105° or 106° until he feels a slight sensation of chill, then wrap him in warm blankets, and, as a rule, he will sweat profusely. I have arrested many simple malarious remittent fevers by one or two cathartic doses of calomel, the free use of cold water during the pyrexia, followed by large anti-periodic and febrifuge doses of quinine. If the temperature in these fevers is 104° or more, skin dry and hot, pulse frequent, brain excited, and back aching, I am confident we give our patient the speediest relief in the shortest period and simplest manner by cold affusion. It rapidly lowers the temperature, and tends to the production of free perspiration.

Among the exanthematic fevers, the temperature of the skin is perhaps hotter in *scarlatina* than any others, and in none do we derive greater benefit from sponging or the cold affusion of water. Currie was of opinion that it "extinguishes scarlatina," preventing the eruption, and arresting the further progress of the fever. He considered it applicable only to the forming stage of the more sthenic forms of the disease, when the temperature was from 105° to 108° F. His plan was "to strip the patient and dash four or five gallons of the coldest water to be procured over his naked body." The affusion was repeated as the obstinacy of the fever indicated.

Many practitioners, of later date, have followed the suggestions of Currie. Dr. Laycock, of Edinburgh, has resorted to cold affusion and the wet sheet with very marked advantage; and I believe the profession everywhere to-day, although perhaps less enthusiastic than Dr. Currie, regard the practice with favor. When the febrile action is free and strong in the inflammatory or anginose form of the disease, the little sufferer, restless, burning with fever, and exhausted for want of sleep, will often perspire freely and fall into a sweet slumber after the use of the bath. If there is any doubt as to the propriety of further use of the shower bath, or sponging with cold water, the inunction of oily substances, or sponging with tepid water to which small quantities of glycerine are added, may be substituted.

If the time allotted to the present paper permitted, I might multiply instances of the value of cold water in all *overheated conditions of the blood*. The testimony is constantly increasing and becoming more specific on this point. Wilson Fox, M.D., Prof. of Clinical Medicine in University College, London, has recently published an exceedingly interesting monograph *On the Treatment of Hyperpyrexia, as illustrated in Acute Articular Rheumatism, by the external Application of Cold*. The dangerous effects of excessive temperature have specially claimed his attention. In a carefully observed series of cases, he found that when the temper-

ture suddenly rises from 103° or 104° to 107°, 108° or 109°, the case usually proved fatal within one or two hours after the temperature of 109 had been attained. This sudden rise of temperature is regarded by Wünderlich as one of the phenomena of death; indeed it often continues, and sometimes increases, for one or two hours after death.

Fox publishes a number of cases, in which, by repeated immersions in the cold bath, life was protracted for nearly thirty-six hours after the temperature in acute rheumatism had reached 109°. But, notwithstanding the great and imminent danger of sudden and high rise of temperature, he reports many cases in which rapid fall of temperature and recovery followed the cold bath. One case is specially notable from the gravity of the symptoms, which indicated speedily approaching death. The temperature rapidly rose from 107.1° to 109.1°, when the patient became entirely unconscious. She was put in a bath of 96°—"unconscious, pulse imperceptible, the face in the highest degree cyanotic, and the breathing such as commonly precedes the act of death." In five minutes after she was in the bath, the temperature in the rectum was 110°. Ice was placed on her chest and on her abdomen; a bag filled with ice was also placed to her spine. Within fifteen minutes the temperature in the rectum had fallen to 109.1°, in five minutes more to 108.4° (the average temperature of the bath being then 66°); and thus it continued to fall. Within an hour and a half from the time she was put in the bath, the rectum temperature was 99.5°, the circulation was restored, and consciousness had returned. Brandy was freely given; the patient took six ounces within an hour. The subsequent treatment consisted in resort, from time to time, to the cold bath, and the application of ice, as before, to counteract returning elevation of temperature—the free use of quinine, brandy, beef-tea, milk, and eggs. At the end of a week "the patient sat up in bed, and ate a boiled sole for dinner." In this case—and it only illustrates many others—the immediate cause of the dangerous symptoms was undoubtedly the *sudden elevation of temperature.*

I cannot follow out the many interesting observations of Fox in the use of the cold bath in the treatment of hyperpyrexia, especially in acute articular rheumatism. His records are among the most interesting of modern medical literature, and clearly demonstrate that, so far as we at present know, the application of cold to the surface stands unrivalled as an antipyretic in all cases of excessive elevation of bodily temperature.

I have thus far, it will be observed, spoken of the uses of cold water as a hemostatic, a general nerve-tonic, an antiphlogistic, and a general and most valuable antipyretic. But the advantages of modern hydropathy are perhaps more clearly illustrated in the treatment of *abdominal affections* than any others. Many such cases have been over-drugged, their nervous system disturbed, their digestion impaired, their nutrition at fault; or perhaps they may be worn out from habits of dissipation and luxury. What they often need is what they will not, as a rule, submit to in private practice, namely: a thorough system of *hygiene*;—sunlight, fresh air, systematic exercise, the shower bath, the douche, the pack, frequent draughts of pure cold water instead of more doubtful beverages, simple diet, milk, brown bread, and rest of body and mind, such as they find at the best hydropathic institutions of the country. These hygienic agents, intelligently administered, often effect cures when drugs alone had failed—when, indeed, drugs are positively injurious.

But the varied therapeutic uses of water, and the several plans of application, such as by *irrigation, ablution, affusion*, the *douche*, the *shower bath*, and the *pack*, do not come within the general scope of this paper. It has been my object, mainly, to revive the discussion of an old subject, and especially to attract attention to the use of the cold bath in all cases of excessive and dangerous elevation of temperature. In our eager search for "new remedies," we are prone to forget old ones, and especially such as nature furnishes us so bountifully as water. Some of us, of late years, in our enthusiasm of progress, have almost forgotten, if we ever knew, that Currie and Armstrong, and Jackson and Forbes and Smith wrote so well and so truthfully about the virtues of water.

Attention is directed in the paper to the following points:—

1st. That the therapeutic action of water, as a hemostatic agent, is mainly and primarily upon the nervous system, and through that upon the capillary blood-vessels.

2d. Its direct action as a sedative in the treatment of some forms of inflammation, with suggestions as to its mode of application.

3d. Some points in the natural history of pneumonia, the effect of *excessive temperature*, especially upon the heart and respiratory muscles, and the necessity of using cardiac stimulants when resorting to the cold bath.

4th. The danger, in the essential and other forms of fever, from the *increase of bodily temperature per se*, and its effects in producing paralysis of the heart; together with the value of cold baths or spongings in such cases as an antipyretic.

5th. And lastly, the uses of the shower bath, the douche, and the pack as general hygienic agents in the management of chronic, abdominal, and nervous diseases.

In my hurried presentation of the subject, I have purposely avoided detailed statements as to the mode of applying cold water in medicine. Nor have I dwelt upon its dangers other than in pneumonia. All these questions I leave to the individual judgment of the practitioner, trusting that the merits of the remedy may secure for it the consideration it deserves. As a remedial agent it has been subject to great vicissitudes of fortune; and that its virtues may have been greatly exaggerated in the past, is no reason why we should allow a valuable remedy to fall into comparative disuse.

A CASE OF TORTICOLLIS; ILLUSTRATING SOME PRINCIPLES OF TREATMENT.

By Wm. R. FISHER, M.D.,

NEW YORK.

On the nineteenth of January, 1869, E. M., a boy of eleven years of age, was brought to Dr. C. Fayette Taylor for the treatment of torticollis on the right side. His parents attributed the deformity to an exposure to cold, which had occurred when he was about three years of age; but, from the character of the distortion, together with the fact that there was an obscure history of an abscess in the neck, which was reported to have discharged in the early period of the affection, it was suspected that inflammation might be progressing slowly at the fifth or sixth cervical vertebra, although there were few constitutional signs of Pott's disease. For the sake of security the appropriate treatment for the latter disease was at once commenced, and the proper mechanical apparatus was worn for several

months. The wry-neck, however, was not cured, and further mechanical treatment was suspended.

On the fifth of April, 1873, E. M., now aged fifteen, was brought again to the office by his parents, with the request that we should assume the treatment of the case. Five days previously a homœopathic surgeon had performed an operation upon the contracted muscles, with the view of overcoming the deformity; but no perceptible improvement followed, and they came to us for further advice and treatment. An examination showed that this operation had been incomplete. The clavicular branch of the sterno-cleido-mastoid muscle had been only about half divided, and there had been no attempt to divide the sternal branch. The wry-neck, of course, still existed. There was a decided inclination of the occiput forwards and to the right, while the chin looked upwards and to the left. By an effort he could straighten the neck, and bring the median line of the face to its normal position, but, in so doing, the sterno-cleido-mastoid muscle on the right was rendered tense and prominent, and the right shoulder was elevated. The movements of lateral flexion and of rotation to the left were restricted to nearly one-half of their proper extent. The features all showed the effects of the prolonged continuance of the abnormal position. The right half of the face was slightly smaller than the left, and on that side the eyebrow and lid, the nose and the angle of the mouth inclined slightly upwards. The right sterno-cleido-mastoid muscle was thickened and shortened, while that upon the left side was flattened out and attenuated; and in these changes the clavicular portions of the trapezii participated to some extent. The scapular muscles, especially the rhomboidei and the trapezius, were found to be slightly larger on the left side than on the right; but this might be accounted for by the fact that he was naturally left-handed. The scapulæ were of the same size, but the inferior angle of the right hung an inch lower than that of the left sides and pointed outwards and forwards. The right clavicle was half an inch higher than the left at the sternal articulation, having been pulled up by the shortened sterno-cleido-mastoidens. Beyond these there were no apparent variations in symmetry between the two sides of the body. The firm, well-developed chest had resisted the action of the contracting muscles, and the spine did not present the compensatory curves which are usual in cases of torticollis of long duration, especially in girls.

It was evident that another operation would be necessary before any mechanical treatment could be used with success, and on the sixth of April Dr. Taylor, assisted by Dr. Chrystie, thoroughly divided subcutaneously the right sterno-cleido-mastoid muscle. An apparatus to reverse the position into which the deformity had thrown the head, and thus to maintain a separation between the divided ends of the muscle, was applied as soon as the effects of the anæsthetic had passed off, and this was worn, night and day, during the following three weeks. The day after the operation an exercise of the muscles of the neck was commenced. At first it consisted of passive movements, but soon active exercises were substituted, and continued to be used for about ten minutes twice a day. On the fourteenth of April a special faradization of the left sterno-cleido-mastoid and the right trapezius and rhomboidei muscles, together with a general application over the muscles of the back and neck on both sides, was added to the previous treatment. The patient progressed so rapidly under this combination of therapeutic means, that on the twenty-eighth of April, twenty-two days after the operation, he was allowed to suspend the treatment for three days, with the exception of the mechanical apparatus, which he still continued to wear during the day and night. Upon his return it was found that the rigidity on the right side in lateral movements and rotation of the head had increased somewhat, and the former treatment by active and passive exercises, together with electricity, was resumed, and continued for ten days longer. The flexibility of the neck at the end of that time was completely restored, and although there was still a decided difference in development between the sterno-cleido-mastoid muscle on the two sides, there had been so much improvement during the month's treatment that he was discharged, with the recommendation to wear his apparatus during the day for two or three weeks longer and to keep up certain prescribed exercises for the purpose of acquiring facility in rapid movements of the head. He returned for examination twice, at intervals of two weeks, and was found to be improving so steadily in power and control of muscular action, that no further treatment became necessary.

The diagnosis of wry-neck, as this case shows, is not always an easy matter. The congenital and the paralytic varieties, together with the traumatic distortions of the neck which result from loss of tissue after burns or wounds, do not usually present any great difficulties. Spasmodic torticollis, however, associated as it is apt to be with obscure derangements of the central nervous system, often involves very serious questions of diagnosis. But that form of wry-neck which sometimes accompanies, and becomes a prominent symptom of, inflammation of the cervical vertebræ, is perhaps more important than any other in its relations to diagnosis, prognosis, and treatment. Disease of the spine in this location is rapidly and almost inevitably fatal, where it is left to itself; while under a proper and carefully conducted mechanical treatment it is, to say the least, quite as amenable to the orthopædist's skill as the disease is found to be at any other region in the spinal column. Its early recognition is therefore of the utmost importance. A tendency to hold the head on one side should always arrest the attention of the physician, and in every case whose history is in any way obscure, it should receive a special investigation. When the deformity depends upon disease of the vertebræ it is met with as an early sign, because it arises from the instinctive tonic muscular contractions which are set up to prevent movement at the seat of disease. The position which may be assumed by the head, as a result of this involuntary muscular act, varies greatly. It is by no means always flexed and rotated, so as to resemble the ordinary wry-neck, and, indeed, can readily be distinguished from it, in most cases, by an experienced observer. But sometimes this is not so easily done, and then an error in diagnosis may bring about disastrous results. Tenotomy and passive movements in a torticollis from Pott's disease must do harm, and might result in death. The diagnostic value of torticollis in relation to disease of the cervical vertebræ depends greatly upon its association with additional symptoms. Pain is almost always an early sign. It may be felt in the chest or abdomen, though a more usual seat is in the back of the neck and base of the skull. It is not uncommon to find a severe, steady ache, extending from the neck down the arm. Sometimes the pain is steady and sometimes paroxysmal, but motion always tends to aggravate it. Next there are symptoms which indicate irritation of the nerves that preside over the respiratory function: such as hiccough and paroxysms of coughing. These are very characteristic when they occur. Then there are a series of physical signs by which the diseased tissues express

their need for rest. The peculiarly distinctive attitude which the patient assumes during locomotion and the straightening of the normal dorsal curve of the spine are striking instances of an unconscious effort to protect the seat of disease from movement and shock. If the affected point be as low as the seventh cervical or first dorsal vertebra the respiration is apt to be short, jerky, and incomplete, because full inspirations would bring about motion through the costal action, and increase the pain. To this class of symptoms belongs the fixed position of the head which we are considering. Sometimes its relation to disease of the cervical vertebræ may be determined by observing, in addition to other signs, that the patient supports and steadies his head by his hands, or tends to lean against support whenever he can; but often the diagnosis presents difficulties which large experience and cautious tentative treatment can alone resolve.*

The treatment of this case of torticollis comprised a variety of therapeutic means. The surgical procedure of myotomy was regarded as a necessary preliminary, on account of the duration of the existing deformity. In some of the cases of congenital wry-neck, and in that form which arises after exposure to cold, it is sometimes possible in the early stages to remove the deformity by means of electricity, manipulations, frictions, or active exercises of the muscles of the neck; but usually the cases which present themselves for treatment have existed for so long a time that secondary changes in bone, ligament, and muscle have taken place which are not likely to yield to these mild measures. In two cases of torticollis in children, arising after an inflammation following exposure to cold, I have faithfully tried the effects of manipulations and exercises alone, without perfect success. One was of six months' duration when the treatment was commenced, and, though it was continued for eight weeks with decided benefit in increasing movement and in allaying muscular spasm, which previously had been developed whenever voluntary motion of the head away from the contracted side was attempted, still the cure was by no means perfect. The second case was also of about the same duration, and the treatment was continued for a month with a similar partially successful result. The indication for myotomy is plain whenever the structural changes have advanced so far as to transform the normal elastic muscle into a shortened, unyielding band. The operation, under ordinary circumstances, when performed with care, is not a dangerous procedure, and by its employment the patient may be helped, in a few seconds, over ground which weeks of treatment by less radical measures might fail to secure.

Next in order comes the mechanical contrivance for holding the head properly after the operation, and preventing a return to the abnormal position. The instruments which are sold in the shops and described in the text-books as applicable for this purpose, are, as a rule, constructed without due regard to the instability of the head upon the neck. A traction is usually exerted upon one side or the other of the head by means of elastic bands, adhesive plaster, or metallic rods, from some unstable point of attachment on the shoulders or trunk; but sufficient care is not taken to prevent the patient from disarranging the contrivance in his efforts to avoid an irksome confinement. This is objectionable even in the simplest cases; but in cases of long standing their defective construction renders them practically useless. In females and in boys of delicate frame, the spinal column eventually becomes bent as a result of the permanent contraction of the muscles of the neck, and a secondary lateral curvature results. The clavicle and mastoid process are approximated by the shortened muscle, and, in the efforts of the patient to keep the face in a vertical position, the shoulder is elevated and the dorsal spine is curved convexly towards the side on which the contracted muscles are situated. In the treatment of such instances the chief mechanical problem consists in securing the shoulders and upper part of the cervical vertebræ in such a way as to prevent this bending of the spine, when force is applied to the head to antagonize the contracted muscles. But the mechanics, in their ignorance of anatomy, entirely overlook this point.

The following figure illustrates the form and mode of action of the mechanical appliance which Dr. Taylor devised to counteract the deformity, after the sterno-cleido-mastoid muscle had been divided by the knife. It will be borne in mind that in this case the spinal complication, to which reference has just been made, was not present.

The fixed point upon which the effectiveness of the whole instrument depended was a padded fulcrum (B), which rested upon the left side of the neck, close to the base of the skull. From this a curved piece of steel passed upwards behind the ear and over the crown to the right parietal bone, where it pressed upon the scalp by means of a padded plate (A), being held in place by a strap which encircled the head. In order to exert a constant force upon the point A, there passed downwards from the fulcrum B another curved steel piece, and this terminated in the bow, which is seen in the figure, passing over the shoulder, *although not resting upon it*. The arms of this bow were therefore levers, acting at the point A through the fulcrum B; and it can readily be seen that by tightening or relaxing the strap C, which passed from the extremities of the arms of the bow around the chest, the amount of force to be exerted at A could be graduated with precision. If the bow had rested upon the shoulder this could not have been done, but as the instrument did not touch the person except at the points A and B, a traction exerted upon the extremities of the arms of the bow could be directly transmitted to the point A. When applied, this contrivance was practically immovable, and the patient could not by any possibility rotate the head or bend it laterally to the right.

Many surgeons rely in the treatment of torticollis sole-

* For a full account of the diagnosis of disease of the cervical vertebræ, see THE MEDICAL RECORD for Sept. 15th, 1873, p. 413. Paper by Dr. T. M. L. Chrystie.

ly upon the knife and mechanical apparatus, and undoubtedly these are capable of producing successful results in some instances; although the uncertainty of effecting a radical cure in a long-standing case is recognized by all the authorities. In a case like that before us there is need for something more. The deformity which has existed for so many years does not arise alone from contractions of the superficial muscles, which the knife can reach; the deep cervical muscles are involved, and there are organic changes to be overcome. The overstretched muscles have grown weak and attenuated; the contracted muscles have undergone a structural shortening. The cervical fasciæ have participated in these changes, and sometimes the cervical vertebræ are seriously altered in shape by a continuous lateral pressure, and compensating curves are found in the spinal column below. Hence it does not always suffice to rely solely upon measures which act mechanically to release one binding tissue and to keep its divided ends apart. We must employ means to modify the nutrition of all the tissues, and these we find in active and passive movements and electricity.

Within thirty-six hours of the time of operation the patient was subjected to gentle passive stretchings of the neck on the right side, for the purpose of assisting the surgical measure by stretching the deeper tissues. On the third day active movements of the head were added to the stretchings, which had been increased in force, after the following manner: The patient was seated in a chair, with the shoulders strapped firmly back, so that they could not yield with the motions of the head. The operator stood behind, grasping the head on either side with the palms of his hands, and at his direction the patient executed the various movements of rotation, flexion to the right and left, forward and backward, etc. These sittings were of about ten minutes' duration twice a day, and as the muscles recovered their tone, the vigor of the exercises was increased, until finally they were performed against strong resistance by the operator. At the beginning of the second week local faradization was added to the foregoing means, and continued during the remainder of the treatment. The applications were not made solely upon the anterior portion of the trapezius and the sterno-cleido-mastoid muscles of the left side, as some of the authorities recommend. These were specially electrified, but all the muscles of the neck, shoulders, and upper portion of the back were subjected to the current, and it answered admirably in assisting to promote their development. The galvanic current was not employed, although in other cases I have seen excellent results from it in relaxing spasm and improving muscular nutrition.

There is still another use for active exercises, which is of the utmost importance in these cases of long-standing torticollis—namely, to educate the motor apparatus to respond quickly to motor impulses, and thus to break up the influences of habit. Long after a divided muscle has healed, and the subsequent treatment has brought about a relaxation of contracted tissues, a proper flexibility of action and a well co-ordinated muscular movement in response to special volitional effort, it will be found that the *habit* of holding the head on one side, and of turning the body instead of performing rotation of the head upon the axis, is still automatically maintained when the attention of the patient is diverted during the execution of natural movements. As a final method of treatment, therefore, the patient should be practised in making all the motions of the head and neck with rapidity, two or three times a day, until he acquires a complete automatic control of them. Our patient was instructed to continue the performance of such manœuvres after he passed from immediate observation; and an examination during the past week has shown that to his faithful observance of the directions he owes the high degree of perfection in function to which his cervical muscles have now attained.

October 21, 1873.

ON THE DIAGNOSIS OF SEX OF THE FŒTUS IN UTERO.

By WILLIS E. FORD, M.D.,
HOUSE-PHYSICIAN, CHARITY HOSPITAL, NEW YORK.

The diagnosis of the sex of the fœtus in utero has long been a subject of inquiry and investigation among scientific men. To be able to decide definitely regarding the sex of the child still unborn is certainly desirable to the medical practitioner, and would frequently be of great utility in cases involving legal questions relating to inheritance, titles, etc. Those who have investigated the subject have suggested several methods of arriving at a definite diagnosis, such as the external appearance of the abdomen during the last month of gestation; the actual length of the period of gestation; the sensations of the mother regarding the amount of movement or life in the fœtus; and lastly, the auscultation of the fœtal heart.

The former methods have been found of no practical use by the profession, and are only considered of value by midwives and the laity.

Such rapid advances have been made in the art of physical diagnosis, from the more thorough appreciation of facts elicited by auscultation, that it has been believed by some that this would also indicate the sex of the child before birth. A few papers have appeared based upon observation of cases, and tending to prove the truth of the assertion, that the sex and presentation of the child can be determined in the last month of pregnancy, by the rapidity and position of the pulsations of the fœtal heart. In the *New York Medical Journal* for July, 1872, seven cases, examined during the ninth month, were cited, and the following conclusions were drawn. Fœtal pulsations heard below a line drawn transversely to the body and dividing the uterus into halves, denote vertex presentations; above this, breech presentations. When the pulsations are 144 per minute it is a female; 124 per minute, a male. Variations of six beats from these numbers will not endanger a diagnosis.

While we recognize the value of such rules to the practitioner, we cannot consider them established by the small number of cases reported. Thinking further investigation might be of interest, we examined eighty cases from the wards of Charity Hospital, with results briefly as follows:—

All our observations were made and the results recorded during the ninth month of pregnancy; twin births, premature deliveries, and cases not fully recorded, being carefully excluded.

Of the whole number, there were 62 single births at term accurately recorded.

The average number of pulsations per minute of 24 cases of female children was 143; the highest noted was 160, the lowest 120. The average number per minute of 38 cases of males was 142½; the highest was 170, the lowest 110.

The fœtal heart was heard beating on the right side of the mother in 34 cases, on the left side in 25 cases. The heart-sounds were heard at the umbilicus of the mother in 4 cases above the middle of the uterus, in 6 cases; below, in 56 cases.

The presentations were as follows: Left occipito-anterior, 56; right occipito-posterior, 3; breech, 3. Of the cases of breech presentation, one was heard at the umbilicus, the other two below the middle of the uterus. Of those of the second position, one was heard at the umbilicus and two in the left iliac fossa. The conclusions we must necessarily arrive at, from a consideration of the above cases, are:—

That no indication of the sex of the child can be obtained from the pulsations of the fœtal heart.

Also that the position of the fœtal heart during the last month of utero-gestation is no guide to the presentation.

It was frequently observed during these investigations that the point of maximum intensity of sound changed from one examination to another; and that the nearer the approach to the time of delivery, the greater was the proportion of cases in which it was heard in the left iliac fossa.

In many cases during the first stage of labor the fœtal heart was heard on the left side of the mother, which for weeks previously had been heard on the opposite side.

In the course of these observations, special inquiries were made concerning the relative ages and vigor of the parents. From these elements we found that the sex of the child could be foretold with more certainty than by any other method with which we are acquainted. In the vast majority of cases the sex of the child followed that of the older and more robust parent.

This, however, did not occur with enough uniformity to establish any positive rule.

NOTES ON THE TREATMENT OF PUERPERAL CONVULSIONS.

THERE is no complication which can occur in the lying-in chamber more alarming to the attendants than the occurrence of puerperal convulsions. The wildest emotions are exceedingly apt to be manifested, and it is towards the medical attendant that all eyes are turned for assistance, for it is upon his knowledge and the ability to put it into practice that the life of the woman depends. The general features of treatment as practised by some of the obstetricians of New York are given below, and will not be uninteresting, we trust, to any reader who may be liable to be called to attend such cases.

The plan of treatment adopted by

PROF. T. GAILLARD THOMAS, OF NEW YORK,

is essentially embraced in the following: When a toxæmic condition of the blood is recognized in the pregnant woman from the presence of albumen in the urine, keep the mucous tract of the alimentary canal very active, prevent the woman from eating a large amount of animal food, and guard the skin against atmospherical changes in temperature. The *first* indication may be met by the use of saline cathartics, such as bitartrate of potassa and Rochelle salts. The *second* indication is met by keeping the woman as much as possible upon a vegetable and farinaceous diet, giving but a small amount of animal food; and the *third* indication is met by stimulating the skin once in twenty-four hours by hot-water or hot-air baths, followed by frictions with a rough towel, used by an *assistant*, until the skin is in a perfect glow, and causing the woman to wear flannel. Perhaps by these means further interference will be entirely avoided. In the worst forms of uræmic toxæmia premature delivery will be required, and it should be accomplished at the end of the eighth month, unless the life of the mother is seriously jeopardized previous to this time. The child will almost surely die if left to the end of the ninth month, and the life of the mother is greatly risked by the same postponement.

Suppose the woman is at the end of the ninth month, or before, and has a convulsion. The indication is to stop the convulsions and not permit them to return. Get the kidneys to work as soon as possible, and deliver the woman as soon as can be done with safety to the mother and child.

If the condition of the woman is such as to warrant it, draw blood. This is done for purely mechanical reasons, viz., to diminish the tendency to rupture of cerebral vessels, and the production of apoplexy. But you have bled, and another convulsion comes; place the woman under the influence of chloroform. Venesection and chloroform are the two means for stopping this kind of convulsions. Now bring on labor, and remove the child as soon as you can do so safely; but you are not obliged to deliver immediately.

The patient being under the influence of chloroform, if the os is closed, the warm douche may be used, throwing a stream of warm water against the cervix for twenty or thirty minutes at a time, to favor the softening and dilatation. The process of dilatation may mostly be left to nature, and within six or eight hours the os may be found to be dilated to the extent of an inch and a half or two inches in diameter.

If the pains are of moderate severity, the case may be left to nature chiefly until dilatation has taken place sufficient to admit of the use of the forceps or a resort to version, and either of these operations will be performed according to the circumstances of the case. There is generally no hurry about the delivering, for the woman is under the influence of chloroform.

The pressure now being removed from the kidneys, keep the bowels as loose as you can without prostrating the patients; sustain the strength by nutritious material, give stimulants if the pulse begins to flag, and keep the patient perfectly quiet.

The essential features of the plan of treatment adopted by

PROF. EDMUND R. PEASLEE, OF NEW YORK,

are as follows: The management of the puerperal condition can generally be so conducted as to prevent the occurrence of convulsions. If, upon examination of the urine, albumen is found present in quantities sufficient to give any apprehensions with regard to its toxæmic effect upon the blood, the first indication is to make the kidneys act. This may be done by the application of dry cups over the region of the kidneys; sometimes a plaster of some kind is sufficient; and very generally acetate of potash will produce sufficient diuresis if other measures fail. If there is an œdematous condition of the extremities, a pretty sharp drastic purgative may be given, and repeated consistent with the effect and general strength of the patient. By the use of these means no further trouble, generally, need be apprehended. If the case is sufficiently serious to demand the induction of premature labor, it should be performed as soon as the woman shows any symptoms of convulsions. If it becomes necessary to bring on premature labor, which is rarely the case if the woman is properly managed, it may be done by the use of the warm-water douche, sponge-tents, and Barnes's dilators.

But we will suppose that the woman suddenly, in the progress of her pregnancy, has a convulsion. The first thing to be done is to place the woman under the

influence of chloroform, for the purpose of preventing the further occurrence of convulsions. She may be held under its influence for almost any length of time if it is nicely and carefully administered, and not carried to the extent of producing stertorous breathing.

If the veins about the face are full and turgid, it may be well to take a pint of blood by venesection, but I have not found it necessary to resort to this measure during the last fifteen years. It is done with the view of saving the brain,—relieving the pressure upon the great nervous centres.

Next, in every possible way hurry up the labor.

If the os is closed, the warm douche, sponge-tents, and Barnes's dilators may be used; but the great objection to their use is, that too much time is consumed in effecting an entrance into the uterus. A more expeditious method of effecting an entrance into the cavity of the uterus than either sponge-tents or the dilators, is mechanical dilatation by means of the hand. Introduce the whole hand into the vagina, press firmly and steadily with the tips of the fingers against the os, insinuate first one finger into the os and cervix, then another and another, until the entire hand can be introduced and complete dilatation accomplished. The dilatation being accomplished, sufficient delay may be made to determine what the labor-pain will accomplish. If the chloroform prevents the convulsions, sufficient delay may be made to permit the head to come down, so that it can be readily delivered with the forceps; but if, after dilatation, there is necessity for immediate delivery, or there is any doubt with regard to the efficiency of the labor-pains while the hand is in the uterus, deliver by version—for there are even chances that the child will perish in either case, and the life of the mother is first to be regarded. After the child is born, chloroform is usually sufficient to prevent the occurrence of convulsions; but it may be assisted by the hypodermic injection of from five to ten drops of Magendie's solution. I would not advise the administration of more than one injection, and this may be used at any time before or after delivery, if the chloroform and venesection do not arrest their occurrence. The same remarks are applicable in case of a rigid os, in case of a labor at any part of the process in which the dilatation is not complete. The dilatation with the hand is much more expeditious than dilatation by any other means. The first principle in the management of a case of puerperal convulsions is to look for the safety of the mother. Get rid of the child as soon as possible, save it if possible, but at the same time do not risk the life of the mother.

PROF. A. L. LOOMIS, M.D., OF NEW YORK.

At a stated meeting of the New York Academy of Medicine, held April 3, 1873, Prof. Alfred L. Loomis read a paper upon the treatment of acute uræmia. Reference was made in the course of the paper to the subject of puerperal eclampsia. The plan of treatment which was particularly recommended in the management of cases of acute uræmia, was to produce diuresis by the use of an infusion of digitalis; and if convulsions appeared, to control them by the use of morphine administered hypodermically.

The Professor stated that he had treated one case of puerperal convulsions after this plan, and the result was entirely satisfactory. Reference also was made to cases treated by the use of morphia administered hypodermically.

In the discussion upon the paper of Prof. Loomis, the following remarks were made upon the treatment of puerperal convulsions:—

DR. ANDERSON, ex-President of the Academy, remarked that he believed "vent must be given somewhere." In one case which he treated by the use of ether inhalations, with only partial success in controlling the convulsions, he gave the patient grs. xx. of calomel, and followed it soon after with an injection of turpentine and soapsuds, and the result was an overflow of the bed, and a complete subsidence of the convulsions. The results in this case were sufficiently satisfactory to warrant him in the repetition of the treatment whenever the opportunity presented itself.

DR. BAXTER remarked that he was heartily sick of the use of chloroform, and that he relied upon infusion of digitalis in ℥ss. doses every two or three hours, and blood-letting.

PROF. WHITE, OF BUFFALO.

PROF. WHITE, of Buffalo Medical College, being present upon invitation, gave his views upon the subject of treatment of puerperal convulsions as follows: I am in favor of the use of opium, but I have never felt that it was important to give it hypodermically. My attention was particularly called to its use in a case where there was great œdema, immense distention of the abdomen, in which the anæsthetics pretty nearly controlled the convulsions, but it was deemed unwise to further continue their use. Opium was given in large doses by enema, with the most pleasing results. I believe that opium is beneficial from the fact that it relieves cerebral congestion. Since 1851, and more especially as I withheld the anæsthetics, have I been convinced that opium prevents cerebral congestion, hence has a tendency to prevent the return of the convulsions. But I can see no special advantage to be derived by giving it hypodermically. Again, I think it is important to unload. Calomel may be given perhaps, but I think that it is not as useful as some other remedy. Almost all cathartics are difficult of administration at this time. The cathartic which I prefer of all others is the croton oil. It is easily administered, is efficient, and safe if properly administered. Prepared with a little sugar and placed upon the root of the tongue, it is almost certain to operate quickly, fully, and freely. Another benefit which I think arises from the use of croton oil as a cathartic, is, that it irritates the mucous membrane of the entire intestinal canal, and in this way operates as a revulsive. This I regard as an important benefit. I formerly regarded the puerperal convulsion as something requiring blood-letting. I still think that there are cases of convulsions where the abstraction of blood is important. I would therefore still resort to blood letting occasionally, and the indications are plain which would demand the employment of this measure. The larger proportion of women, however, I believe will not require it.

CHARITY HOSPITAL.

In Charity Hospital, N. Y., Miss ——— remained during her pregnancy, and at no time had she presented any symptoms which would lead to the suspicion that she was to suffer from puerperal convulsions until the morning previous to the date of her confinement. Then she complained of not being able to see well. Her urine was examined, and found to be slightly albuminous. No œdema. Upon the next day, the day of confinement, her urine was loaded with albumen, and soon after her labor began she had a violent convulsion. The patient was immediately put under the influence of chloroform, and the warm douche used to soften the os. She was kept steadily under the influence of chloroform, and as soon as consistent a Barnes's dilator, smallest size, was introduced and allowed to remain. Within a couple of hours, by the continued use of dilators of different sizes, the os was quite well di-

lated. The membranes were then ruptured and a dose of ergot given, the pains already being moderately efficient. Within four hours from the time of having the first convulsion the woman was delivered of twins, of large size, and both living. The third stage of labor was completed promptly. After labor was completed the chloroform was discontinued, and soon after its discontinuance the woman had another violent convulsion. Chloroform was immediately readministered, and special measures at once adopted to secure a freer action from the kidneys, skin, and bowels than had been already employed.

This case fairly illustrates the plan of treatment adopted in that hospital in a case of puerperal convulsions. If, previous to the time for confinement, albumen is found in the urine, or œdema makes its appearance, active measures are taken to secure a freer action of the kidneys, those usually employed being diuretics and dry cups over the region of the kidneys. If œdema is present, the warm bath or hot-air bath are added, the patient well nourished with farinaceous diet mostly, the urine carefully examined, and slightest changes recorded. The remedies ordinarily employed, as being the most effectual in producing active diuresis, are the infusion of digitalis and the acetate, citrate, or bicarbonate of potash.

When a cathartic is employed, some active and reliable one is selected.

Reports of Hospitals.

ROOSEVELT HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES IN TREATMENT.

OXYGEN GAS IN PHTHISIS.

The administration of oxygen gas has just been commenced in a few cases of phthisis. Two cases which were receiving the oxygen were in the third stage of the disease, both having cavities in their lungs. So far as tried, the effects have been very pleasant, and exceedingly gratifying to the patients. The tonic effect realized has been very marked. The patients have slept better, and the appetite has been much improved. The amount administered was two gallons twice a day.

ACUTE AND SUBACUTE RHEUMATISM.

The leading feature in the treatment of these cases consists in the administration of iodide of potassium in doses varying from 8 to 15 grains, combined with 15 drops of the wine of colchicum-seeds three times a day. To relieve the local pain about the joints, the application of ice in ice-bags has proven most satisfactory. When the acute symptoms have been subdued, or have subsided, the application of kerosene oil to the stiffened joints, accompanied with free rubbing of the parts, has afforded more relief than other applications. Whether the virtue is in the oil, or in the rubbing, or in both, can hardly be stated, but the beneficial results which have been derived from its use warrant its adoption.

HEMI-CHOREA.

A case of this rather unusual form of the disease was noticed, affecting the right side, and was directly traceable to fright as its cause. A variety of treatment had been instituted in the management of the case, but it yielded only to the administration of carbonate of iron in free doses. The patient was a young girl, and although it may be questionable whether the subsidence of the disease was due to the remedy administered or to the natural progress of the disease, yet it is but fair to state that there was no amelioration in symptoms previous to the administration of the iron, and that improvement immediately followed.

GASTRO-ENTERITIS.

Some cases of this character, which were characterized by loose passages from the bowels from two to four in number daily, and more or less of gastric disturbance, have, after resisting other remedial measures employed, rapidly improved by use of a pill composed of nitrate of silver $\frac{1}{4}$ of a grain, and sulphate of morphia $\frac{1}{8}$ of a grain, three times a day.

EPILEPSY.

A somewhat remarkable case of this disease was under treatment, in which the fits made their appearance within fifteen minutes after receiving a fall and striking upon the head. There were no other symptoms present in the case except those relating to epilepsy. The fits, upon admission of the patient, were exceedingly frequent; but under the administration of bromide of potassium in large doses, the number and severity of the attacks have very much diminished, and the patient is feeling very well.

EMPYEMA.

The practice of making a free opening through the chest-walls in these cases, drawing off the pus, and washing out the pleural cavity, has been adopted in some instances in this hospital. In one case 108 ounces of pus were removed in this manner, and in another 60 ounces. Of course their constitutional treatment was pre-eminently supporting. These patients at present are in good condition, and steadily improving. In the same ward were other patients who had empyema, and had been treated by removing the fluid in the usual manner, and with the same general constitutional treatment as was adopted in the first-mentioned cases; they were in good condition and steadily improving. The amount of fluid in the pleural cavity in these cases, however, was far less than in those in whom the free incisions were made; and the question with reference to the treatment is, Would those patients who had such an immense amount of pus in the pleural cavity have done equally as well if they had been treated after the ordinary method by simple puncture, as they have done by making a free opening into the chest, and having the cavity daily cleansed by some slightly stimulating and disinfecting fluid? Carbolized water, varying in strength from 5 to 15 per cent., according to the tenderness and susceptibilities of the patient, is the fluid ordinarily employed for the irrigation of these cavities.

DELIRIUM TREMENS.

The standard prescription for this condition is—

℞ Chloral hydrat..... grs. xxx.
Potass. bromid..... grs. lx.
M.

To be given at bedtime, and continued through the day in smaller doses if necessary. This is the treatment for a case of fully developed attack. Milder cases are treated by two drachms of the tincture of lupuline and a bottle of ale at bedtime, and in a majority of instances this is all that is required; for as soon as the patient has secured a few hours of sleep the crisis is passed, and he will then begin to take his beef tea and milk, and come up rapidly. A patient

present who was suffering from alcoholism, and when admitted was very tremulous, was receiving

℞. Potass. bromid..... grs. xxx.
Morphia sulp..... gr. ½.
M.
S. t. i. d.

ULCERS.

The dressing which gives the most satisfactory results for cleansing a foul, sloughy, ulcerated surface, preparatory to strapping, consists of a solution of chloride of lime, one-half ounce to a pint of water, and applied three times a day upon a cloth or pledget of lint.

GRANULAR LIDS.

A number of cases of this kind have been successfully treated by the use of liq. plumbi subacetatis after all other ordinary means had failed. In one case ectropion was present in a marked degree, and with this treatment had almost entirely disappeared. About two drops of the undiluted liquor are dropped into the eye once in three or four days. It is important that the remedy should not be applied too often, lest the irritation produced should be continued, and prevent the beneficial effects which may follow if used at somewhat lengthy intervals.

Give the lids an opportunity to get better after each application.

CHANCROIDS.

First, a free cauterization with nitrate of silver or nitric acid, and after the separation of the slough dress the ulcer with iodoform. The results attending this method of treatment are uniformly good.

ABSCESSES.

The popular method of removing pus from the cavity of an abscess is by means of the aspirator. As a means of diagnosis, or a means for the simple removal of the fluid from a cavity, it is one of the most successful and convenient. As a curative measure it is not regarded so favorably. The simple removal of the fluid in many cases is not sufficient to prevent its return, and it becomes necessary to lay the walls open by free incision; secure a drainage by seton, and cause the cavity to heal from the bottom.

SPERMATORRHŒA.

℞. Ferri sulph.,
Acid. nitric. āā..... ʒ i.
Aquæ..... ʒ i.
Quiniæ sulph..... ʒ ss.
Acid. arsenic. et
Strychnia sulph. āā ..... gr i.
M.
S. Gtts. x., t. i. d.

The above prescription is regarded as more than ordinarily efficacious.

APPARATUS FOR MAKING EXTENSION AND COUNTER-EXTENSION DURING THE APPLICATION OF A PLASTER SPLINT TO FRACTURED THIGH.

Dr. Lagarde, House-Surgeon, has devised an apparatus for this purpose which differs somewhat from those now in use at other hospitals. It is described as follows: First, two blocks of wood six inches square are nailed to the edge of a firm table, one foot apart. A leather band five inches wide and thirty inches in length is stretched from the surface of one block to that of the other, and firmly nailed. This band is for the support of the small of the back, the shoulders and head being supported by pillows behind. For the purpose of counter-extension, and giving support to the pelvis, two straps, one inch in width and four feet in length, are to be nailed to the table at the inner border of each block, with a free buckle near the attachment of each. The patient now lying upon the small of the back across the broad leathern band, the two narrow straps are brought over the perineal and inguinal regions and buckled on each side. Extension is made from the middle of a horizontal bar, which has been designated as Butt's footpiece, which should be placed on the same plane with the surface of the blocks. The shoulders should be somewhat depressed from this plane. This apparatus can be made portable by arranging a support for the back, something after the fashion of an ordinary camp-stool, arranged so that it can be fastened to a table with screws. The ordinary belting leather, which is strong and soft, is best adapted for this use. It will be noticed that this apparatus has no perineal iron bar and no sacral plate, found in other apparatus devised for the same purpose. The perineal bar, besides being in the way of the adjustment of the roller bandage, has been known, from its firm pressure upon that region, to cause extensive slough and injury to the urethra. The sacral plate, unless the patient is under the influence of an anæsthetic, oftentimes causes greater pain than the fracture itself. Patients can be swung upon this apparatus for half an hour without suffering the least pain. In private practice the apparatus can be extemporized in a very short time.

TEMPERATURE TABLE.

Dr. Lagarde has also adopted a modification in the use of the ordinary table which makes the reference to the pulse and respiration record much simpler than the ordinary method. It is simply that the pulse and respiration are recorded at the angle of the wave. A single glance at the table thus arranged brings the pulse, respiration, and temperature under the eye at once.

BELLEVUE HOSPITAL.

DELIRIUM TREMENS.

What this class of patients most need is food and rest. Generally, if rest can be secured, there will be no further trouble in the management of the patients, for they will return to taking food, and in a short time the immediate effects of their debauch have passed.

Rest is usually secured by the administration of either potass. bromid. in large doses, grs. xxx. every two hours perhaps, or chloral hydrat. grs. xx. every hour. It is necessary in using the latter remedy to be cautious with regard to the size of the first doses, until the strength of the preparation and the susceptibility of the patient is fully understood. Then it may, perhaps, be given in much larger doses than indicated. Occasionally even large doses will be of no avail.

A very common prescription employed is the following:

℞. Potass. bromid..... ʒ ijss.
Chloral hydrat..... ʒ iss.
Syr. aurantii,
Aquæ āā..... ʒ ij.
M.

S. Half fluid ounce, and repeated every hour if necessary to procure sleep.

Sometimes the nausea and vomiting are so persistent that the patient cannot retain either food or medicine. These are not unfrequently distressing cases. The common method of managing such cases consists in the employment of nutritious injections and free administration of ice. Death occurs in this disease in

different ways. Some patients, who apparently are doing very well, die suddenly of syncope. Some patients lapse into a comatose condition, exhibit brown, dry tongue, feeble pulse, and death ensues.

Some patients, especially in the winter season, contract pneumonia, and when this occurs it is a grave complication, but not necessarily fatal. One important item in the management of cases of delirium tremens consists in a daily examination of the chest; for the approach of pneumonia is not infrequently very insidious, and in general it requires the attention of the physician rather than reliance upon the complaints of the patient for its early recognition.

ITEM OF TREATMENT.

An old lady, 70 years of age, was seen with œdema of lower extremities, ascites, and effusion into both pleural cavities, probably due to renal disease. She was the subject, however, of emphysema and chronic bronchitis. Pulse 84, and feeble. Diuretics, diaphoretics, and hydragogue cathartics were not regarded with favor in such a case as this, notwithstanding the patient had prominent dropsical manifestations. Dyspeptic symptoms were a leading feature of her case, and in private practice the administration of a small amount of champagne could be adopted. Tonics and stimulants should form the leading measures adopted for the removal of the fluid accumulation, rather than others mentioned. If it shall become necessary to call the assistance of other measures, diaphoresis is to be first employed, for the reason that it is thought to give less strain upon the system than either active diuretics or hydragogue cathartics. In other words, treat the general condition of such patients first, and dropsical manifestations afterwards. In many cases the former will be all that will be required.

INJURY IN THE MASTOID REGION.

An exceedingly interesting case was seen in the person of a young man, æt. 23, single, and a clerk. He was admitted to the hospital, at 3 A.M. Oct. 24th, 1873, in a state of coma. Right side completely paralyzed; complete loss of motion and sensation. There was a discharge of bloody serum from right ear. Temperature not elevated. Pulse 60. No signs of external injury. Urine negative. 10½ A.M. Sensation returned. Hemiplegia only partial. Temperature not elevated. Breathing stertorous. Consciousness almost entirely suspended. 3.30 P.M. Consciousness improved. Catheterism.

Oct. 25th. Patient has passed a very comfortable night and has taken a little coffee and milk. Catheterism. Discharge from ear diminished.

Oct. 26th. Patient more conscious still. Answers some questions, and takes some food. Discharge from ear more profuse. Catheterism. Temperature very slightly elevated. Pulse about normal.

Oct. 28th. Paralysis entirely recovered from, and sensation returning. To-day a large ecchymosis has been discovered behind the right ear, immediately over the mastoid cells.

The treatment of this case has consisted in perfect rest in bed, head elevated, and application of cold and the administration of such nourishment as the patient could be induced to take, and attention to the natural wants of the body. An interesting question in this case is, How is the hemiplegia to be accounted for? The injury and the hemiplegia were both upon the right side.

Was it due to the effect of alcohol (for the patient was out on a debauch when he fell, and has no recollection of what struck him, if he was struck), or was it due to some lesion explained upon the ground of *contre-coup*? It was believed that the latter was the most consistent explanation of the symptoms. Again, had the *contre-coup* produced laceration of brain-tissue, or had it resulted in the wounding of one of the veins going to the longitudinal sinus, and permitted a slight effusion of blood, which, associated with the concussion, had given rise to the symptoms? There was no spasm or rigidity of the muscles. These are interesting points in diagnosis, and are not altogether unimportant, especially in connection with "picked-up" cases of intoxication. The prime features of the treatment are worthy of extensive patronage.

INTERMITTENT FEVER.

It is allowable for the patient, after admission, to have one chill, in order to determine the character of his disease; but subsequent to that the occurrence of chills is not permitted. The certain arrest of the disease is looked for under the influence of what are denominated Clark's powders, which are formulated as follows:—

℞. Quiniæ sulphat.....grs. x.
Pulv. capsicum.....grs. iij.
Pulv. opii.....gr. i.

The patient receives one powder twelve hours previous to the time for the occurrence of the chill, and another about an hour previous.

The powders are continued in this manner for three or four days, and then continued every morning as long as may be desired. An important consideration affecting the continuation of the remedy is the following: It not infrequently happens that the chills return after they have been stopped, and the most common time for them to return is at the end of two weeks. Near the expiration of two weeks, therefore, it is well to return to the full-sized powders, if they have been diminished in size, and continue them in full doses for three or four days, twice a day, as at the outset. In cases which have been of long standing, and proved themselves very intractable, when the chills have been once stopped the remedy should be continued over three or four periods of return at least. By this method of treatment cases of chills and fever can be cured which have resisted all former treatment.

After the breaking of the chill the administration of iron is about as useful as the administration of quinine before. If the second chill occurs after admission to the hospital, the question, Why? is asked at once, and search made for the answer.

ECZEMA CAPITIS.

Cure it if possible, notwithstanding the somewhat prevalent idea to the contrary. The method of procedure recommended is as follows:

First, apply a poultice every night until all the scabs are removed. The ulcerations, which are sometimes present after the scabs have been removed, are best cured by the application of a wash made of nitrate of silver grs. v. to the ℥i. of water. The following is then used with good success:

℞. Aquæ Cologn..... ℥iv.
Glycerine..... ij.
Carbolic acid crystals..... i.
Borax..... i.
M.

Continue the application of this remedy for some time for the purpose of curing the eczema.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE AND SURGERY.

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, December 1, 1873.

HOSPITAL APPOINTMENTS.

We believe that it is pretty generally understood that it is very difficult to get any hospital appointment in this city. The colleges have had the reputation of controlling positions on the medical staffs, and we believe they have fairly and honestly earned it. Every medical man appreciates the necessity of clinical teaching in connection with didactic instruction, and on general principles no objection can be made against medical professors holding hospital appointments, and making use of them for the benefit of their pupils. There are many reasons why these gentlemen should enjoy these special facilities, reasons which would not hold good with men whose object is not to let their light shine. The objection has always been, however, that there has been a little too much of the grasping principle among these teachers to impress the professional public with their disinterestedness in anything save the cause of clinical teaching *per se*.

We have taken some little pains to collect some statistics concerning hospital appointments in this city, which it will not be uninteresting to analyze, in the hope of explaining some of the reasons why. There are eighty-one gentlemen, physicians and surgeons, who hold good appointments in our different hospitals. In this number we only include such as are in active duty, such as are supposed to visit the wards as attending physicians or surgeons, the consulting staffs being omitted. Of these eighty-one gentlemen forty-three are professors or instructors in our medical schools, and are very evenly distributed throughout the different charities. In fact it would seem to prove that the schools had compromised the matter so thoroughly that no special advantages would be taken one over the other, the aim of each being to keep its quota in hospital position at all hazards, and irrespective of outside influences. Eighteen gentlemen of the eighty-one hold two hospital appointments each, and all of these, save three, are teachers in our medical schools. This certainly speaks well for the appreciation of facilities for clinical study on the part of our medical professors. We are happy to say that we can find but two gentlemen who occupy three positions each. In this estimation of the number of positions we leave out altogether those of the New York Hospital, the said institution having departed from the sphere of its former usefulness four years ago. If we had taken these appointments into account we should have had more double ones to add to the list. As it is, the only evidence of the existence of any staff at all for this defunct institution, is the yearly publication of the names of its members in the *Medical Register*.

It is always more or less interesting, in alluding to enviable positions occupied by our fellows, to speculate upon the chances which have secured them. Those who have been defeated in a struggle for any position always find consolation in the thought that merit is not always successful, that favoritism and influence are the best explanations of good fortune. Let us see how their rule will work in reference to our hospital appointments. In the first place, there are forty-three appointments confined to the schools. It is but just to say that many of these are due to merit, but special school influence has so much to do with obtaining them that individual merit is completely overshadowed by expediency. Then again we know that school positions go a great deal by influence and favor, and of themselves are no real criterion of individual worth or individual fitness for such positions. Although this rule has many exceptions, where merit is the controlling element from beginning to end, still it is, nevertheless, a general one, admitting of the general interpretation that the fact of being a member of a faculty is of primary consideration.

To prove this we will give our readers an instance. When the staff of a recently organized hospital was made up by a college faculty, several worthy applicants were informed that they could not hope to be successful, for the simple reason that they did not belong to the said school, or were not avowedly pledged to its interests. This certainly does not look as if absolute merit was the controlling element of such appointments.

In regard to the matter of influence, unconnected with schools, we find that forty appointments have been secured. Of this number there are only fourteen gentlemen concerning whom it can be said that pure professional merit was the only explanation of their appointment. We are ready to prove this statement on the ground of a pretty thorough acquaintance with the circumstances attending the appointment of all the gentlemen holding hospital positions, and of the professional work which each and all have done to merit them.

And, after all, it is a matter for congratulation that in the great struggle for these appointments a few can obtain them irrespective of any school or political influence, and by sheer and simple fitness for the position. The purely meritorious man has some hope when he applies, provided the vacancies sought be not desired by some one of the medical schools. There are at least three hundred medical men in this city who are thoroughly capable of occupying these positions, and of these we can safely say that one-third are anxious to secure them. The applications compared with the places to be filled are two to one, and yet we find that there are eighteen gentlemen who occupy two places each, and two who occupy three. Their excuse for so doing cannot certainly be that none can be found to divide responsibilities with them. If there be any doubt in their minds on this score, they have but to vacate one of their positions and clear their consciences.

THE AMERICAN PUBLIC HEALTH ASSOCIATION.

THE meeting of the American Public Health Association, which was held in this city on Nov. 11, 12, 13, was a singular and gratifying success. The papers read were, without exception, models of their sort, and were written by practical hygienists for the purpose of gaining the public ear upon the great questions which lie at the very foundation of healthful existence. The subjects were exceedingly well chosen, and there was a harmony and dignity in the discussions which not only reflected credit upon the distinguished gentlemen who took part in them, but afforded an example of what a few earnest professional men can accomplish who assemble for the purpose of seeking and developing scientific truth. We were pleased to see many of the papers which were of special interest to the public, which appealed to their understanding, so fully reported in the daily papers. We believe in educating the people, and this Association can do a great deal in this direction. Many of the subjects presented were also of great importance to the profession, in way of suggesting the proper channels for the exercise of influence individually and collectively, towards perfecting and generalizing systems of sanitary reform and hygienic regulations. We propose to remark upon some of these topics at length at some future period.

THE BOGUS DIPLOMA TRAFFIC.

THE bogus diploma institution in Philadelphia is likely to have a chance to vindicate what the faculty please to call their "fair fame." Mayor Stokely of that city has been informed that the State Supreme Court has issued a writ of *quo warranto* against the said institution, returnable at the next session of the court in that city. Of course the President, Dean, and others of the "university" are anxious for an investigation, but we imagine that they are not quite so clamorous for the justice that may follow. The law, however, gives the greatest swindlers a chance for escape.

ACCIDENTAL POISONING.

EVERY little while we hear of a death from accidental poisoning, and are impressed with the necessity of guarding against similar mishaps in future. Not long ago we reported the case of the death of a physician from carbolic acid, taken by mistake for whiskey; and quite recently another physician in Dutchess Co., N. Y., has died from a dose of aconite, under very similar circumstances. In both instances the bottles containing the poison were very like those containing the articles for which the said poison was mistaken. This, in fact, appears to be the explanation for most of these accidents, and is the easiest method to insure them. The remedy suggests itself to any one who will give the matter a moment's thought, and that is, to have the bottles for poison so peculiarly constructed as to render mistake impossible, even in the darkest night. There is a particular kind of bottle made by one of the glass companies of this city which answers every such purpose. The glass is blown in such a way as that the outside of the bottle is raised at short distances in diamonds, which can be felt the moment the vessel is grasped. In our opinion, this kind of glassware should be in universal use for containing poisons, as affording the surest prevention for the most melancholy of accidents.

Another cause for accidental poisoning is the want of proper labels upon bottles containing medicine; and when we consider how careless physicians who carry their own medicines generally are, the wonder is that mistakes do not more frequently occur. The rule should be with physicians and every one else, never to use any bottle without a label, in fact not have any such in their possession.

PRIVATE MEDICAL CLASSES.

THE so-called "quiz class" system connected with our medical colleges is growing more and more in favor. This is as it should be; supplementing as it does in so effective a manner the regular course of lectures. We believe that the time is not far distant when the professors themselves shall see the necessity of incorporating the plan in the curriculum.

Reviews and Notices of Books.

THE DISEASES OF THE PROSTATE, THEIR PATHOLOGY AND TREATMENT; COMPRISING THE JACKSONIAN PRIZE ESSAY FOR THE YEAR 1860. By Sir HENRY THOMPSON, F.R.C.S., etc. Fourth Edition. 8vo, pp. 355. Philadelphia: Henry C. Lea. 1873.

IN its present fourth edition, the above well-known work still maintains its reputation as the standard monograph on diseases of the prostate. The few changes and additions made from the third edition are mainly of a practical character; and, as stated in the preface, "the existing material has been compressed so

much as somewhat to reduce the size of the volume, and at the same time to increase its utility. The following is a short summary of the most important parts of the work :—

The first and second chapters are devoted to the elaborate consideration of the topographical and structural anatomy of the prostate; size, weight, position, measurements, "with facts relating to the morbid condition of the organ," embodied in a tabular review of 194 dissections; its lobes, in regard to which, to the author belongs the credit of having first prominently dispelled the idea of the "median portion" being an isolated or third lobe; the analogy of the prostate to the uterus, and its minute anatomy.

The third chapter treats of the acute and chronic inflammation of the organ. In the treatment of acute prostatitis, besides general antiphlogistic regimen, the author favors the application of leeches to the anus and the use of the warm hip-bath. The patient should be allowed to remain in the latter, at a temperature of 100–5°, for a period not exceeding six or eight minutes, not in order to induce a flow of blood to the pelvic viscera, but to expand and fill the vessels of the skin by a smart impression upon it, thus producing a temporary congestion of the surface, with the result of relieving the deeper parts. In case of suppuration, the discharge of the abscess, either spontaneously or by operation, *per rectum*, is less favorable in its results than by an incision in the perineum made at as early a period as fluctuation is detected; when the swelling is so considerable as to cause retention of urine, the necessary passing of a catheter will often cause the discharge of pus. The author recognizes three causes of chronic prostatitis: 1st, Morbid persistence of unhealthy action after an acute attack; 2d, a long and tedious resolution; 3d, the condition may commence in the chronic form, being either primary or dependent on disease of some neighboring organ. Here, as also in the chapter on hypertrophy, the author cautions against the frequent diagnostic error of confounding the enlargement of chronic prostatitis with hypertrophy. In the treatment of chronic prostatitis, the author now always employs counter-irritation at the surface of the perineum by the acetum cantharidis, at the same time improving the general condition of the patient by the use of iron, quinine, and nux vomica. When chronic inflammation of the organ gives rise to nocturnal emissions, the contact of a foreign body ordinarily increases the existing irritation, and the application of nitrate of silver in solution, grs. v.–x. ad ℥, is preferable.

The subjects of hypertrophy of the prostate and tumors are discussed in the fifth and six chapters. The former is divided into four varieties: 1st, Simple increased development of all the component tissues of the organ in about equal ratio; 2d, excess of development of the stromal over the glandular portion; 3d, excess of development in the glandular over the stromal portion; 4th, rearrangement of the structures, stromal and glandular, in the form of tumors. In considering the etiology of enlarged prostate, a distinction must be made between the enlargement occurring in young and in old men. "In youth the organ becomes enlarged by interstitial plastic effusion, the result of inflammatory action. In old age, there is an unnatural development of the prostatic tissue itself. A prostate, therefore, which has been enlarged by inflammatory effusion, is probably less likely subsequently to exhibit an hypertrophic tendency; nutrition is impeded, not encouraged." Hypertrophy is attributed to necessity of structure, all other causes which have been assigned being untenable. "The prostate, finding its analogue in the uterus, is, like this, prone to the formation of tumors in its substance." In regard to the frequency of enlarged prostate, the author regards it rather as an exceptional change than as an invariable occurrence, "it being highly probable that a slight tendency thereto, almost if not quite unrecognizable during life, may occur in about one out of three individuals after sixty years, and that a marked enlargement may not be met with in one out of seven or eight at that age and upwards." The differentiation of retention, "*engorgement*," and overflow are dwelt upon at considerable length in Chapter IX. In regard to treatment directed to the enlargement of the organ itself, all operative and mechanical interference, hitherto employed, is condemned, as the slight temporary benefit attained does not compensate for the consequent irritation. The treatment must be palliative, directed to allaying the derangements of the bladder, such as chronic cystitis, atony, irritability, incontinence, and hemorrhage; directions for the relief of these are very fully given, and the author concludes, "no therapeutical agent is known which has the power of reducing an actual *hypertrophy* of the prostate." After reviewing the different plans for overcoming the obstructing bar at the neck of the bladder, the author does not think himself justified in recommending any of them, believing that the condition of patients so afflicted can be much ameliorated by proper care and management.

The chapters on cancer, tubercular disease, and atrophy are as fully considered as the comparative rarity of these diseases admits. The concluding chapters of the work, on prostatic concretions and the relations between hypertrophied prostate and stone in the bladder, are modified in accordance with the author's latest views in his work on "Lithotomy and Lithotrity." The book is handsomely illustrated by twelve lithographs of the normal and morbid anatomy of the organ, and several woodcuts.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Nov. 6, 1873.

DR. AUSTIN FLINT, PRESIDENT, in the Chair.

INTRA-RECTO-ABDOMINAL EXPLORATION.

THE first paper for the evening was read by Dr. Charles A. Leale, entitled "Intra-recto-abdominal Manual Exploration."

The speaker first called attention to the important assistance which this means of examination may give in diagnosticating various conditions of the viscera found in the lower portion of the abdominal cavity, such as are immediately connected with the bladder, uterus, ovaries, and even as high up as the kidneys, stomach and liver, and spleen. The method of procedure was described as follows: The patient upon whom the operation was performed, was already perfectly relaxed, having swallowed a poisonous dose of chloroform. The hand and arm were well smeared with some lubricating substance, the hand, closely folded into a cone shape, was carefully passed through the sphincter ani, and then a moment's pause was made; the hand was carried on until it reached the sigmoid flexure of the colon, when it was partially turned upon itself, permitting the back of the hand to look towards the concavity of the flexure, and then permitted to

pass through the flexure, when another pause was made; from this point the hand was carried along the colon until it reached a point four inches above the umbilicus, then being sixteen inches from the anus, as measured upon the arm. While in this position the fingers could be distinctly felt through the abdominal walls, and were readily recognized by an assistant. As the hand was being withdrawn, an exploration was made of some of the pelvic organs, although this was not the object which gave rise to the introduction of the hand, as will be seen further along. The patient was a sufferer from dysmenorrhœa. The uterus was found displaced, and could be as easily grasped and examined as if being examined through an opening made in the walls of the abdomen. An interstitial fibroid was also recognized upon its surface. The ovaries were grasped and the bladder recognized. The hand was then withdrawn without being stained in the least by blood. The greatest dilatation of the anus was ten inches in circumference, corresponding to the size of the forearm.

The operation was performed substantially as described by Prof. Simon, of Heidelberg, to whom is due the great advance which this method of exploration has made within a few years past. A brief history of the case in which the operation was performed by Dr. Leale, and the reason for performing it, is as follows:—

Mrs. H., æt. 45, drank two ounces of pure chloroform for a suicidal purpose. As soon as the Dr. arrived, an emetic of salt and water was immediately administered, and which almost as immediately produced free emesis. No odor of chloroform was detected from the contents of the stomach. Strong odor of chloroform was recognized in the breath, showing that the chloroform had been entirely absorbed, and was being eliminated rapidly by the lungs. The stomach was washed out in addition to the emesis. The patient remaining insensible, and giving unmistakable evidences that death from asthenia was rapidly approaching, it was determined to pass the hand into the abdominal cavity, and irritate the solar plexus of nerves with the hope that respiration might be sufficiently aroused to carry the woman over the extreme point of danger. The result of the operation certainly justified its performance; for simultaneously with the irritation of the root of the diaphragmatic plexus of nerves the respiratory act became more vigorous, was soon followed by returning consciousness, and the patient was saved from a fatal narcotism.

Three days after the operation the woman was again at work, the sphincter retained the fæces in a normal manner, there was no gastritis, and recovery was made without an unpleasant symptom, save a sharp headache which lasted for a few days.

Irritation of the solar plexus of nerves in this case was suggested by the results obtained, in a case of like character, from the use of electricity over the region of the solar plexus for the purpose of increasing the force of the respiration. In that instance the patient was restored from impending death by the use of artificial respiration, and the application of electricity as referred to.

Dr. Benjamin Howard commented upon Dr. Leale's paper substantially as follows: I feel hardly able to share the enthusiasm expressed by the author of the paper respecting the employment of internal abdominal explorations in the diagnosis of pathological conditions within that cavity. I am of the opinion that there is a debit and credit side to the question.

From this point the doctor very pleasantly illustrated his ideas by drawings upon the blackboard.

In the first place, with regard to its value as a means of resuscitation. Although Dr. Leale has fortified his case by the results obtained, I am not sure but that the same results might have been obtained by striking sharply upon the epigastrium, where we can come into very close proximity with the solar plexus, and produce marked effects by blows. I am of the opinion that, although admissible, the use of both electricity and internal abdominal exploration, for the purpose of irritating the solar plexus of nerves as a means of resuscitation, should only be employed as a *dernier ressort*, and for the reason that less formidable and equally efficient means can be obtained by externally slapping the epigastric region.

The Doctor mentioned some precautions to be taken in the performance of the operation, to which the author of the paper did not make special reference. The use of an anæsthetic is always required to render the operation possible. The anus should be fully dilated, by making firm traction with the fingers inserted into it, and making traction in opposite directions. As soon as the promontory of the sacrum is reached, the hand should be gently turned, bringing the back of the hand uppermost, to facilitate its passage through the sigmoid flexure.

With regard to the value of this method as a means of diagnosis of stone in the bladder: When the bladder is full, a calculus lying in the *trigone vesicæ* may be raised upon the ends of the fingers, and it would seem as if it could be grasped in the hand, but that cannot be done. The space is so small, and so much tissue intervenes between the hand and the stone, that it is impossible to seize it. Some idea of the weight of the stone may be derived by this method, and that is all.

I am of the opinion that this method of examination promises to be an exceedingly valuable one in the diagnosis of tumors of the uterus, ovarian tumors, displacements of the uterus, etc. By this means much can be learned of the density and connections of tumors existing in the pelvic cavity. That which would most justify this method of examination, is the existence of a stricture, especially when it occurs at the sigmoid flexure of the colon. The stricture can be much more advantageously reached with the fingers than with a bougie, and some estimation can be made of its character and extent, which can scarcely be derived by any other means than the touch.

So much for the advantages attending its use. There is, however, a debit side of the question. In some cases, where the hand has been introduced with apparent success, and the amount of dilatation has been very moderate, a good deal of difficulty in controlling the fæces has followed. In those cases where it is most justifiable it may do the most harm, perhaps. There is great liability, in case of stricture of the intestine, of having ulcers just before or just beyond the stricture, and the violence necessary for the introduction of the hand into the bowel may be sufficient to convert the ulceration into a perforation, and with this comes collapse and death. Such cases have already been recorded in *The Lancet*, and should have an influence upon the employment of the method of examination. Too much should not be expected from its adoption, and it should be resorted to only in exceptional cases, and perhaps only as a *dernier ressort*.

Dr. Peaslee would place a check upon the indiscriminate use of this method of exploration. It can be employed with benefit in certain cases, in which abortion has habitually occurred in consequence of displacement of the uterus backward. If resorted to for this purpose it is probably well to wait until the

pregnancy has advanced to four months, and it should not be longer postponed for reasons which are evident. If practised earlier than this, the uterus will immediately fall back, and no benefit will be derived.

The use of this method in gynæcology is very important, and so long as the hand is kept within the pelvis, no harm can well be done; but as soon as the hand passes above, there is a liability to do injury which corresponds to the size of the hand and the size of the intestine.

In some cases the curves of the intestine are such that it is impossible to pass beyond them without lacerating the gut. Its chief use should be restricted to exploration in connection with diseases within the pelvis. The bowels should be thoroughly emptied before the operation; and when high exploration is resorted to, throwing a stream of warm water alongside of the arm, by means of a long-nozzled syringe, will materially facilitate its passage. The operation, in general, should be employed only in exceptional cases.

It is justifiable when a differential diagnosis is to be made between a fibroid cyst of the uterus and an ovarian tumor, or whether the tumor is an ovarian tumor or a tumor which comes from above, such as an enlarged kidney or liver. Still it should not be resorted to, only when other means have failed in arriving at a diagnosis. As a rule, the loss of power in controlling the passage of the fæces lasts only for a few days; yet this is one reason against an indiscriminate use of the method.

Dr. Leale was of the opinion that, with a very pendulous abdomen, such as his patient had, irritation of the solar plexus could not be as satisfactorily accomplished by external measures as by internal.

CHOLESTERÆMIA.

The second paper for the evening was read by Prof. Austin Flint, jr., upon the subject of "Cholesteræmia." The author of the paper gave an interesting and somewhat exhaustive *résumé* of the experiments which he had performed with the view of determining the nature, origin, and termination of cholesterine in the human body, the results of which experiments he brought prominently before the profession in the year 1862. Although the views presented by the author of the paper in 1862 have passed comparatively unnoticed in this country and England up to the present time, they have received some attention in France and Germany, and within a few years some experiments have been performed in Germany which have led the author to believe that his own experiments possessed some scientific importance. "It is well known," says the author of the paper, that "there are two classes of diseases widely differing in their gravity. In the first place there is the ordinary attack of jaundice, which is not very severe, not very dangerous, is relieved by some simple remedy, or relieves itself after a very few days. But there are other cases of jaundice, in which the icterus is not more intense, may be even less intense, than in these moderate cases, but which are characterized from the very beginning by very grave symptoms, referable to the nervous system, and almost invariably terminate in death.

In occasional cases of cirrhosis of the liver, there are manifested grave disturbances, referable to the nervous system, with more than an ordinarily severe sequence from the pathological lesion existing in the organ.

An effort has been made to explain the pathology of such striking cases by supposing that some of the constituents of the bile have been retained in the blood, which should have been eliminated; but physiological experiment has never verified the supposition. The reason why the biliary salts have not been found in the blood is because they are not secreted. "The distinction between secretion and excretion is almost absolute. The elements of secretion do not pre-exist in the blood, but are manufactured in the substance of glands out of materials furnished by the blood; that their flow, as a rule, is when there is necessity for their function; that when the function of the gland is interfered with the materials do not accumulate in the blood. The elements of excretion always pre-exist in the blood; they are never manufactured by special organs, but are the result of the general processes of disassimilation; they are not manufactured by glands, but separated from the blood by glands, and when the function of excreting organs is interfered with, an accumulation of the elements occurs in the blood and produces a toxæmic effect."

The Professor then gave a somewhat extended but interesting account of the experiments which he had performed to demonstrate that cholesterine is always found in the blood, is always found in the nervous tissue, and is always found in the bile.

It has been found by his experiments that the blood gains something over twenty-three per cent. of cholesterine while passing through the brain, and loses cholesterine in very near the same proportion while passing through the liver.

It has also been found that, in cases of hemiplegia of some standing, the blood taken from the affected side contained *no* cholesterine, while upon the unaffected side it was found as in normal blood. These experiments proved that cholesterine is formed in nervous tissue, is eliminated by the liver, and is therefore placed among the excrementitious substances, and its disappearance from the body is under the form of stercorine.

"If it be true," says the Professor, "that it is an excrementitious substance, we should expect that if the liver becomes disorganized, so that it cannot be eliminated, the term cholesteræmia would be justified in science."

The result of examination in a grave case of jaundice, accompanied by serious nervous disturbances, such as stupor, coma, and convulsions, showed extensive structural disease of the liver, and the quantity of cholesterine increased to three times the quantity found in the blood in a case of simple jaundice.

Over 50 per cent. above the average amount of cholesterine has been found in the blood of a patient who died of cirrhosis of the liver, attended by grave nervous disturbances. Finally, the views of the author of the paper are summed up in the following:—

"Cholesterine is an excrementitious substance, produced chiefly by disassimilation or physiological wear of brain and nervous tissue, is taken up by the blood and carried to a special organ for its elimination, and that organ is the liver. In the liver it is separated from the blood, and finds its way into the bile discharged into the small intestines, and there changed into stercorine, which is discharged from the body at about the rate of ten grains each twenty-four hours. In certain cases of disease of the liver, accompanied by grave nervous symptoms, there is an accumulation of the cholesterine in the blood, giving rise to the condition which has been called cholesteræmia."

The present paper was called out by the report of some experiments which have lately been performed by an eminent German professor in Leipsic, by injecting cholesterine into the circulation of animals. The results which have been produced will warrant the conclusion, apparently satisfactory at least, that

those symptoms which accompany severe jaundice, and are not unfrequently seen in connection with many diseases of the liver, are the manifestations produced by an abnormal accumulation of cholesterine in the blood, which conditions have been improperly recognized under names such as cholæmia and others.

Dr. Barker made the following remarks and suggestions upon the paper read by Prof. Flint: I wish to call attention to certain practical bearings the discovery possesses. There are certain conditions which every man is familiar with, and which are characterized by a well-known mental sluggishness and general torpor of the system, that yield at once to what is termed a free bilious evacuation from the bowels. Bilious attacks, bilious headaches, etc., are the terms commonly applied to such conditions. Now it seems to me the paper upon cholesteræmia proved that, through the medium of the liver, there is eliminated from the system an effete *débris* of nerve-tissue, and that the failure in elimination of this material gives rise to those phenomena called "biliousness;" and by the action of proper remedies the effects of this retained element are caused to pass away. One of my patients, an eminent lawyer, was in the habit, for many years, when he was called upon to make a strong mental effort, of taking ten grains of blue-pill, and following it with a bottle of congress water, a few hours before entering upon his labor.

Physiologists have been long accustomed to recognize a certain form of disease, called cholæmia, by the presence of bile in the blood. The culmination of the disease consists in three classes of phenomena: first, those which are referred to the nervous system, such as delirium, convulsions, and sometimes coma; second, those which are referable to the nutritive system, resulting in typhoid symptoms; and, third, a class of phenomena referable especially to the circulatory system, the mucous membranes, and the kidneys, resulting in hemorrhages from the mucous membranes, etc., etc. There are also cases of so-called melæna, which are attended with great disturbance of the nervous system; and the thought has been brought to my mind many times, may not some of the phenomena which have heretofore been classed under the head of bile-poisoning be due to the presence of cholesterine in the blood?

In my own special department I have seen a few cases in which the symptomatic phenomena finally culminated in convulsions, dependent upon the condition of the liver, as I believed, and not upon the condition of the kidneys.

From my experience in connection with some of these cases I am convinced that there is a certain class of cases which are dependent upon cholesteræmia rather than upon uræmia, in which convulsions were developed; and in accordance with that belief I have directed my treatment towards the liver, and have witnessed the most gratifying results.

I simply throw out these hints, which are of a practical nature, and may be of service in the consideration of the paper to which we have listened.

[The practical application of the theory set forth in the paper is to be made the subject for discussion at some future meeting of the Academy.]

Prof. Denning, of Columbus, O., was introduced to the Academy, and stated that in the year 1842 he introduced his hand into the rectum of a man 48 years of age, in search of a supposed stricture. No unpleasant effects followed the operation, and the man was able to retain the contents of the bowel without difficulty.

JOURNAL AND LIBRARY ASSOCIATION.

Regular Meeting, Nov. 7th, 1873.

Dr. Peters, President, in the Chair.

THE USE OF WARM WATER IN SURGERY.

The paper for the evening was read by Dr. Frank H. Hamilton, on "The Use of Warm Water in Surgery." It consisted principally in the recital of cases which have been treated with warm-water dressings in the service of Dr. Hamilton, at the various hospitals with which he is connected either as visiting or consulting surgeon.

The use of warm water as a surgical dressing is nothing new; but from time to time, as it has become popular, it has lost its popularity and fallen into disuse. But the Dr.'s late experience has led him to the belief that better results can be obtained by the use of warm water as a surgical dressing than by the use of cold water.

Formerly irrigation was regarded as the most useful method, and the use of water at about a temperature of 60°; but the results obtained in the cases lately under observation has taught that submersion is better than irrigation, and that the temperature most desirable to be secured is from 90° to 98° F.

The number of cases whose histories were given was ten, and embraced a great variety of injuries and diseases which demand surgical interference. The results obtained by the use of the warm-water dressing in these cases was uniformly good, and it was the uniform good results which gave rise to the belief that it constituted one of the most valuable surgical dressings within our reach. There was no distinct inflammatory reaction in any case. The most reliable effects appear to have been obtained by employing submersion at a temperature of about 90° F.

In some cases it was impossible, either from the condition of the patient or from surrounding circumstances, to employ submersion. In such cases water fomentations were employed by means of compresses covered with cotton and oil-silk, and these are only second in value to the submersions. Both are regarded as being superior to irrigation. In most cases where submersion was employed the limb became considerably œdematous, and in some cases extremely so. This would excite alarm perhaps in the mind of one not accustomed to see such developments; but in no case has any injurious results attended its occurrence. Fomentations do not dispose the limb so much to œdema. When irrigation is employed there is no tendency to œdema, but inflammatory reactions are very liable to occur and continue.

In no case where the bath or fomentations were employed did erysipelatous inflammation occur, nor has gangrene extended beyond the parts actually destroyed by the accident, nor pyæmia, nor septicæmia, nor the accumulation of pus or the formation of sinuses taken place except in one case. In one case gangrene had set in, but was speedily arrested by raising the temperature of the water to somewhat above 90°, it having been permitted, through carelessness, to fall considerably below that point.

The first three cases were cases of excision of the great-toe joint, in which the wounds left by the operation were large.—Bath 14 days.

The fourth case was one of resection of the elbow-joint. The joint was exposed and all the tissues found filled and dripping with pus. The limb at the time of operation was enormously swollen.—Bath 14 days, and fomentations subsequently.

The fifth case was a contused wound of leg. The

limb was almost completely smashed. Fomentations chiefly for 30 days. The ankle-joint was exposed.

The sixth case was a lacerated and contused wound of the foot. The bones were considerably broken, and the bottom of the foot extensively lacerated. This was the case in which gangrene made its appearance, but was arrested by raising the temperature of the bath.—Bath 16 days, and subsequently fomentations.

The seventh case was one of necrosis of humerus. Fomentations were employed. The case is doing well.

The eighth case was one of lacerated wound and fracture of leg. The laceration of soft parts was extensive. This patient was treated for three or four days by the application of oakum and a roller bandage. When first seen at the hospital his condition was such as to forbid amputation. The limb was enormously swollen, and appearances indicated that the patient would probably lose his life. Fomentations of warm water were employed, and continued two weeks, when the condition of the patient was such that the bath could be substituted, and that was continued for five weeks, and then return was made to the fomentations. The man was wounded in Aug., 1873, and Nov. 1, 1873, the wound was closed.

The ninth case was an injury of the foot in which the bones and flesh were broken and crushed by the falling of a heavy weight upon it. The third day the condition of the limb was such as ordinarily demands amputation. It was at once submersed in water at a temperature of 90° F. The gangrene was at once arrested, and the man made a good recovery.

The tenth case was one in which the leg had been traversed by a street-car. The patient was in excellent health at the time of the occurrence of the accident. At the end of thirty-six hours after the accident the limb was enormously swollen, fracture of both bones was found, but there was no laceration of the soft parts. Inflammatory action had set in before the patient was reached, and immediate amputation was not warranted. Fomentations were applied and changed hourly. Vitality in the limb diminished, and gangrene set in. The gangrene implicated all the parts injured, but *did not extend above* the line at which the car-wheel traversed the limb. Amputation was performed in imitation of Esmark's method, and the loss of blood was very slight. The water-dressings were continued, and the case is doing well.

Dr. Rose remarked that, in his experience with water-dressings in surgery, he had found a temperature of 60° uncomfortable to the patient, but that a temperature of 86° or 90° can be very comfortably borne. The benefit of this treatment may be especially seen in those cases where it is difficult to determine whether amputation should be performed or not. Place the limb in a warm-water bath, and the question of amputation may be fully considered before it is performed.

Reference was made to the Report of Billroth, who gives 277 cases of injuries of the hand treated in this manner, and only three cases of pyæmia were developed. The action attending the slight lowering of the temperature, such as obtained by a water-bath at 90°, is more powerful than even the application of ice-bags. According to his experience, the warm-water dressings had prevented both local and general reaction after injuries. In some cases, where suppuration is nearly established, these dressings may prove injurious. Granulations may be caused to swell and obstruct the free discharge of pus, inasmuch as pus is not itself soluble in water. According to his experience the average length of time that submersion is employed is fourteen days. During the first twenty-four hours after the removal of the part from the bath, both local and general temperature will be considerably increased, and this will usually last for some days. This again is evidence of the power that the warm-water baths or fomentations have on the reduction of temperature.

Dr. Weber mentioned three cases of warm-water dressings, as illustrative of his experience in its use, which substantially sustained the views already expressed by Drs. Hamilton and Rose. The temperature which he commonly employed was about 90° F.

Dr. Sell referred to the uniformly bad results attending the use of hot poultices at the siege of Paris, and desired some explanation upon that point, inasmuch as we have been led to regard the application of water in the manner of fomentations as nothing more nor less than a poultice.

Dr. Rose suggested that the water-dressing prevented the occurrence of certain foments which would cause a great deal of reaction. The hot poultice is ordinarily constituted of material which would contribute largely to the production of fomentation, hence the great disadvantage attending its use.

Dr. Howard remarked that he had treated many thousands of cases by the use of cold-water dressings, and it would be very natural for him to contrast the cold-water treatment with the warm-water treatment. Regarding cold water, it will be admitted by all that it has a vast diversity of uses and effects. It may be very highly valuable, or it may be as full of danger.

In military surgery the patient ordinarily has been cut down in full strength, and there is present every ability for reaction and over-reaction. The danger is usually from over-reaction. Under such circumstances the cold water may be used very freely, and, as a rule, it is the best dressing. On the contrary, when the patient is in a low condition constitutionally, and when the wound is in the lower extremities, where we have in addition perhaps a low local vitality, then the application of cold water, especially if long continued, would do much harm. Adhesion by first intention may be absolutely prevented by the application of cold water under such circumstances.

The irregular application of cold water has induced tetanus, and may favor the development of other surgical diseases. Such he believed to be the fact, and the opinion was based more especially upon his experience at the battle of Antietam, where a great amount of tetanus was seen. It is therefore seen that cold water is beneficial in certain cases, and in other cases may be very injurious.

In the use of warm water, we may start by assuming that it is usually beneficial, and, perhaps, in no case is it dangerous, or no case can be related where it has been followed by bad results produced by itself.

The valuation of warm water may be considered under three heads: First, the maintenance of an equable and proper temperature of the part; second, the complete exclusion of all animalculæ; third, continued immersion of the parts.

The value of the warm water over the cold water, upon the first point, is this: the cold water, if too cold, may lower the vitality of the part too much, and, if continued too long, may do serious injury.

Warm water, on the contrary, will abstract an undue local heat without reducing the vital heat lower than may be desirable. However long continued, if the proper temperature is observed, there can no harm come from the reduction of the temperature of the part. It will completely exclude animalculæ, and by continued immersion it promotes continued capillary circulation.

In closing, the Doctor threw out two questions: What is the cause of the œdema which occurs in every case? Is there any osmosis in the case? Next, What is the action which promotes capillary circulation? Fortunately, there is one principle to guide us in the continuance of either cold or warm water. If *pain* is produced, it is evidence that a change should be made, and the change from cold to warm is the most common.

Dr. Jacobi wished simply to refer to the fact that the indications for cold or warm water will vary according to the individual. Cold-water bathing is especially beneficial to those who have a vigorous constitution and a high degree of reaction, and it is well known that other individuals will derive the same benefit from the use of the warm bath. The difference consists simply in the fact that there is a more vigorous circulation in the one than in the other, and the same effect will be obtained in both cases. The same principle may be applied to the treatment of wounds. There is one point which might have been settled more positively, and that is that ice-cold water applications should be contrasted with hot-water applications; cold-water bathing with warm-water bathing, etc., if we would form a proper estimate of their comparative value. The idea of constitutional peculiarity might be carried still farther, and the same principle be applied with regard to cold or warm air. Different persons in the same pathological condition may be favorably affected, the one by being exposed to cold air, and the other by being exposed to the influence of warm air. The study of the constitutional peculiarities of each patient should enter into the treatment of every case.

Dr. Grant dissented from the opinion expressed by Dr. Howard with regard to the development of tetanus.

Dr. Howard replied that he saw fourteen cases in one hospital where the wounds were dressed with extra-cold water, and threw out the suggestion thinking that there might be some value in it.

Dr. Caro referred to the treatment of old ulcers, in his service, in the years 1844 and 1845, in *Sicily*. Cold water was the chief application, and in the obstinate ones immersion of the part was attended with the greatest success. It was thought at the time that the success of the treatment depended materially upon the exclusion of animalculæ from the surface of the ulcer.

Mrs. Dr. Jacobi presented a single question, and that was, Whether the œdema spoken of as being present in every case, was not due largely to an exosmosis of the fluids from the distended blood-vessels, and whether that action does not prevent the accumulation of white blood-globules, which is the cause of suppuration?

Dr. Hamilton replied that it would be exceedingly rational to suppose so. When the limbs are in the baths they are always dependent, and the question has arisen whether the dependence of the limb would not explain the success of the treatment; but the success of the treatment is altogether out of proportion to be the mere result of dependence.

Dr. Hamilton mentioned that the application of cold on the army was essentially a warm-water application, for the cloth, although applied cold, is not changed, perhaps, for several hours, and becomes thoroughly heated.

Dr. J. G. Adams.—At a quarterly meeting of the trustees of the College of Physicians and Surgeons, held on the 11th instant, Dr. John G. Adams was elected trustee, in place of John Torrey, M.D., LL.D., deceased.

Medical Items and News.

The Academy of Medicine.—The twenty-sixth anniversary of the founding of the New York Academy of Medicine was duly celebrated on Thursday evening, Nov. 20. The annual address, on "Parasitic Growths," was delivered in the hall of the College of Physicians and Surgeons, corner of Twenty third street and Fourth avenue, by Dr. John C. Dalton, after which the members repaired to the Ashland House to partake of a supper.

The toasts were as follows:—

"New York Academy of Medicine—*Una fides altare commune*—gathered on this twenty-sixth anniversary, its Fellows renew their expression of veneration of the wisdom of its founders, and renew their pledges to maintain the noble purposes for which it was designed." Responded to by President Flint.

"Divinity, Law, and Physic, triplets nurtured by Faith, animated by Hope, inspired by Charity." Responded to by Dr. Post for the clergy, Edgar S. Van Winkle for the Bar, and Dr. A. M. Bell, of Brooklyn, for the physicians.

"The Building Fund." Responded to by Dr. James Anderson.

The festivities closed shortly before midnight.

The American Public Health Association convened in New York on Tuesday, November 11, 1873, in accordance with the adjournment of the annual meeting. The following papers, which, without exception, were of great interest to the general public, were read in the course of the three days' session.

The meetings were held in the hall of the Union League Club, Madison avenue, corner of East Twenty-sixth street.

Tuesday, November 11.—Address by the President, Dr. Stephen Smith, N. Y. On "Foreign Hospitals," by Dr. Beekman. A report upon the "Influence of Existing Social Systems upon Health and Longevity," by Francis Bacon, M.D., of New Haven, Ct. 2. A paper upon "Perfection of Structure and Function in the Human Body, as a Leading Element of Hygiene," by Nathan Allen, M.D., of Lowell, Mass. 3. A report upon "The Power of the Housekeeper over, and Responsibility for, the Health of the Family," by Edward Jarvis, M.D., of Dorchester, Mass. 4. A report upon the "Physical and Moral Causes of Bad Health in American Women," by James E. Reeves, M.D., Wheeling, W. Va. 5. A paper upon "Relations of Climate to Tuberculosis, and the Relations of Phthisis to other Diseases," by Henry A. Johnson, M.D., of Chicago, Ill. 6. A paper upon "Relations of Race and Nationality to Mortality in the United States," by Gen. Francis A. Walker, Superintendent U. S. Census, Prof. Political Economy, etc., New Haven, Ct.

5 o'clock P. M.—A report on "Sanitary Relations and Health Principles of Architecture," by Carl Pfeiffer, C.E., Secretary of the American Institute of Architects.

7.30 o'clock P.M.—Edwin M. Snow, M.D., Rhode Island, presiding. "Presentation of a Summary of Evidence and Local Reports upon Cholera as it has prevailed in the Mississippi Valley and elsewhere in America during the Present Year." Illustrated with maps and explained by members of the Association from the various localities: C. B. White, M.D., President of the Louisiana Board of Health; Ely McClellan, M.D., U. S. Army, of Kentucky; J. H. Van Deman M.D., of Chattanooga, Tenn.

Wednesday, November 12.—The morning and afternoon sessions were devoted to reports upon the sanitary care of cities and utilization of refuse.

11 o'clock A.M.—Special reports upon topics in physical knowledge relating directly to hygiene: "The Sanitary Care and Utilization of Refuse of Cities," by Dr. C. A. Leas, of Baltimore, and Mr. Storer, of Boston. A report upon "Alimentation Considered in its Relations to the Progress and Prosperity of the Nation," by A. C. Hamlin, M.D., of Bangor, Me. A report upon "Non-Periodic Changes of Heat as an element in Sanitary Climatology," by Lorin Blodget, Esq., of Philadelphia. A report upon "Sewerage," by Hon. C. C. Cox, M.D., President of Board of Health, Washington, D.C. The afternoon session was devoted to discussion on yellow fever, and a paper, "Relations of Race and Nationality to Mortality in the U. S.," by Gen. F. A. Walker.

7.30 P.M.—C. B. White, M.D., Louisiana, presiding. "Discourse upon the Future Distribution and History of the Population of the United States, as affected by Physical Geography" [illustrated with maps], by J. S. Newberry, M.D., LL.D., State Geologist of Ohio, and Prof. of Geology, School of Mines, Columbia College. A paper upon "Evidences of the Relations of Drinking-Water to the Propagation or Localization of Typhoid Fever and other Diseases," by Austin Flint, M.D., of New York.

Thursday, November 13.—A paper upon "Sanitary Organization in Villages and Rural Districts," by Ezra M. Hunt, M.D., of New Jersey. Report upon the "Sanitary Chemistry of Waters and the Practical Methods of Perfecting the Water Supply of Towns and Cities," by C. F. Chandler, M.D., LL.D., President New York Board of Health, and Prof. of Chemistry in the School of Mines, Columbia College. "The Principles and Practice of Quarantine in the Ports and Cities of the United States," remarks by Dr. S. Oakley Vanderpoel, H. O. of the port of New York. A report upon "House-to-House Inspection, and the Sanitary Care of the Sick when Cholera is Impending," by Stephen Smith, M.D.

Evening.—Hon. Dorman B. Eaton, presiding. Addresses in Association Hall, south-west corner Twenty-third street and Fourth avenue. 1. An address upon "Sanitary Science in its Relations to Public Instruction," by Hon. Andrew D. White, LL.D., President of Cornell University. 2. An address upon the "Germ-Theory of Disease in its Relations to Hygiene," by F. A. P. Barnard, LL.D., President of Columbia College. 3. An address upon the "Relations of Hygiene to Pauperism and Insanity," by John Ordronaux, M.D., LL.D., of New York, State Commissioner in Lunacy, and Member of State Board of Charities. Dr. Stephen Smith was re-elected President; Dr. C. B. White, of N. O., First Vice-President; Dr. E. Harris, M.D., Secretary. The next meeting will be held in Philadelphia.

DR. S. O. VANDERPOEL AND QUARANTINE.—The following resolutions were passed by the Medical and Surgical Society of New York:—

Resolved, That the thanks of the Society be tendered to Dr. Vanderpoel for the very agreeable entertainment we have this day enjoyed.

Resolved, That we avail ourselves with great satisfaction of the present opportunity of expressing our approval and admiration of the able, efficient, upright manner in which he has hitherto discharged the arduous and responsible duties of his position as Health Officer of the Port of New York; an office involving most important interests affecting the health and commercial prosperity of our city.

Resolved, That a copy of these resolutions, duly authenticated, be communicated by the Secretary to Dr. Vanderpoel, and that a copy be sent to THE MEDICAL RECORD for publication.

(Signed)

GEO. A. PETERS, M.D., *President*,
GEO. G. WHEELOCK, M.D., *Secretary, Medical and Surgical Society, New York.*

September 27, 1873.

INFANTILE MORTALITY.—During 1871 there died in New York city 10,701 children less than two years old, or 39.6 per cent. of the total mortality, the percentage in 1870 having been 40.8 per cent. There occurred 8,042 deaths of infants one year old and under, of whom 1,083 or 13.4 per cent. died in hospitals. The mortality of children less than five years of age amounted to 12,791 or 48 per cent. of the total, a slight gain upon the previous year.

EPILEPSY AMONG CRIMINALS.—J. B. Thomson, Resident-Surgeon to the General Prison for Scotland at Perth, states, that out of a prison population for ten years amounting to 6,273, or 627 per annum, the percentage of criminal epileptics under his charge was 0.94, or nearly one per cent. per annum—very different from the army and civil population of England, where the death-rate of epileptics is estimated at 0.009 per cent. only—showing a great excess of epilepsy among criminals.

ALCOHOLISM.—The report of the New York Board of Health for 1872 shows that alcoholism proper, as a direct cause, was credited with 220 deaths in that year, of which delirium tremens occasioned 101. An accurate record, however, was kept throughout the year of *all* cases where intemperance was certified to have been *instrumental* in producing death, and the result of this inquiry was as follows: 556 cases, 300 being males and 256 females—about 11 each week. But 7 of these inebriates passed beyond the age of 70, but 18 beyond 65, and 45 beyond 60 years. The largest proportion of deaths (102) took place between 35 and 40; ten fell victims between 15 and 20 years of age, and 48 before they had arrived at 25. In 225 instances, no occupation was stated upon the certificate, most of these being females. Seventy of those given were laborers, 19 clerks, 18 carmen or drivers, 13 carpenters, 8 pedlars, 8 machinists, 8 liquor dealers, 7 bartenders, 7 butchers, 7 painters, 7 shoemakers, 6 blacksmiths, 6 boatmen, 5 merchants, 5 grocers, besides other occupations—315 were Irish, 125 Americans, 61 Germans, and 20 English.

CENTENARIANS.—During the year from April 11th, 1871, to April 10th, 1872, 14 persons died in New York city who were 100 years old or more, of whom one was said to be 108, one 106, one 105, two 103, and two 102 years old. Ten of the centenarians were Irish females, 3 Irish males, and 1 a West Indian female.

TUMORS OF THE BRAIN.—T. S. Clouston, M.D. (*Jour. Mental Science*), gives the history of six cases of tumors of the brain, which fell under his observation out of 214 autopsies, being in the proportion of 28 to 1,000. The statistics furnished by several authors on the subject are noted, but in none of them were tumors found in so great a percentage of cases.

ACONITINE FIRST DISCOVERED.—Geiger and Hesse, in 1833, each by his own process, first extracted from the leaves of Aconitum Napellus, a peculiar substance—bitter, amorphous, extremely powerful in its action on the animal economy—to which they gave the name of *Aconitine*.

Pennsylvania Hospital for the Insane.—The thirty-second annual report of this hospital for 1872 presents the following particulars: At the date of the last report there were 372 patients; 325 were admitted during the year, and 302 were discharged or have died, leaving 395 at the close of the year. The number of males admitted during the year was 182, and the number of females 143. Of the patients discharged, there were—

	Males.	Females.	Total.
Cured,	65	62	127
Much improved,	10	25	35
Improved,	38	21	59
Stationary,	19	13	32
Died,	32	17	49

Of the patients who died, 24 were admitted for mania, 9 for melancholia, 1 for monomania, 14 for dementia, and 1 for delirium.

Since the opening of the hospital 6,390 patients have been admitted, and 5,995 discharged. Of those admitted 3,403 were males and 2,987 females; 2,922 were single, and 2,923 were married. During the last 32 years $344,553.77 were expended, or $10,767.30 per annum. *Physician-in-Chief and Superintendent*, Thomas S. Kirkbride, M.D.; *Ass't Physicians*, Drs. S. Preston Jones and William P. Moon; *2d Ass't Physician*, Dr. William H. Bartles.

Association of American Medical Editors.—The following officers have been chosen for 1874: President—Dr. W. K. Boling, of Nashville, Tenn. Vice-President—Dr. W. S. Edgar, St. Louis. Secretary—Dr. F. H. Davis, Chicago, Ill. Committee on Prize Essays for 1874—Drs. N. S. Davis, Chicago; J. P. Logan, Atlanta; and J. M. Toner, Washington.

Epidemiological Society of Maryland.—This Society grew out of the appointment of about one hundred medical men "by the Baltimore City Fathers," to serve as a vaccine association at a monthly stipend, to continue in force for six months, in order to combat and stamp out the present epidemic small-pox, which they have accomplished pretty effectually, as well as organized the above-named Society, and formed a constitution, by-laws, and appointed committees on the various epidemics, as well as to appoint foreign correspondents—Prof. Ed'w. Warren, late of Baltimore, to act as such in Egypt, while serving in the army of the Khedive.

Chautauqua County Medical Society (N. Y.), at the annual meeting at Dunkirk, July 8, 1873, elected officers for ensuing year, viz.: President, Ai. Waterhouse, M.D., Jamestown; Vice-President, S. M. Smith, M.D., Dunkirk; Secretary and Treasurer, T. Charles Wilson, M.D., Portland.

What it Costs to Support Hospitals in New York City.—According to the official estimates for 1873 we have the following: *Department of Charities and Corrections*:—Out-Door Poor Department, $128,066; Bureau of Out-Door Sick Poor, $5,300; Bellevue Hospital, estimated number of patients 700, $103,370, or $147.67 each patient; Charity Hospital, estimated number of patients 950, $133,302, or $140.31 each patient; Hospital for Contagious Diseases, 180 patients, $20,667; Fever Hospital, 60 patients, $6,179; Small-Pox Hospital, 175 estimated inmates, $24,950; Hospital for Incurables, $13,393; Asylum for the Blind, 150 inmates, $8,055; Convalescent Hospital, 250 inmates, $22,041; Lunatic Asylum, 1,300 patients, $119,919, or $92.25 per patient; New York City Asylum for Insane, 650 patients, $83,026, or $127.72 per patient; Hospital for Epileptic and Paralytic Patients, 120 patients, $13,172; Hospital for Infants, 450 children, $51,780, or $115.06 per child; Randall's Island Nurseries, 650 inmates, $61,282, or $93.58 per inmate; Nursery Hospital and Idiot House, Randall's Island, 450 inmates, $47,887; Inebriate Asylum, $23,611; Reception Hospital, Centre street, $10,180; Reception Hospital, 115th Street, $5,920; Ambulance Establishment, $3,995; General Drug Department, salaries, $2,500. Total, $888,595, as the estimate for the above hospitals, etc., Department of Charities and Corrections.

"Rest" in the Treatment of Consumption of the Lungs.—Dr. I. B. Berckert recommends the maintenance of rest of the thoracic walls as an important element in the treatment of diseases of the lungs, for the same reason that it is resorted to in inflammation of joints and other organs. It is to this fact that he attributes the relief experienced by persons who apply plasters of different sorts to the walls of the chest in order to prevent or relieve the pain accompanying pulmonary troubles. In his own practice he depends on the application of strips of adhesive plaster.—*The Lancet*, Oct. 18, 1873.

Dysidrosis.—In the *Br. Med. Jour.* of Sept. 27, Tilbury Fox describes an eruption, unmentioned before, which he terms *dysidrosis*. The disease is dependent upon a disordered condition of the sweat-follicles, and has heretofore been confounded with eczema, which it resembles at first sight. Owing to obstruction of the sweat-follicles, the secretion collects in the form of vesicles, which coalesce, to form bullæ; papulæ result from the abortion of vesicles, and white patches are caused by uplifted cuticle, which has become macerated by sweat. The disease varies greatly in extent and duration; it may happen that one or several successive outbursts of the eruption occur, and the disease may last a week or ten days, or several weeks if there are several exacerbations. In the treatment, Dr. Fox depends mainly upon diuretics, with large doses of quinine, nux-vomica, and sometimes arsenic. Soothing local applications are employed, according to the requirements of each case.

Athetosis.—Another case of this peculiar nervous affection is reported by Dr. H. S. Purdon, of Belfast.

Bloodless Operations.—*The Lancet* of Oct. 11, speaking of the plan which has recently been adopted by Esmarch for preventing hemorrhage during operations upon extremities, says that it has been introduced into England by Mr. Wm. McCormac, of St. Thomas's Hospital. The method is not exactly new, and was practised by Stromeyer and Langenbeck twenty years ago, and more recently by an Italian surgeon named Silvestri. The details are as follows: An elastic bandage about two inches and a half in width, and from five to ten yards long, is firmly bound around the limb, commencing at the toes or fingers, as the case may be, and is then continued upwards so as to drive the blood before it out of the veins and arteries. When the desired point has been reached, a strong india-rubber band, about half an inch in diameter, is tightly drawn two or three times around the limb, just above the elastic bandage, and fastened by hooks. The bandage is then removed, leaving the tissues blanched and exsanguined. Not a particle of blood is lost during the operation, which is really more bloodless than when performed on the dead subject. After the operation is completed the india-rubber rope is removed, and the blood then finds its way into the vessels, which are ligatured or twisted according to the inclination of the surgeon. On this plan, which has been carried out at

St. Thomas's, Guy's, London, and St. Bartholomew's Hospitals, many operations have been performed, including excision of the knee and elbow joints, amputations, and the removal of dead bone; and Mr. Wagstaff has recently amputated through the thigh, for gangrene of the foot, on this plan—the precaution having been taken to commence the application of the elastic bandage several inches above the mortified part. No ill effects have thus far been observed from the use of this contrivance. Although the durations of the operations have varied from a few minutes to half an hour, and even more, during which time the circulation has been completely arrested, no evidence has been afforded of the formation of emboli or thrombi in any case.

THE TREATMENT OF BURNS AND SCALDS.—Dr. De Breyne highly recommends the following treatment in *L'Union Pharmaceutique*: Hydrate of lime (newly precipitated), forty-five grains; glycerine, five ounces; chloric ether, forty-five drops. It makes up a transparent, colorless liquid, with an agreeable odor, and an alkaline reaction, according to the amount of hydrate of lime. It calms the pain and prevents or abates inflammation.

PUERPERAL FEVER IN AUSTRALIA.—*The Australian Med. Jour.* for July speaks of the existence, apparently for the first time in that country, of an epidemic of puerperal fever, which began in May and continued through it and the two following months. At a meeting of the Medical Society of Victoria, Dr. L. J. Martin read a paper on the subject, and adduces a number of observations in proof of the atmospheric origin of the disease.

IMPERFORATE ANUS.—M. Verneuil, in a communication made to the *Soc. de Chir.*, of Paris, proposes a modification of Amussat's proceeding in the case of those notoriously difficult and uncertain operations, performed for congenital imperfections of the lower part of the rectum, which consists in the simultaneous resection of the *os coccygis* in whole or in part, and the establishment of the artificial anus at a position slightly behind and above the normal situation. The value of his method is vindicated by the record of six cases in which he has adopted it with complete success. The advantages he claims for it are: The innocuity of the excision; the considerable and safe enlargement of the field of operation attained by it, thereby facilitating all the steps of the undertaking and much shortening it; the much-increased facility of finding the gut; and, above all, the greater ease and certainty with which the bringing down and attachment to the cutaneous parts of the mucous membrane (which form the cardinal points in Amussat's design) can be accomplished.—*Jour. des Connaissances Méd.*, Aug., '73, and *Irish Hosp. Gaz.*, Oct.

ENLARGEMENT OF BRONCHIAL GLANDS.—Dr. Guensan de Mussy, in a paper read before the section of Medicine at the late meeting of the British Med. Association, observed that the enlargement of the bronchial glands noticed by the anatomists as very common, has been described by the pathologist only in its most severe forms and is very rarely met with in adults. It is, however, he thinks, very common. It may complicate all the affections in which the respiratory organs are concerned and modify both the physical and physiological symptoms of these affections. It usually produces cough or dyspnœa, in some cases aphonia and vomiting, according to the relations of the enlarged glands to portions of the pneumogastric nerve. Protracted whooping-cough, lasting, it may be, some years, is connected with this enlargement. The physical sounds are rubbing, impairment of elasticity, and acute percussion sounds at the upper part of the sternum, the inner part of the first two ribs, the intercostal spaces, and the sterno-clavicular joint, and posteriorly over the laminæ of the first four vertebræ, usually on one side. On auscultation there are weakness, acuteness, roughness of the respiratory murmur in one part or in the whole of one lung; generally protracted respiration, sometimes localized sibilant rhonchus; and very often, near to the spine and to the sternum, an expiratory *souffle*, which is the tracheal respiration conducted by the enlarged glands. Sometimes these sounds may be modified by the movements of the neck. The treatment recommended by Dr. De Mussy was iodine internally, and locally chloride of sodium, arseniate and carbonate of soda, and such general means as improve the lymphatic constitution.—*Br. Med. Jour.*, Aug.

THE CAUSE OF KLEPTOMANIA.—The most ingenious explanation ever proffered perhaps in explanation of this peculiar diathesis was that lately stated in New Jersey, "because the individual had been vaccinated with virus from a hooking cow."

REMOVAL OF THE SPLEEN.—The *Raccoglitore Medico* contains a history of a case by Dr. Sonsino in which, on the 20th of June, Dr. Attilio Urbinato, of Cesino, removed a hypertrophied and movable spleen. The incision was about seven inches in length, and was prolonged above the umbilicus. Little difficulty was experienced in the operation, and but few vessels required the ligature. The patient died three days afterwards of peritonitis. The spleen weighed two and a half pounds.

ABUSE OF NUX-VOMICA AND ITS ALKALOIDS.—Dr. James Thompson, of Leamington, writes to the *British Med. Jour.* of Oct. 11, that he is satisfied of an increasing disposition on the part of many people to resort to nux-vomica as a stimulant, and cites a few cases in which the practice had led to serious results.

THE KHEDIVE OF EGYPT is about to construct a hospital at Emirghian, on the Bosphorus. The institution will, it is said, be a model one of its kind as regards the plans for the complete separation of the sexes, and of diseases of a contagious nature from others, without interfering with the administration of the establishment.

THE AGE OF EGGS.—*The Lancet* quotes the following from a French authority as a mode of ascertaining the age and consequent freshness of an egg: Dissolve 120 grammes of common salt in a litre of water. If the egg is one day old, it will sink to the bottom; if it was laid the day before, it will not reach the bottom; if three days old, it floats, and if more than five, it comes to the surface, and the shell projects more and more according to staleness.

MORTALITY AMONG CLERGYMEN.—Of 236 clergymen, whose deaths and ages were reported last year, 7 were over 90 years old, 29 were between 80 and 90, 46 between 70 and 80, 49 between 60 and 70, 61 between 50 and 60, 23 between 40 and 50, 22 between 30 and 40, and 9 between 20 and 30. The average age at death was about 61.

DR. BEVERLEY ROBINSON.—In the last number of THE MEDICAL RECORD (November 15), the abstract of a lecture on Laryngeal Phthisis, by Dr. Morell Mackenzie, London, should have been credited to Beverley Robinson, M.D., as the writer.

THE "New York Laryngological Society" has been organized. The Society is composed of professed

laryngoscopists of New York and vicinity, and has for its object the "promotion of the study of affections of the larynx, pharynx, and adjacent parts;" meetings to be held on the second Thursday of each month, at the residences of the members.

The officers are: *President*, Robert F. Weir, M.D.; *Vice-President*, Clinton Wagner, M.D.; *Secretary*, Woolsey Johnson, M.D.; and an Executive Committee of three members: Dr. Morris J. Asch, Dr. Charles McBurney, and Dr. Beverley Robinson.

The Medical Victims of Yellow Fever at Memphis.—At a meeting of the members of the Medical Profession, held in the parlors of the Peabody Hotel in Memphis, Tenn., on the 7th of November, 1873, Dr. J. H. Pittman was called to the chair, and Dr. E. Miles Willett appointed Secretary.

Dr. A. Erskine, Dr. Avent, and Dr. W. V. Taylor having been selected as a committee for the purpose of presenting resolutions expressive of the sentiments of the assemblage, reported the following, which were unanimously adopted:

Whereas, It has pleased Almighty God, the Great Ruler and Arbiter of the destinies of men, to visit our city with a malignant pestilence, which has swept away in its desolating march seven of our professional brethren and friends, viz.: Drs. Crone, Minor, Kennon, Hatch, Blount, Freeman and Williams; therefore be it

Resolved, That we who have been so fortunate as to have passed safely through its ravages do deplore and mourn their fall with a true and manly sorrow.

Resolved, That in their deaths the medical profession of Memphis, and the profession throughout the land, have sustained losses immeasurably great.

Resolved, That we feel a common sympathy and a personal affliction, the result of a common sorrow, and the rupture of the tenderest ties of sympathy and love.

Resolved, That humanity, affected and bereaved, weeps over their fall. On its altar they, with manly devotion, laid down their lives.

Resolved, That the city of Memphis could have sustained no greater sacrifice than the death of her noble and gifted physicians.

Resolved, That we tender to the families of the deceased our sincerest sympathies in their irreparable loss.

Alex. Erskine, M.D.
B. W. Avent, M.D.
W. V. Taylor, M.D.

E. Miles Willett, M.D.,
Secretary.

New York Physicians' Mutual Aid Association.—The annual meeting of the New York Physicians' Mutual Aid Association was held Nov. 13, 1873, for the election of officers for the ensuing year, which resulted as follows:

James Anderson, M.D., *President*; W. W. Reese, *1st Vice-President*; Austin Flint, *2d Vice-President*; C. T. Hubbard, *Treasurer*; W. R. Gillett, *Rec. Secretary*; S. Ayres, *Asst. Secretary*; Wm. H. Thayer, *Cor. Secretary*.

Trustees for one year: Geo. A. Peters, Erskine Mason, Ernest Krackowizer.

Trustees for two years: Joseph Kammerer, J. R. Van Kleeck, W. J. Percell.

Trustees for three years: Geo. J. Bennett, M. Herzog, J. S. Monell.

The Association is increasing in numbers. It has a permanent fund already of $1,345.50. Five deaths have occurred during the past year.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from November 4, 1873, to November 18, 1873.

McParlan, T. A., Surgeon.—Assigned to duty at Fort Leavenworth, Kas., as post surgeon. S. O. 169, Dept. of the Missouri, October 31, 1873.

Hasson, A. B., Surgeon.—Granted twenty days' leave of absence, provided he furnishes satisfactory medical attendance during his absence. S. O. 59, Headquarters Military Division of the Atlantic, November 12, 1873.

Ghiselin, James T., Surgeon.—So much of S. O. 206, October 15, 1873, from this office, as relates to Surgeon Ghiselin, is revoked. S. O. 217, War Dept., A. G. O., November 3, 1873.

McKee, J. C., Surgeon.—To report to the Commanding Officer of the Presidio of San Francisco, to relieve Asst.-Surgeon De Witt of his duties at that post. S. O. 130, Headquarters Dept. of California, October 30, 1873.

McClellan, Ely, Assistant Surgeon.—Relieved from duty at Headquarters Department of the South, and to return to his proper station, Lebanon, Kentucky. S. O. 189, Department of the South, October 31, 1873.

Wolverton, W. D., Assistant Surgeon.—Leave of absence extended thirty days. S. O. 219, War Department, A. G. O., November 5, 1873.

Wolverton, W. D., Assistant Surgeon.—To report to the Commanding General, Department of the South, for assignment to duty. S. O. 227, War Department, A. G. O., November 14, 1873.

Greenleaf, Charles R., Assistant Surgeon.—To report to the Commanding General, Department of the South, for assignment to duty. S. O. 227, War Department, A. G. O., November 14, 1873.

Knickerbocker, B., Assistant Surgeon.—Assigned to duty at Camp Harney, Oregon. S. O. 146, Department of the Columbia, October 17, 1873.

Waters, W. E., Assistant Surgeon.—Relieved from duty at Fort Leavenworth, Kas., and assigned to duty at Fort Riley, Kas., as Post Surgeon. S. O. 169, Department of the Missouri, October 31, 1873.

Caldwell, D. G., Asst. Surgeon.—Relieved from duty in the Dept. of the South, and to report to the Commanding General, Dept. of Texas, for assignment to duty. S. O. 227, War Dept., A. G. O., Nov. 14, 1873.

Taylor, M. K., Asst. Surgeon.—Relieved from duty in the Dept. of the South, and to report to the Commanding General, Dept. of Texas, for assignment to duty. S. O. 227, War Dept., A. G. O., Nov. 14, 1873.

De Witt, Calvin, Assistant Surgeon.—On being relieved by Surgeon McKee, to comply with Paragraph 9, S. O. 197, C. S., from the A. G. O. S. O. 130, Headquarters Department of California, October 30, 1873.

Kimball, J. P., Asst. Surgeon.—Leave of absence extended thirty days. S. O. 99, Headquarters Military Division of the Missouri, Nov. 5, 1873.

Patzki, J. H., Asst. Surgeon.—To report in person to the Commanding General, Dept. of the Platte, for assignment to duty. S. O. 227, War Dept., A. G. O., Nov. 14, 1873.

Matthews, Washington, Asst. Surgeon.—Assigned to duty at David's Island, New York Harbor. S. O. 59, Headquarters Military Division of the Atlantic, Nov. 12, 1873.

Original Lectures.

CLINICAL LECTURE ON CHRONIC ALBUMINURIA.

DELIVERED AT BELLEVUE HOSPITAL, N. Y.

BY PROF. AUSTIN FLINT, M.D.

(Phonographically reported for THE MEDICAL RECORD).

GENTLEMEN: The topics which I shall present to you to-day embrace many features which are of much interest and importance, but which I shall be able to consider only in part. We have already considered acute desquamative nephritis, and now I wish to introduce for your consideration and study the different forms and manifestations of chronic disease of the kidneys. The existence of these affections is recognized by the changes which are manifested in the urine, and also by certain consequences resulting from renal disease. I wish to call your attention to certain points which will somewhat simplify and systematize your study, and I shall ask you to carefully read what has been written by some standard author or authors upon the different forms of chronic degenerative diseases of the kidneys, the effects which result from these different forms, and the circumstances which are involved in the differentiation, each from the others.

The most generally adopted classification of chronic diseases of the kidneys, or chronic Bright's disease, embraces four forms, namely: The large white kidney; the cirrhotic, or fibroid kidney; the fatty kidney, which some authors do not regard as a distinct form; and the amyloid, waxy, or lardaceous kidney. What effects do these different affections severally and collectively produce in the body?

These may be conveniently arranged in two classes: First, a diminished density of the blood due to a constant elimination of albumen in the urine. This undoubtedly is an important element in the production of the dropsy which is so constantly present in these affections; but I would not be understood as saying that the loss of albumen, and consequent reduction in density of the blood, is the sole cause of the dropsical manifestations.

The second class embraces effects which are due to the retention in the blood of excrementitious materials which should be eliminated from the system by the kidneys.

With the impoverished condition of the blood, which is in proportion to the loss of albumen, we have the dropsy, anæmia, and all those ulterior effects which arise from an anæmic condition; and with the second class, we have all the effects which arise from the morbid conditions of the blood caused by the retention of the excrementitious constituents of the urine.

The symptoms to which the latter of the two classes of effects give rise may be divided into the minor and grave symptoms. Among the minor symptoms are headache, nausea, and vomiting; looseness of the bowels, muscular cramps, etc. These are important symptoms, for the reason that they furnish evidence of a renal affection leading us to investigations which relate to the kidneys. More serious symptoms are those which denote inflammations, chiefly of the serous membranes; namely, pericarditis, pleuritis, and meningitis. Still graver symptoms are convulsions and coma. With this brief outline, I shall bring before you cases illustrative of chronic renal disease.

The first case is a girl æt. 18, a domestic. The countenance of this patient is quite typical. It is pallid, showing anæmia; and puffy, showing dropsy. There is a certain amount of anasarca present, not marked, but sufficient to show that the dropsy is diffused through the areolar tissue. A very reliable method of determining whether diffused dropsy is present or not, even in a very slight degree, is to make pressure over the sternum. If there be œdema, it can be recognized at that point. An important question to be decided now is, does the dropsy in the present case arise from an affection of the kidneys, or from an affection of the heart? It may be laid down as a general rule that, if there be much general dropsy, unaccompanied by difficulty in breathing, the dropsy can hardly arise from cardiac lesion. There is no evidence of heart-disease in this case. Examination of the urine gives a s. g. 1018 acid; it contains considerable albumen, epithelial and granular casts and urates.

Let us now turn to the history of the case. Her family history is good. Patient is temperate; no evidence of specific disease. Two years ago—and this is a point of much interest—the patient had scarlet fever. It will be recollected that, while studying the acute form of Bright's disease, your attention was called to the fact that a great majority of the cases of acute albuminuria, or tubal nephritis, are cases in which the affection is a sequel of scarlet fever. It was also remarked that the acute affection rarely terminates in a chronic condition. But it seems probable that the case before us is a chronic affection, and that it dates its commencement from the occurrence of the scarlet fever; in other words, that we have here a chronic affection of the kidney following an acute tubal nephritis. Since she had the scarlet fever her feet, face, and body have occasionally become puffy, and the amount of urine passed has been sometimes quite scanty. Her face has never regained its natural color, and her strength has been very much diminished. She dates her present sickness at four days before her admission into the hospital. While in a profuse perspiration she sat down in a current of cold air, and she was seized with slight chill, with severe pain in the left side and afterwards in the right side. Upon admission the pulse was frequent, the temperature raised, and the respirations rapid. To-day a physical examination of the chest reveals fluid in both pleural cavities. Now a question of interest is, is this hydrothorax dependent upon the renal disease, or is it a case of double pleurisy? I do not hesitate to say that it is a case of double pleurisy. It is a case of double pleurisy which proceeds from renal disease, without much general dropsy. With but little general dropsy, and with no disease of the heart, it is out of all experience to have as much dropsical effusion within the chest as in this case. This case may therefore be regarded as an illustration of the occurrence of chronic affection of the kidney following acute tubal nephritis, and also an illustration of double pleurisy produced by renal disease. Her pleurisy has been treated by the application of dry cups to the chest; she has had, in addition, ten grains of quinine once a day, and pills of iron, aloes, and strychnia.

The second case gives us the following history:

Mrs.——, æt. 33, English, and admitted to the hospital September 22d. Family history good. Patient was healthy until one year ago, when she began to suffer from attacks of dyspnœa without cough, which were probably asthmatic in character. Vomiting and œdema of lower extremities first occurred about six months ago. During the past two weeks she has suffered from some pain in the back, and her urine has been scanty and high-colored. The vision has always been good. Upon admission the patient presented an anæmic ap-

pearance, the breath was short, and the appetite poor. Examination of the urine gave s. g. 1010, albumen and casts. Physical examination of chest negative.

Sept. 26th.—Under the influence of diuretics and tincture of iron the patient's urine became more abundant, but giving same results by chemical and microscopical examinations.

Oct. 28th.—The patient does not pass much urine; complains of pain in her back and shortness of breath.

Upon physical examination of the chest, the area of cardiac dulness is found to be very much increased, and with this there is a murmur with the first sound of the heart at the base. This patient now has pericarditis, with considerable effusion of serous fluid into the pericardial sac. There is considerable œdema of the lower extremities, and also considerable fluid in the abdominal cavity. Her face does not show any dropsy, and there is but slight indication of its diffusion by making pressure over the sternum. The question may arise here, is this a case of pericarditis, the inflammation giving rise to the effusion into the pericardial sac; or is it a case of hydrops-pericardium due to the chronic renal affection? There is a slight, but a sufficiently distinct friction murmur occasionally heard, and this sign, be it ever so slight, indicates pericarditis, with a single exception. Sometimes, when there is a pleurisy of the left side, the action of the heart causes the exterior of the pericardial sac to rub against the pleural surface, causing a friction murmur with the cardiac rhythm, and this is called a cardiac pleural friction murmur. If the murmur were of this kind, it should be heard at the left lateral portion of the pericardium. But the friction murmur is more to the right, nearer to the base; it is superficial in character, being a slight grazing sound.

Taking into account the existence of pericardial effusion, there can be no doubt that the murmur denotes pericarditis. Pleurisy can be excluded because an abrupt line of dulness denotes the boundaries of the distended pericardial sac, good resonance on percussion being found everywhere without these boundaries. A simple enlargement of the heart would not produce the dulness which is here found to extend above the base of the organ. The increased space of dulness in cardiac hypertrophy is downwards and to the left. This patient is not suffering much pain, nor is pain a constant symptom of pericarditis. Pain in this disease is sometimes extreme, and sometimes almost entirely wanting. We have, then, in this case another example of serous inflammation developed in the course of chronic renal disease, belonging among the grave secondary affections.

As regards the measures of treatment addressed to the pericarditis, in this case some soothing applications should be made to the præcordia; a light poultice, or the water dressing covered with oiled muslin, and an abundance of flannel. If the kidneys are found to respond to diuretics, these are indicated for a twofold purpose, as follows: to eliminate urea, and to promote the absorption of the liquid in the pericardial sac. Rigid quietude is to be enforced. There is danger of sudden death by syncope on exertion in cases of pericardial effusion. The condition of the patient will not admit of the employment of the active hydragogues with a view to the absorption of the effused liquid; but if the kidneys do not respond to diuretics, saline cathartics, or perhaps the pulvis purgans, may be advisable. The patient should be well nourished. Digitalis will be likely to be useful by increasing the power of the heart's action.

The third case illustrates a condition associated with, but probably not dependent upon, the renal disease.

The patient's name is Miss C——, æt. 22. She was admitted to the hospital on the 2d day of September. Family history good. Since last May she has had more or less œdema of the lower extremities. The dropsy extended up the limbs, appeared on the face, and then about the body. She has had occasional nausea and diarrhœa. Exercise gives rise to palpitation of the heart and want of breath. This patient has a pallid countenance, but this is not as marked as when first admitted. Examination of the urine at the time of admission gave a low specific gravity, with albumen and granular and epithelial casts; subsequently, hyaline casts were found.

September 5th, hydro-peritoneum made its appearance, which has continued and somewhat increased up to this date, Oct. 30th; and at the present time there is, as you see, considerable œdema of the lower extremities. No œdema of the face. The question arises in this case, is this hydro-peritoneum due entirely to the renal disease, or in part to some other cause? Although we have evidences of renal disease, I am quite sure that there is some other affection to account for the hydro-peritoneum. The hydro-peritoneum in renal disease sustains a relation to the dropsy in other parts of the body. But the general dropsy in this case is not an important feature, and this leads us to conclude that the hydro-peritoneum is due to some other disease than the renal disease. It is probably due to disease of the liver—but the expiration of my hour prevents further consideration of the case.

Original Communications.

ON THE TREATMENT OF SOME OBSTINATE FORMS OF EPILEPSY.

By ALLAN McLANE HAMILTON, M.D.,
NEW YORK.

The want of permanence in the cure of those cases of epilepsy (by the bromides especially) when there is a relapse, after the patient and physician have congratulated themselves upon the mastery of the disease, is, I am convinced, due to an insufficient use of these drugs. Even when a careful remedial course is pursued, there are many conditions which will delay, or entirely thwart, the cure of epilepsy, and these are:

1. Strong hereditary taint.
2. Unusual violence of seizure.
3. Long periodical intervals.
4. Idiopathic origin of the disease.
5. The existence of intercranial pressure.

Russel Reynolds* suggests other unfavorable conditions, viz.: A long duration of the disease, and mental failure.

The pathological condition of the brain and its appendages in old cases, may be such as to make the cure impossible, or almost so. Van der Kolk† examined the medullæ of fourteen patients who had died while suffering with epilepsy, and discovered that in cases of long standing, an induration of the medulla caused an exudation of albuminous matter from the impaired walls of this organ. An excessive vascularity permits an extraordinary blood-supply; these vessels are so repeatedly congested during the paroxysm, that their walls become degenerated, and as the disease advances they become too greatly weakened to resist the force of the circulation. In cases of still longer

* A System of Medicine, Vol. II., p. 321.
† Transactions of Sydenham Society, 1859, p. 211.

standing, Foville and Van der Kolk both found fatty degeneration. In these old cases there was an increased vascularity in the fourth ventricle, penetrating into the medulla, to considerable depth. Of course these are conditions calculated to be out of reach of the most energetic treatment.

I think it has been the general opinion of writers upon this subject, that there is a greatly heightened reflex excitability of the medulla; that these nerves supplying the muscles of the neck and the organs of respiration, receive and transmit exaggerated impressions; that the irritation of the vagi and other nerves coming from the upper part of the cord will produce epilepsy in many conditions, and, as Marshall Hall demonstrated, the spinal accessory, which takes its origin from this part of the cord, and presides over the muscles of the neck, will so influence them as to produce a contraction, thereby constricting the blood-vessels, producing the loss of consciousness, which is an important element of the epileptic attack. When their influence is remitted, there is return of consciousness due to suspension of pressure.

A consideration of these facts enables us to understand that an abnormal reflex activity of the medulla must be the important indication to meet and overcome in our treatment; that a tendency of the vessels of the medulla to become engorged, is also a feature of the disease to be noticed. In the treatment of a case we should not lose sight of the fact that there may be a remote cause; and of course if this cannot be done away with, there is very little use of expecting good results from the administration of remedies calculated to work local changes.

But my purpose was to discuss the management of those hopeless cases that the practitioner meets at the dispensaries, or who come to him after years of suffering, and after running the gauntlet of drugs, from cotyledon umbilicus to nitrate of silver. Some of them may have been taking the bromides, or equally efficacious remedies, in an irregular way without benefit, and have given up, disgusted and despondent. One person, on coming for treatment, informed me that he had taken "pounds upon pounds." These are certainly disagreeable patients to treat.

So large is the list of remedies that have been, and now are, used in epilepsy, that the medical man is bewildered by the array of medicines which have been recommended by different text-books. They have been proved, most of them, of little worth, with the exception of two or three. Musk, castor, and valerian, the drugs of the last half century, are now seldom used. Conium and hyoscyamus have been used by some practitioners, but the bromides and two or three others have been so successful that they are now generally adopted. My experience has taught me to rely upon a few good remedies. The objection to some of the narcotics is their tendency to ultimately excite reflex activity; and however carefully these may be given by the stomach or skin, a condition will remain, after their first effects have passed away, which will be conducive to a violent renewal of the attacks; and oftentimes when drugs have been followed by apparent relief, the recurrence of several severe seizures of epilepsy, after slight decrease of the dose, will occur almost immediately, denoting a reaction after a condition of exalted reflex excitability.

The only hope of cure can be derived from the knowledge that a permanent change of the condition of the medulla takes place before its vascular tone is so lowered as to permit exudation—or even a disposition to abnormally receive reflex impressions.

Counter-irritation, either by the actual cautery or sometimes by the seton in cases of long standing, may produce alteration. If we see the case early, we may keep the cerebral vessels in a state to withstand the continual injurious impression of the seizures, which will inevitably entirely destroy the integrity of the medulla. Ergot and belladonna are the best agents I know of as local alteratives, while quinine and cod-liver oil will help the general condition. I propose to dwell briefly upon three drugs which I am convinced give the best results, and these are: the bromides of sodium and potassium, belladonna, and ergot.

Before their administration, however, we must inquire as regards the condition of the patient, his age, duration of sickness, and the existence of a proximate or remote cause; and we should discover whether the attacks be diurnal or nocturnal. Upon these facts depends the selection of medicine; for instance, the bromides are almost useless in nocturnal epilepsy, and they often aggravate the symptoms, but are invaluable when the attacks come on in the day-time.* The bromides produce slower effects in those cases of long standing than they do in recent ones. In cases where *le petit mal* is the feature, belladonna and ergot are particularly indicated, and not the bromide, which increases the severity and number of the seizures.

The bromides, according to Clarke and Amory,† produce a contraction of the arterioles of the medulla, and this contraction must be permanent to prevent a recurrence of the paroxysm. Dr. Russel Reynolds says that a considerable amount of these salts should be present in the system, and that is not obtained by the mere administration of small repeated doses. This statement substantiates my assertion, that in my experience those patients who took heroic doses were cured the soonest. Clarke and Amory, whom I have before referred to, discountenance the toxic administration of the bromides; but I believe that a state closely bordering on bromism is to be reached before we can expect permanency of cure. We must stop here, however, and employ the greatest caution in their subsequent use. Staggering, anæsthesia of the fauces, and mental cloudiness are to be reached; after these come a train of deplorable symptoms which it is almost impossible to stop. The skin will be characterized by a waxy hue; œdema of the limbs and loose tissue beneath the lower eyelids; utter loss of appetite (not always constant), and a mental state of imbecility will ensue. The patient will fall into a low state of exhaustion, attended by delirium, irritable pulse, coldness of skin, followed by a sudden rise of temperature, and finally death.

The sequelæ of this secondary stage of bromism, if death does not follow, will be dementia, and a loss of power and energy that will continue for years.

In the cases I have treated, I have usually begun with 20 grains of the bromide of sodium thrice daily, for smaller doses are ineffacious. At the end of a week, if there is no change for the better or worse, the dose may be increased by 10 grains, and so on till we give 160 grains in the course of the day. It is then necessary to watch carefully for the appearance of symptoms which will indicate the toxic effects of the drug. The patient may be seized with an irresistible desire to sleep at all times. He may fall asleep over the table, or may appear absent-minded. If spoken to, his mind will sometimes be "wool-gathering," and he will not heed the first summons, but regain himself suddenly to pay attention, which is an effort. As other

* Dr. Duckworth Williams, *London Lancet*, May 20, 1857.

† Clarke and Amory, The Bromides of Potassium and Sodium. Boston, 1873.

symptoms increase, he will display an irritability of temper, an indisposition to go out into the open air, a staggering gait combined with a bending of the knees, and consequent sinking of the body. His face will wear a blank, expressionless appearance, and the color of his skin will appear a dirty white. His breath becomes foul with the odor of bromine, and his pharynx devoid of sensibility. An eruption of acne may be present on the forehead and chin.

As we advance into the second stage we find that a number of alarming symptoms will develop themselves in succession. The process of waste goes on with excessive rapidity; a loose cough and an œdematous condition of the lung-tissue will ensue; in fact, there may be anasarca of the entire body when the patient is bromized to this extent. As the stomach has been a sufferer for a long time, it is reasonable to expect a change in this organ. The secretion of gastric juice is interfered with, and it is often extremely difficult to find an article of diet that will be digested. The patient's pulse becomes weak and intermitting, large dark circles surround the eyes, followed by total mental aberration, and then come the signs of dissolution alluded to before. The symptoms towards the close of life may resemble those of typhoid. Clarke and Amory give two very graphic cases of bromism, one of which was fatal.

After reading this brief list of symptoms, we have certainly cause to avoid its excessive use; but if care is used the patient may be kept hovering on the borders of bromism without going further. Certain adjuvants in the treatment will stave off the severe effects of the bromides, and when bromism is produced will quickly restore the patient. The various preparations of cinchona and iron, combined perhaps with cod-liver oil or strychnia in small doses, will do almost immediate good. A temporary suspension of the remedy will diminish the violence of the symptoms.

It has been suggested that the combination of strychnine with the bromides is efficacious; but the effect of this alkaloid, in the cases I have seen and treated, has been to aggravate the disease. In *very* small doses, with iron and quinine, it may have some efficacy.

Belladonna, given by the stomach with the bromides, has also been tried; but the properties of atropia are apt to be neutralized by the alkaline bases of these salts, particularly calcium.

Perhaps my remarks upon the use of the bromides would be of more interest should I illustrate them by a recent successful case.

—— ——, aged fifteen years, with history of decided nervous hereditary taint, maternal grandmother and other relations having been the victims of nervous diseases of a more or less grave character. The patient's sister had died several years before of a disease which was undoubtedly cerebral sclerosis of the left side, though no very accurate statement could be obtained.

The patient himself is of marked nervous-bilious temperament, large framed, with dark dry skin, hair, and eyes, and a restless bearing. He shows a large surface of the sclerotic coat, which is of a blue-white. His lips are full, the lower one particularly, and there is occasionally an expressionless appearance of the face. Dr. Brown-Séquard and other distinguished specialists had given a hopeless prognosis for the case, and it was with very little assurance of success that I began treatment. His previous history was as follows: From the time of his early infancy he had repeated epileptic convulsions. These did not seem aggravated by any particular external circumstances, but would occur in the course of a day, and perhaps he would pass a long interval without them of several days, or again they would come every day for some weeks. His family described these seizures as a species of trance, the eyeballs being rolled upwards, and a tetanic contraction of the muscles occurring at the same time, which would cease in a few seconds.

It was not till about two years ago that he had any attacks of "*le grand mal*," and these were violent and of long duration, occurring generally at night or in the early morning. He would then fall, gnashing his teeth and exhibiting all the ordinary symptoms of *epilepsia gravior*. These attacks became more frequent and violent, quickly succeeding each other. They would come usually after intervals of three weeks, and he has had as many as seventeen at a time—the attacks occurring usually within a period of two days. There would be excessive pallor, general languor, and great exhaustion after the attacks. He would apparently recuperate and be in a convalescent state when the next attack would take place. During these years, seizures of "*le petit mal*" would come and go, and there would be from six to thirty a day. At these times his features would suddenly lose their expression, his dull leaden eyes would roll up, and breathing would be apparently suspended. In from a few seconds to several minutes he would recover, with no remembrance of his seizure. At the table these attacks would occasionally come on, when he would drop his knife or whatever happened to be in his hands. His mental condition had changed very slightly, his memory was good, he was unusually bright and witty, was fond of amusements where thought and ingenuity were concerned. His sensitiveness was great, and I was obliged to use the greatest caution in questioning him for fear of hurting his feelings. I first saw him on the third of January, 1873. He had had several convulsions of the severer variety three days before, and was apparently weak and miserable. After taking his history (and perhaps it would be well to mention here that there was no exciting cause for the disease), I put him upon the bromide of sodium in doses of 20 grains, with $\frac{1}{10}$th of a grain of strychnia thrice daily. On the same day he had three convulsions of a very severe character. I immediately stopped the strychnia. An entire change of diet was instituted, and he took about a quart of strong beef *consommé* daily, besides milk and dry rolls, made without "saleratus" or other culinary abominations. His last meal was taken at 5 P.M., and this was extremely light. Confectionery and pastry were of course tabooed. An attendant was procured, and walks in the fresh air were ordered. These regular habits, with a moderate amount of mental work, produced a change for the better. The next expected time for his instalment of "fits" would arrive in about three weeks, and as the bromide had not given rise to any unfavorable change, the dose was first increased to 140 grains daily. After a week from this change (Jan. 21, 1873), I was enabled to detect the peculiar odor of the breath. He was slightly drowsy, and his step was uncertain. Caswell, Hazard & Co.'s preparation of the pyrophosphate of iron was then given, and in less than two days he was as bright as ever, but with no change in the breath. I might mention that his appetite had been voracious from the first, and it was hard to keep him from eating his food with inordinate haste. The time for the expected seizures came and went without their occurrence, the dose of bromide being kept up with the idea of stopping the attacks of *petit mal*; but no effect was produced upon them, except it might be to increase them. I finally gave 160 grains a day, as I thought I detected premonitory symptoms of a severe

seizure. I gave half-ounce doses of cod-liver oil with the elixir of the pyrophosphate of iron, which evidently agreed with the patient. At this time symptoms of bromism developed themselves to such an alarming extent that the dose was decreased to 60 grains per day, when the patient rallied completely, with no convulsions as yet. This condition of bromism alluded to consisted of severe headache, loss of appetite, irritability of temper, weakness of the knees, with soreness of the throat, hesitating speech, incontinence of urine, general mental obscurity; but there was no eruption. Feeling that the bromide was powerless to stop the seizure of *petit mal*, which had not been greatly benefited since he came under my charge, I injected $\frac{1}{100}$th of a grain of sulphate of atropia beneath the skin of the mucha. Very few of the physiological effects of this drug were visible; but when the dose was increased to $\frac{1}{75}$ th of a grain, his pupils were dilated and there was marked dryness of the throat. The bromide was kept up to 120 grains at this time. After several hypodermic injections of sulph. of atropia had been given daily, the attacks of *petit mal* were reduced to two or three a day, and finally ceased. At the beginning of March, two months from the time he came under my notice, he was permitted to leave town, but still under surveillance, and the bromide continued with the tonics and cod-liver oil.

He had not had a convulsion since the 3d of January, and for some weeks had had very few attacks of the lesser disorder. He had undergone the ordeal of sitting for his photograph and having his hair cut, without the least spasm. He was mentally bright and very well. On the 12th of March, from some cause or other, he had two of the seizures of "*le grand mal*." I have since ascribed them to a day of exposure spent in coasting down hill, and great consequent muscular fatigue.

The dose was again increased to 160 grains from 120. I left him in a semi-stupid state.

March 17th.—Patient has been in a drowsy state; has had a few attacks of *le petit mal* since last date, very little appetite, slight cough; after a light dinner went to sleep.

March 20th.—Impossible to get patient to lie comfortably; head felt heavy; all medicines discontinued. Has been in bed all day, waking occasionally to say a few incoherent words; eats more. Patient staggers greatly when he arises. It is difficult for him to hold anything for fear of letting it drop. Belladonna internally.

March 26th.—Great improvement, mental and physical; cough abated, appetite good; lesser attacks abated.

March 31st.—Has steadily improved. Patient still irritable and "nervous," disliking the sound of the piano. Twenty grains of bromide thrice daily; a glass of wine also prescribed three times a day. As it is impossible to regularly give him hypodermic injections, Bonjean's capsules of ergotine were given; each capsule contains five grains. The fourth dose reduced the attacks of *petit mal* to one or two trifling seizures daily.

July 1st.—The patient has had but one grave seizure in some months.

Sept. 12th.—Patient has had no more attacks of "*le grand mal*." Occasional facial spasms are all that remain of disease.

Belladonna.—The great advantage of this drug where it is desirable to diminish the hyperæmia of certain organs, particularly those of the nervous system, makes it of particular benefit in epilepsy. Trousseau has given belladonna extensively, and with great success, curing twenty of one hundred and fifty patients to whom it was administered. Drebreyne cured two hundred cases. We are not told by the author what forms are most benefited. Other writers contend that only recent cases are at all relieved. My experience has led me to believe that the variety of epileptic seizures occurring in the day-time were most readily abated by this form of treatment. Large doses of belladonna greatly lessened the form of attack known as *le petit mal*. Belladonna, as we know, diminishes the amount of blood in the vessels of the cord, and establishes a condition antagonistic to spasm of these vessels. Trousseau's method of giving belladonna, which I have taken from Ringer,* is this: "During the first month of treatment the patient takes a pill composed of ext. of belladonna and the powdered leaves of belladonna, of each one-fifth part of a grain, every day, if his attacks occur chiefly in the day-time, or in the evening, if they are nocturnal. One pill added to the dose every month; and whatever be the dose, it is always taken at the same period of the day. By this means the patient may reach the dose of from five to twenty pills, and even more."

As yet I have not heard of the administration of belladonna and its alkaloid by the hypodermic method, locally. In several cases I made this the sole treatment, and though it was tried somewhat empirically, I had the gratification of witnessing most important results. From one-hundredth, increased to one forty-eighth of a grain of the sulphate of atropia solution, were injected beneath the skin at the base of the skull, for several weeks, with intervals of one or more days between each application. The want of sensibility of this part of the skin made the pain inconsiderable, and the patient scarcely minded the operation, repeated even as often as it was. The effect seemed to be more immediate than when belladonna was given by the mouth. The results were gratifying, inasmuch as one case of ten years' standing was improved notably after three weeks; and another case, when this treatment was combined with the bromide, was cured.

Harley† has found belladonna serviceable in curing epilepsy due to emotional causes.

Ergot.—In the spring of 1873 I had occasion to try ergotine for a case of epilepsy, since which time a most excellent article by Dr. Kitchen,‡ of the Utica Asylum, has appeared, giving his success with this agent in various nervous disorders. He has used the preparations of Squibb and Merck, as well as the fluid extract of ergot.

My experiments have been made with the ergotine of Bonjean of Paris, and propylamin, which is identical with secaline, the active principle of ergot. Though my observations were not as extensive as those of Dr. Kitchen, I have several cases under my care which have notably improved under the ergotine treatment. Those cases the most benefited were of the variety known as *le petit mal*. In one case coming to my notice, I found that the patient, who had been having fifteen or twenty slight convulsions, was relieved greatly after a week; that two was the average number of daily attacks, and these finally disappeared. One of Bonjean's capsules, containing about 6 grains, given three times daily, is enough to begin with. The fluid extract produced less satisfactory results. Propylamin has been tried in one case in doses of ℥v. suspended in mucilage. Though this

* Ringer's Handbook of Therapeutics.
† "Old Vegetable Neurotics," Harley.
‡ Am. Journal of Insanity, July, 1873, p. 83.

case is unusually severe and has been under all kinds of treatment, a great diminution in the number of attacks is evident.

The influence of ergot on the muscular coat of the blood-vessels of the cord is to contract them, and restore their tone through the vaso-motor nerves. Its action is much the same as that of belladonna, though in a far more energetic degree. Ergot notably diminishes exaggerated reflex power, and is therefore clearly indicated in epilepsy. It will combine well with the bromides, and the therapeutical effects of both will be increased, as Dr. Kitchen has also shown. Dr. Kitchen's cases number five, and in every one a cure has been effected; three of them were treated with the fluid extract, and two with ergotine. I have been successful in stopping the convulsions in three cases, but as sufficient time has not elapsed since the commencement of treatment, it is impossible to say whether a permanent cure has been established. I hope that others will try propylamin and give their results to the profession.

In spite of the medicines given, the physician will sometimes find that his patient does not recover, and perhaps he will give the case up, feeling that nothing can be done. We should always look for a deeper evil in these cases, for a hidden cause may exist in very many instances, which when removed, there may be a rapid cure. One case of this kind has come under my charge in the last few weeks. The patient, a young girl, had been treated ineffectually for over a year, and still the attacks, though of a mild form, occurred as frequently as ever. A rigid series of questions brought out the fact that some uterine trouble existed, and an examination by a prominent gynæcologist resulted in the discovery of an anteverted uterus and serious concomitant conditions; under the proper local treatment, she is recovering with very little difficulty.

Uterine and ovarian derangements are a very common cause of the disorder.* Barnes says the irritation is transmitted very slowly from the sentient nerves of the cervix to the cord, and more slowly to the brain, and consequently grave nervous disorders occur usually in old cases, and take a violent form. "Continuous hyperæmia of the genitalia implicates the general nervous system. It is rare for epileptic paroxysms to be superinduced unless they occur at or near the first menstrual periods, it being necessary for the production of so deep a perversion of the nervous power, that congestion of the internal genitalia should occur suddenly, and before these organs are developed by and habituated to the physiological fulness of their vessels." The prospect of cure depends upon the return of function through disappearance of the cause, and consequent return of tone of the cerebro-spinal system. Wright† states that when the convulsions occur in women, they are most apt to take place at the time of menstruation, and with the periods of uterine changes. I have found this to be the case in several instances, the menstrual periods being those when the patient was most often seized. Even if the severe convulsions were omitted, attacks of *petit mal* supplanted them. The hope of benefit in these cases depends upon the time of life, and the proximity to the commencement of menstruation. It is much easier to cure a young patient than one in whom the disease has become deep-seated. Any prolonged irritation of the pudic nerve is apt, whether in the male or female, to be followed by epilepsy, and such causes of irritation it is well to discover. Barnes gives cases, on page 375, where congestion of uterus and vagina existed, with epilepsy and finally dementia.

Besides these causes, we will be able to find that injuries of the head, ascarides, and renal and biliary calculi may also be frequent causes of the trouble. A form of epilepsy which gives the physician much annoyance, is that depending upon or caused by disturbances of the digestive apparatus, and this occurs in persons having a nervous diathesis. The important part which the stomach plays in epilepsy may be studied when we watch the disagreeable results which follow an abuse of this organ. A heavy meal at night will generally produce a series of epileptic attacks which are always severe. Gastric epilepsy is usually nocturnal. In a lecture delivered by Dr. G. E. Paget at Addenbrooke Hospital, Cambridge,* eight cases of this kind were mentioned, and in all the convulsions were nocturnal; six of the patients were children, and the other two adults; the time of cure averaged two years. All of these cases were treated by bismuth, magnesia, and medicines of this class, and as soon as the condition of the stomach was improved there seemed to follow an amelioration of the disease.

There are other kinds of eccentric irritation which will cause epilepsy, and may escape the attention of the practitioner: a carious tooth, or an injury of the jaw; the presence of some irritating body such as a needle or bullet. These centres of irritation may be internal, and escape the attention or be out of reach of the physician. Dr. Greenhow† reported the case of a girl in whom epilepsy appeared. A splinter of wood was subsequently discovered beneath the thumb-nail; four months after the removal of this the patient was cured.

Those forms of epilepsy which depend upon injuries of the head or intracranial tumors resist all forms of treatment, except it may perhaps be trephining. I have not myself had occasion to use the trephine, and cannot speak in regard to its merits. Echeverria gives three cases where trephining effected a cure. Of the other subjects trephined for secondary nervous disorders, 149 cures are recorded by various authors. Epilepsy due to syphilis is often caused by a tumor in the brain substance; and specific treatment will usually benefit or cure the patient.

TREATMENT OF UTERINE FLEXIONS

BY THE

INTRA-UTERINE SELF-RETAINING STEM.

By ELY VAN DE WARKER, M.D.,

SYRACUSE, NEW YORK.

In an article in *The New York Medical Journal* for October, 1873, I gave a description, with an illustration, of a new form of self-retaining intra-uterine stem. In order to make that article as brief as possible, I said nothing of the peculiarities of the treatment of uterine flexions with my form of stem. I shall in this article detail those conditions which are essential to the successful wearing of the self-retaining stem. In the first place, it is of course understood that there exists no lurking perimetric or parametric inflammation, either acute or chronic. It is best to make sure of this by a careful examination of the history and present condition of the patient; for it is a

* *London Lancet*, July, 1868. † Quoted by Paget.

matter of common experience how easily a slumbering intra-pelvic peritoneal trouble, or its allied affections, can be roused into troublesome if not dangerous activity by untimely manipulation. The next thing to be considered: Is the womb in such a condition as to bear the persistent presence of a foreign body in its cavity? This is a very important matter. In some conditions of the uterus and of the nervous system, the slightest intrusion of a foreign body into its cavity leads to serious results. I shall never forget my astonishment when a young and strong woman passed into a state of convulsion, with insensibility, the moment a sound, carefully used, passed into the cavity of her womb. From this extreme degree there are all shades of resentment at the introduction of a foreign body into this cavity. Some idea may be formed of the amount of uterine tolerance by the tenderness with which the organ responds to the touch. In a retroflexion, for instance, when the finger comes in contact with the fundus in the retro-vaginal *cul de sac*, a keen sensibility to even slight pressure may be elicited. The introduction of a sound or repositor would also cause great and lingering pain. In such a case the wearing of an intra-uterine stem might lead to severe symptoms. The first of these contra-indicating conditions ought to be carefully treated before the employment of the stem. Another thing to be considered is, whether the fundus in its abnormal position has contracted such adhesions as would render its reposition exceedingly painful or doubtful. In case such a condition is found to exist, it is necessary to understand the theory of this form of stem, in order to appreciate the extent to which the stem would give correction to the error. If the adhesions are firm and unyielding, the mere flexion might be corrected; but this could be done only by throwing the neck forward above the pubes, while the fundus, yielding nothing to the presence of the stem, would cause the womb to occupy a position at about right angles to the axis of the vagina. It is evident at once that this or any other form of stem could not be borne. This follows from the fact that the self-retaining stem will correct a flexion, but is powerless to restore a version. I said in *The New York Medical Journal* article, that the existence of a version is not incompatible with the cure of a flexion. While this is true to a degree, I am not prepared to announce it so unequivocally here. The use of this stem in a case in which the organ persists in its retroversed position, will often develop pain in defecation, and a bearing down, with extreme backache, not present in so extreme a degree previous to the correction of the flexion. Whatever version there may be present then, if it requires any treatment at all, must be treated independently of the presence of the stem, in the manner I shall describe. A retroflexion corrected by the stem is almost sure, if the womb is a small one, to result in a retroversion. This results, I believe, from a weakening of the forces which sustain the uterus in a normal position, owing to the long-depressed state of the fundus.

So far as the uterine supports are implicated, a flexion is an intensified form of version; the sustaining forces of the fundus being more involved in the former than the latter state of dislocation. It is possible also that partial adhesions may exert more or less restraint to the organ assuming the erect position. This tendency is, however, no bar to the successful use of the self-retaining stem, as its correction is a simple matter.

The condition of the uterine surroundings not contra-indicating the treatment of the flexion, it ought to be ascertained how well disposed the cavity of the womb is to the intrusion of a foreign body. If the cavity of the womb is very sensitive to the presence of a sound, or if its introduction is followed by long continued or severe pain, and possibly by some blood, we have most likely a chronic endometritis to contend with. So far as this state of extreme tenderness is concerned it ought to be remedied before the employment of the stem. To cure the endometritis, under the most favorable circumstances, involves too much time and uncertainty to delay the treatment of the flexion on this account. The sole purpose of the preliminary treatment is to remove that degree of sensibility which renders the wearing of the stem painful or inconvenient.

There are two ways of doing this. The first is by frequently passing a sound and leaving it in position for ten minutes or half an hour, and repeating this from day to day until the sensibility of the diseased membrane is changed. This sometimes takes more time than either the patient or physician has to give to it. A quicker and, I think, better way, is to treat the inordinate sensibility of the endometrium by the free use of the intra-uterine caustic instrument. The cavity of the womb is to be freely touched in every part with the nitrate of silver, by moving the instrument back and forth and slightly turning its point. This is sometimes followed by acute pain, which I think is better treated by a medicated pessary charged with morphia and coneia—gr. ss. vel gr. i. morph., et gr. i. vel gr. ii. coneia—than by morphia either by the mouth or hypodermically.

This treatment may need to be repeated three or four times, at the necessary intervals, before the acute sensibility of the cavity is removed. But those are extreme cases which require any treatment so heroic as that named above. In the majority of cases it is usually sufficient to train the womb by passing the sound and twirling it forward or backward as the flexion may require, as much for the purpose of keeping the organ straight for the introduction of the stem, as for testing the degree of sensibility. So far as tenderness of the body upon pressure is concerned, I have yet to see the flexed uterus in which slight pain to the touch has not been present. In the majority of cases I think this sensitiveness to pressure is more physiological than inflammatory, due to a partially constricted state of the pendent fundus. This idea is corroborated by the facts that this tenderness often disappears upon wearing the stem; and that it is circumscribed, as is proved by passing a sound with the proper curve; and pressing the uterine wall directly involved in the flexion back upon the sound, considerable tenderness will be developed; but by pushing the sound against the opposite wall, the tenderness is much less marked.

The introduction of the stem is a simple matter. It is necessary to straighten the organ in the manner mentioned above. No judicious amount of force will insert the stem into a uterus acutely flexed without this preliminary repositing to about the normal axis. Ten to fifteen minutes are usually sufficient to keep the sound in position; on its withdrawal, the organ will retain its place long enough to allow the insertion of the stem. In case the uterus returns to its flexed position

directly on the removal of the sound, the posterior vaginal *cul de sac* may be tamped with cotton-wool with the sound in position, which, on the removal of the sound, retains the organ in position and the stem glides in easily. No speculum is necessary either in the preliminary use of the sound or in the insertion of the stem. The stem placed upon a wire is used in the same manner as the sound. The finger, after the stem is well in position, is placed against the small button projecting from the external os to prevent the withdrawal of the stem while the wire is being removed.

The patient should be kept under observation for three or four days before being sent home—if she resides at a distance—in order to observe the tendency to version, and how well the stem is borne. In some cases the stem will slip partly out after being worn for a day or so. This results from either the cross-section of rubber tubing being too short, or the perforation for the tubing being too near the uterine end of the stem. In either case it is easily corrected. A longer piece of tubing may be passed, or the cross-section passed through a new perforation nearer the internal os. In future, I shall direct the maker to make two perforations for the cross-section, so that its position can be changed. If version should exist to a degree requiring correction, the posterior vaginal *cul de sac*, in a case of retroflexion, may be filled with a pessary of carbolized cotton-wool in sufficient amount to support the womb at the proper angle. This is the best material I have yet found for this purpose. I have removed such a cotton pessary after being in position ten days, and have found it free from any offensive odor. The pessary ought to be changed once a week. The stem, well in position and well borne, should remain in for from two to three months. I have not found that its presence produced any noticeable change in either the symptoms or character of the menstruation.

To inform those who have not seen the description of my stem already published, it may be well to give a few words in description. It consists of a hard rubber stem, two and a half or two and three-quarter inches long, slender and slightly bulbed at the extremity; the portion projecting from the external os is in the form of a small button with rounded edges; at this end a small hole is drilled for the wire by means of which it is introduced. The self-retaining portion is very simple. It consists of a cross-section piece of French rubber tubing, one-sixteenth inch calibre, and three-eighths of an inch long, passed through a perforation in the shaft of the stem half or three-quarters of an inch from the bulbed extremity. The purpose of this cross-piece of tubing is, that after being pressed down by the side of the stem, in passing through the canal of the neck, it will expand in the cavity of the uterus at right angles to the stem, and thus retain it in position. In ordering, the physician should designate the length of the stem after careful measurements.

Dr. John P. Adams, dentist, 70 South Salina street, Syracuse, has kindly consented to vulcanize a few of these stems, so that those who wish to test the value of the invention can procure the instrument through him.

To the gynæcologist many of the details presented in this paper are not necessary for the intelligent use of the stem; but to the general practitioner, who may not be so familiar with the manipulations in this department of medicine, an attention to these details will save much annoyance in case of employing this instrument.

Dr. Peter Van Buren, of New York, died Dec. 7, 1873, aged 71.

Reports of Hospitals.

BELLEVUE HOSPITAL.

Notes of Practice and Peculiarities in Treatment.

ASCITES.

A case was noticed in which this symptom was developed in a very marked degree. The man was 50 years of age, and had but little in his history to account for his present condition.

The dropsical accumulation was so extensive that the case presented some features of interest relative to arriving at a correct diagnosis. He had been in the habit of taking brandy "straight," and upon an empty stomach. That might be suggestive of cirrhosis of the liver as being the cause of the ascites; but the accumulation of fluid was so great that the suggestion could not be confirmed by physical examination.

There was, however, enlargement of the veins running over the abdomen, which almost absolutely proved that there was portal obstruction if the flow of blood in them is upwards.

The flow in this case was from below upwards.

Auscultatory percussion is the most satisfactory method of marking out the size of the organs in the abdominal cavity under such circumstances.

In this case there was some œdema of the lower extremities, which might be due to different causes: First, Bright's disease; second, the general cachexia incident to cirrhosis or contraction in the liver, causing pressure upon the vena cava.

In treating such a condition, the kidneys are almost always first addressed. When such extensive accumulations of fluid exist in the abdominal cavity, these organs are also usually oppressed; but it does occasionally happen that diuretics will carry off the fluid. The success of diuretic treatment is exceptional.

If cathartics are employed, the salines are regarded more favorably than the drastics, on account of the exhaustion of strength which the latter are liable to produce.

A valuable prescription, and one which can be repeated for a long time without producing any special exhaustion, is the following:—

℞ Magnesiæ sulph. . . . . ℥ i.
Fld. ext. sennæ. . . . . ʒ i.
M.

This may be repeated every other day. Two conditions of the liver may give rise to the ascites—cirrhosis and peri-hepatitis. In either case the principle is the same, viz., obstruction to portal circulation.

Paracentesis is to be resorted to when the patient suffers imminently from the amount of accumulation. All agree upon this point. Opinions differ, however, with regard to the propriety of performing the operation early. The greater majority of observers adhere to the opinion that it is better to defer paracentesis until all other measures for removal of the fluid have been employed without effect, unless the sufferings of the patient demand immediate tapping. Upon the other hand, there are eminent observers who express the positive opinion that early tapping is the most rational method for removing the fluid. The reason for the hope that is within them is—

First.—Diuretics very generally fail.

Second.—Cathartics less generally fail, but the beneficial effects derived from their administration does not balance their perturbatory effects upon the general system.

Third.—Diaphoretics are but seldom employed, and when employed, very generally fail.

Fourth.—Removal of the fluid relieves the abdominal viscera from pressure, and affords opportunity for the administration of tonic remedies and proper alimentation.

Fifth.—The objection urged that one effusion after another will occur, necessitating a repetition of the operation, consequently exhausting the patient, is not sustained by practical experience. The fluid will return, it is true; but that the patient is worse for that reason, is not believed by this class of observers, for it can be removed at any time when it becomes distressing. Such are some of the arguments in favor of early tapping.

FACIAL PARALYSIS.

An interesting illustration of this common malady was noticed in a man above 45 years of age. No cause could be found for the occurrence of the lesion. The man awoke in the morning and found his face distorted. Upon close examination it was found that there was loss of smell upon the same side of the nose with the paralysis, and also loss of taste upon one half of the tongue upon the same side, thus enabling his medical attendants to arrive at quite definite conclusions with regard to the seat of the lesion.

There was some tenderness over the mastoid region, along the course of the nerve. Iodide of potassium, leeches, and electricity form the main features of treatment. In some of these cases the constant current will act, and the primary current will not; but in this case the constant current would not act, but the primary current would.

COMA AND CONVULSIONS.

Special reference is made to a case of coma and convulsions, in connection with lead-paralysis, and thought to be dependent upon the same cause of the paralysis. A critical and careful examination of the urine furnished no evidence of renal disease. It occasionally happens that renal symptoms are developed in connection with lead-paralysis dependent upon intercurrent renal disease developed by the lead-poisoning. In this case, however, there was no such evidence obtained.

Progress of Medical Science.

THE ECHISES SCHOLARIS AND THE GARCINIA MANGOSTANA.—These two new remedies were presented at the late International Exposition in Vienna. The bark of the first tree is considered a specific remedy against all kinds of fevers. Mr. Gruppe, of Manilla, has extracted from it a bitter active principle called ditaina, which he considers better than the sulphate of quinine, and much cheaper. From the fruit of the second the same chemist has extracted a fluid called Anti-dysenteric Extract of Garcinia Mangostana. This extract has proved a very valuable remedy in dysentery, chronic diarrhœa, catarrhal affections of the uterus and bladder, and in all affections where astringents are indicated.—*Sperimentale*, Sept., 1873.

THE TEMPERATURE OF THE SEXES: AN INDICATION OF DEVELOPMENT.—Under this caption Dr. J. Stockton Hough has published a very valuable paper, showing the most extensive researches in biology. He tabulates his conclusions as follows:—

1. That males have, as a rule, from the beginning to the end of life, a higher temperature and a less frequent pulsation of the heart than females, varying, nevertheless, according to temperament, constitution, age, and condition of health.

2. That children at birth, and for a short time subsequently, have a high temperature which, though slightly lower than that of an adult, nevertheless slowly and gradually declines to a certain point until about the sixth year of age is reached, after which it gradually increases until developmental maturity is reached, when it gradually and slowly declines again as old age (second childhood) advances.

The pulsation of the heart follows just the opposite course, being most frequent when the temperature is lowest, and least frequent when it is highest.

3. That males appear to have a greater variation in temperature than females, thus agreeing with their greater variation in stature and many other peculiarities.

4. From all of which we conclude that the woman approaches more to her condition as a child than the man does, and is consequently less highly developed. —*Phil. Med. Times*, Nov. 8, 1873.

ON THE SURGICAL USE OF GASTRIC JUICE IN THE TREATMENT OF CANCEROUS TUMORS.—Professor Lussana after several years of experiments and observations has arrived at the following conclusions: 1. Gastric juice applied to these tumors softens their tissues, but its action is not powerful enough to arrest the progress of the disease. 2. That natural gastric juice is more reliable than the artificial. 3. It does not destroy the vascular tunics, but arrests local hemorrhage produced by the destruction of tissues. 4. The gastric juice of dogs was found to act slowly; indeed, it did not much retard the development of the tumor. 5. There is a continuous exhaustive loss of substance during treatment, and it is probable that though the cancerous elements are dissolved by this remedy, the further extension of the disease is not prevented.—*Gion. Ven. di Sci. Med.*, Sept., 1873.

PUERPERAL AMAUROSIS: ITS IMPORTANCE AS A SYMPTOM.—Dr. H. W. Williams, of Boston, gives two cases of this form of disease, occurring in his own practice, and adds four that have already been published by Dr. F. Weber, of St. Petersburg. He believes that puerperal amaurosis has some relation with puerperal convulsions, though he does not regard the former as invariably the forerunner of the latter. Indeed, eclampsia occurs far more frequently, and often precedes the blindness. Yet the occurrence of amaurosis during parturition should be regarded as a symptom of grave importance. The presence of albumen, though it frequently occurs, does not seem to have an absolutely determinative influence; it is absent in some cases, and in others may outlive the amaurotic symptoms. Primiparæ are seldom attacked, while the reverse holds true with regard to eclampsia. Fortunately, an attack of the disease at one puerperal period does not involve the probability of its occurrence at any subsequent one.

Dr. Williams does not recommend any special treatment in these cases, though he advises his patients to avoid any unusual fatigue or exertion that may induce cerebral congestion; and if amaurosis occurs, advises great watchfulness on the part of the physician to arrest, if possible, puerperal convulsions.—*Boston Med. and Surg. Jour.*, Oct. 16, 1873.

LUMBAR COLOTOMY.—Dr. Erskine Mason has published a report of six cases in which he has done this operation, and appends a table containing the records of eighty other cases. He believes that in the hands of a

good anatomist and careful operator the difficulties of almost every case will be overcome, and for the majority of cases the operation will be found easy, and, as far as the life of the patient is concerned, safe.

As to the objection which patients will very naturally urge against the artificial opening produced by colotomy, he says that the testimony of very many of those who have been operated on, and the experience of the surgeons who have seen the largest number of cases, is that an artificial anus has comparatively little inconvenience. These patients are not troubled with a continuous discharge of either flatus or fæces, a suitable pad being sufficient to prevent such a condition of things; and they may pursue their vocations and mingle with people without disclosing their ailment. In many cases the bowels have been found to act as regularly, and not more frequently, than when this condition did not exist.—*Am. Jour. of the Med. Sci.*, Oct., 1873.

New Operation for Aneurism.—A novel operation was performed very recently at the Pennsylvania Hospital of Philadelphia, by Dr. R. Levis, and the result, if the case turns out favorably, will be a very decided advance in surgery. The case was one of subclavian aneurism, involving possibly the innominate. As ligation of the artery was deemed inexpedient by the surgeons who examined the case, Dr. Levis determined to carry out a plan of his own, which is a modification of that adopted by Dr. Moore, of the Middlesex Hospital, and since followed by Dr. Donville and Mr. Murray, of England. The plan of these latter gentlemen was to introduce fine wire into aneurisms, to afford a nucleus about which clots could form. Dr. Levis conceived the idea of using horse-hair, believing that it would offer sufficient obstacle to the blood-current to produce coagulation, and also, being animal in its nature, would act like the catgut ligature and not give rise to suppuration. The horse-hair was introduced through a fine sharp needle canula, which was plunged into the sac. No difficulty was experienced in its introduction, and twenty-four feet nine inches were safely stowed away in the aneurism. A marked diminution in the force of the pulsation of the aneurism, and of the pulse of the wrist, was at once induced. This has increased since the operation, the tumor has also gained in solidity, the pain has lessened very much, and no unfavorable symptoms have resulted. At last accounts the case was still progressing favorably.—*Phila. Med. Times.*

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month, by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, December 15, 1873.

RANK OF THE MEDICAL CORPS OF THE UNITED STATES ARMY.

Our readers will recollect that in our report of the last meeting of the American Medical Association there appeared a letter from the medical officers of the army, which set forth, that in the present organization the medical staff was not upon an equal footing with similar corps as regards rank, and that great injustice was done by special legislation preventing promotions or new appointments. It will also be recollected that resolutions were passed expressing the opinion that the rank of the medical staff of our army should be equal to the relative rank held by the same corps in the navy; also that a committee of representative men from different sections of the country was formed to memorialize Congress upon the subject.

The committee in question have performed the labor assigned them, and have made the draft of a bill which must meet with the approval of the medical profession of the country. It is as follows:—

"Section I.—Be it enacted by the Senate and House of Representatives of the United States of America, in Congress assembled, That so much of the sixth section of the act entitled, 'An Act making appropriations for the support of the Army and for other purposes,' approved March 3, 1869, as forbids promotions and appointments in the medical department of the army, be, and the same is hereby, repealed.

"Sec. II.—And be it further enacted, That the organization of the medical department shall be as authorized in the seventeenth section of the act entitled, 'An Act to increase and fix the Military Peace Establishment of the United States, approved July 28, 1866. *Provided*, that from and after the passage of this Act, the Chief Medical Purveyor and four Assistant Medical Purveyors, now authorized by law, shall have the rank, pay, and legal allowances of colonels; and *Provided, further*, that surgeons who have served thirty years and upwards, from the date of their original entry into service, shall have the rank, pay, and legal allowances of colonels, and surgeons who have served less than thirty and more than twenty years, from the date of their original entry into service, shall have the rank, pay, and legal allowances of lieutenant-colonels, and all other surgeons shall have the rank, pay, and legal allowances of majors as now authorized by law, and the rank, pay, and legal allowances of assistant surgeons shall be as now authorized by law. *And Provided, further*, that the foregoing provisions of this Act shall apply to all officers who may hereafter be promoted in the medical department.

"Sec. III.—And be it further enacted, That nothing in this Act shall be construed to permit the appointment or promotion of any person in the medical department until he shall have passed the examination now required by law.

"Sec. IV.—And be it further enacted, That all laws and parts of laws inconsistent with the provisions of this Act be, and the same are hereby, repealed."

Two years ago our brethren of the navy made demands for increase of rank, and after a long fight and by sheer force of argument obtained the passage of the act of March 8, 1871. This act gave the rank of Captain—equivalent to that of Colonel in the army—to fifteen medical officers, and the rank of Commander—equivalent to Lieutenant-Colonel in the army—to fifteen others. Our brethren of the army now ask an equal consideration in their behalf, and as the first step in the direction of justice, have a right to demand that the act of March 3, 1869, prohibiting promotions in the medical staff, be repealed.

As a profession we are more than ordinarily interested in this matter. The medical staff in the army represents us in that branch of the service before our country; and while we pride ourselves upon this representation as being in every respect what it should be, we are mortified to learn that their modest claims for ordinary recognition for meritorious services, of relative rank with other staff corps, is so shamefully, so unnecessarily, so unjustly ignored.

Under the present circumstances, what inducement is there for any well-qualified medical gentleman entering the army? He obtains the rank of first lieutenant at first, it is true; and after, perhaps, thirty years' service, he obtains the rank of major, but here his ambition for any higher grade is effectually checked by a law forbidding him to look higher. When worn out and desirous of availing himself of the retired pay, he receives a pittance hardly sufficient to give himself subsistence, leaving out of the question the support of a family. Can we wonder that there are vacancies in the corps? The vacancies do not exist because the profession do not think it an honor to fill them. The distinction of

being an army-surgeon has always been a proud one, but under existing circumstances it is far from being a desirable one.

Surgeon-General Barnes, in his last annual report, thus truthfully gives the sentiment of the profession upon the subject, and we particularly commend his statements to the powers that be:—

"I am compelled to again repeat the statement made in previous reports, that very serious and increasing injury has resulted to the service from the continued prohibition of appointments and promotions in the Medical Corps. The inducements of pay and rank, as at present established, are not sufficient to make the service attractive or remunerative to physicians already engaged in practice; and though, through the prerequisite rigid examination of candidates, it has heretofore been found possible to secure a high grade of talent and qualification, it is upon the younger portion of the profession, the recent graduates, that we must depend in filling up existing vacancies. As a large proportion of applicants fail to pass satisfactory examinations (which require in each case from three to six days), it will be the work of several years to restore the Corps to the necessary standard of numbers as provided for in the Act of Congress approved July 28, 1866. Although ambition to pass the Army Medical Board brings forward many of the most promising graduates of the medical colleges, additional inducements of rank, pay, and promotion are becoming more and more necessary, not only to make the number of candidates equal to the needs of the service, but to retain the most desirable of them in the service under their frequent inducements to accept advantageous offers in civil life. The action of the American Medical Association, representing the medical profession of this country, regarding the unequal position of Medical Officers of the Army as compared to that of other Staff Corps, is based upon actual investigation of the subject, and presents to Congress all the facts in the case."

The passage by Congress of the bill in question is not only of the greatest possible moment to the Army Surgeons, but to the profession and the country at large. The time has come when we must, individually and collectively, exert our influence in the proper direction. There will doubtless be the same opposition to the passage of this bill as was the case with that for Naval Staff rank, but this should rather encourage than dishearten us. The Medical Staff of the army make a very modest request, and we heartily sympathize with them in their endeavors to have it granted. If they fail—if their meritorious services cannot be appreciated—we can comfort them with the assurance that there are plenty of opportunities for them outside of the army, to reap the rich fruits of their labors in the cause of science and humanity. We have always plenty of room for such men, if the country cannot afford to keep them.

THE CLOSE OF VOLUME VIII.

The present number closes the year and completes the Eighth Volume of The Medical Record. It is always easier to retrospect a task satisfactorily and conscientiously performed than to prospect promises which may not always be fulfilled. We propose at present to adopt the former course; to refer to accomplished facts, that we may enable our readers to draw their own inferences.

It is not our purpose, in speaking of the business success of our enterprise, to say more than that the circulation has markedly increased during the past year, and that the area of usefulness of the Record is extending to a degree that warrants the exercise of our best endeavors to deserve this flattering endorsement of the profession. We are well satisfied that it is doing as well as can be expected of any medical journal anywhere, and all we have to hope is, that the ratio of increased patronage may continue the same as for the past two or three years. We take this as an evidence, not so much of the good fortune of a particular periodical, as of a growing interest in the cause of medical literature in general. We believe that the profession, as a whole, read, think, and write more than they did ten or fifteen years ago. Medical journals are looked upon more as the means of reaching large audiences and of founding reputations, than as mere pecuniary risks of editors or publishers, for whom articles used to be written more for friendly aid than for anything else. Instead of begging for articles as formerly, the Editor finds it oftentimes difficult to find room for such as come unsolicited from the first writers in the country. While this may not be so well for every one who can write as it was twenty years ago, it is certainly better for the readers, giving them the advantages of a wide range of selection. We have endeavored to give our readers such an advantage, keeping constantly in mind the pressing wants of the reading and progressive general practitioner. Our table of contents will show that our transatlantic brethren are beginning to appreciate the benefits of addressing American audiences. Europe is sending to us its best platform speakers; its best novelists fill our literary magazines with original stories; and now its scientific medical men are beginning to offer their fresh manuscripts to American medical journals.

In our Lecture Department we have endeavored to give an array of subjects interesting to the active workers of our profession. Many of these lectures were given by special invitation, and phonographically reported. The advantages of the system which we have followed since the very commencement of the Record are obvious enough to any who will for a moment consider the subject. A lecture has many advantages over an original article. The style is suited to every learner, enabling the teacher to treat of his subject in detail, to give attention to little points, and

to colloquialize them in such a way as shall make them more than ordinarily impressive. In a word, the lecturer gives himself a latitude which would be unexpected and uncalled for in the writer of an original article. Again, such lectures may be looked upon as treasures of thought and as recitals of experience which would be entirely lost to the medical world if it were not for the skill of the phonographer who catches each word as it falls from the speaker.

In the last volume we have introduced a new feature in our hospital department, which we have reason to know meets a want long felt by such as are debarred the advantages of witnessing practice on a large scale. Our idea has been to generalize the experience of the different institutions in such a way as to give each and every reader the advantage of the most extensive observation in the treatment of any particular disease. This has been done by personal visitation of the different hospitals, and from notes carefully taken on the spot from the most authoritative sources. The credit of working up the material is due to Dr. Wesley M. Carpenter, of this city, a member of the staff, who has also reported for us many of the lectures. The admirable manner in which both these tasks have been accomplished we leave our many readers to judge.

We believe we have met another want in supplying to our readers a list of the original articles in our exchanges. It is obviously impossible to extract everything from our exchanges and find room for the same in the department of Progress of Medical Science. We have endeavored to compromise the matter by giving an abstract, as far as we are able, of all items of practical interest to the general practitioner, and merely indicating such papers by title as may be of interest to specialists and other classes of readers who may wish to have a general idea of what is going on about them, or to follow up some particular line of inquiry. The department of Progress of Medical Science represents the conjoint labors of several members of the staff. Dr. F. A. Castle has had charge of the English and French exchanges; Dr. Thomas E. Satterthwaite, of the German and Italian; Dr. Geo. R. Cutter, of the Scandinavian, Spanish, and Portuguese; and Dr. B. S. Thompson, of the American. We have, through the efforts of these gentlemen, been enabled to keep our readers well informed of the progress made in our art in different parts of the globe, every item being selected with special reference to its practical character.

Of the Editorial Department proper it does not become us to speak, except to say that in the discussion of the current medical topics we have striven to maintain for the journal independence of thought and judgment, an earnest desire to arrive at the truth, and a determination to do justice to all, irrespective of any party or clique whatsoever.

The plan of our Review Department has been to have notices written by experts in the different branches of medicine, and to exercise all the care necessary to obtain an impartial judgment of all the works submitted to us.

Our Society Reports are prepared specially for this journal, and mostly from phonographic reports. All the prominent societies have been thus represented.

Lastly, we would remind our readers of the addition which we have made in the establishment, during the past year, of the Medical Department for Life Insurance. As a department it has been a success, and has in many ways exceeded our expectations. Every care has been taken to exclude everything having any advertising tendency, confining the discussion of the various subjects interesting to medical examiners of life insurance companies to their scientific aspects. The credit of the general management of this department is due to Dr. A. H. Buck, the medical director of one of the life insurance companies of this city, whose experience and discrimination eminently fit him for the position.

Reviews and Notices of Books.

A Manual of Practical Hygiene, intended especially for Medical Officers of the Army and for Civil Medical Officers of Health. By Edmund A. Parkes, M.D., F.R.S., Prof. Military Hygiene in the Army Medical School, etc., etc. 4th edition. Philadelphia: Lindsay & Blakiston. 1873. 8vo, pp. 665.

The reputation of this work is well established and well earned. There has been so much said concerning sanitary science, so many crude suggestions made, so many wild theories promulgated by parties who choose to cultivate hygiene as a business, that it is refreshing to come down to the matter-of-fact science of the subject. In regard to accurate information founded upon observation and experience, Professor Parkes's book is not only a model in its way, but leads all other works of its class. When the first edition appeared as a text-book on hygiene for the Army Medical School of Great Britain, its purpose was avowed; and although meeting with the hearty endorsement of every friend of the soldier, and considered as a remarkably exhaustive *exposé* of useful scientific data, it failed to meet a want felt outside of the army. Still there has always been enough to learn on general hygiene to make the book desirable for every practical sanitarian, be he military or civil. In the last edition the long-wished for modification in the arrangement, in giving due prominence to civil hygiene, has been made, which gives the work the widest possible range for the general sanitarian, the scientist, and the political economist. Instead of the military part taking the lead, it is replaced by that portion intended for civil medical officers of health, more particularly.

In consequence of such a change, much new matter has been added, increasing the size of the volume.

For such as may not be acquainted with the general character of the work, it may be necessary to glance in a cursory manner at the divisions of the subjects and the plan of their treatment. The chapter on water, which is the first of the book, comprises a discussion of every matter connected therewith, its quantity, supply, distribution, composition, impurities, etc., and as a whole is full of very interesting, curious, and sug-

gestive facts. Air, which is the subject of the second chapter, is treated in the same exhaustive manner; section II., referring to the diseases produced by impurities in the air, is quite exhaustive and full of accurate information. The chapter on ventilation next follows, and gives a complete *resumé* of the science of the subject up to the present date. The numerous diagrams help the reader to appreciate at a glance the relative merits of the different systems as applied to hospitals, etc.

Food and its preparation occupy two long chapters. The nourishing qualities of each particular article are stated, the mode of detecting adulterations, the best methods of cooking, and the diseases caused by the use of improper articles of diet. The facts bearing upon the latter point are quite curious. In regard to food as a whole, a general mixed diet is insisted upon as the *sine qua non* of health, most of the data upon which such an opinion is founded having been gathered from an examination of the dietaries of armies. Condiments receive their share of attention as accessories; vinegar, pepper, and mustard being accorded their proper rank. Malt and alcoholic liquors are not considered of any special service, but on the contrary are, as far as the examination of the facts, as gathered from the experience of their use in the British army, go, shown to be not only useless but detrimental. Coffee and tea are properly ranked among the mild stimulants and arresters of tissue-waste. The chapters on soils, habitations, removal of excreta, warming houses, exercise, clothing, are full of interesting facts and useful hints. Climate, in its relations to health and disease, is discussed in Chap. XIV., and presents in a very concise and comprehensive manner the present advanced views upon the subject.

In reference to the prevention of common diseases and disinfection, nothing specially new is given, but all the necessary facts bearing upon the different divisions of these general questions are intelligibly presented. The second division of the book is devoted exclusively to the service of the soldier; and the statements made, and the conclusions drawn, are also based upon experiences and observations in the British army. These experiences are of particular value in establishing many points bearing more particularly upon the influence of climate, habits, diet, and clothing.

This edition is elegantly printed, and is embellished with its usual number of beautiful plates of the microscopical appearances of impurities in water and adulterations of different articles of food. Altogether it is the most complete work on hygiene which we have seen.

A PRACTICAL MANUAL OF THE DISEASES OF CHILDREN. With a formulary by EDWARD ELLIS, M.D., London, Physician to the Victoria Hospital for Sick Children, etc., etc. 2d edition. Lindsay & Blakiston. 12mo, pp. 333.

THIS little work treats of the principal diseases of infancy and childhood. It does not claim to be exhaustive in any sense, and consequently not a great deal is expected. The reader will, however, be very agreeably disappointed to find such a large amount of valuable and practical information in such a small space. The author has a faculty of sketching out the characteristics of disease and their treatment in striking outlines, and of making his points very clear and impressive. We have perused it with much satisfaction, and commend it to the attention of practitioners generally as a work of singular excellence.

DR. ALFRED UNDERHILL, of this city, died Dec. 7, 1873, aged 57.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, Oct. 22, 1873.

DR. ERSKINE MASON, PRESIDENT, in the Chair.

DR. JANEWAY presented a specimen for a candidate—as did also the secretary.

Dr. Janeway stated that the tumor of breast presented by Dr. Crosby at the last meeting was one of simple scirrhus. The cells in the central portion were quite granular. The point of interest was, that the periphery of the tumor showed infiltration of disease.

DILATED AND HYPERTROPHIED HEART.

DR. HALL presented a specimen of dilated and hypertrophied heart, adherent pericardium, with fatty and cirrhotic kidney, and fatty and cirrhotic liver.

Mary Hyland, admitted to Charity Hospital July 21, 1873, stated that her mother and daughter died of dropsy. She had swelling of feet and ankles four years ago, which condition lasted two months. No further trouble until one week before admission to hospital, when her feet and ankles became œdematous. At this same time she was taken with pain in the lumbar region. Complains of drowsy feeling and occasional attacks of dizziness. She is poorly nourished and pale. There is œdema of the feet, ankles, and eyelids. Urine contains albumen and fatty casts. Mitral regurgitant murmur. Patient's abdomen began to distend two weeks after admission. The anasarca and ascites slowly increased; in spite of the treatment, patient gradually lost strength and died of exhaustion, Oct. 18, 1873.

The autopsy was made eleven hours after death. Woman large and well nourished. Abdomen anasarcous, sub-conjunctival effusion, pupils very much dilated. Both lungs were œdematous and congested. The heart was enlarged, the walls thickened, and cavities very much dilated. The pericardium was adherent throughout. The kidneys were much reduced in size, the capsules were adherent, and their surface nodulated. The tubes were fatty, and the markings of the cortex were not demonstrable. The intestines, genitalia, and urinary apparatus were normal.

Adjourned.

Stated Meeting, Nov. 12, 1873.

DR. ERSKINE MASON, PRESIDENT, in the Chair.

PERICARDITIS IN A CHILD AGED EIGHT YEARS.

DR. MARY PUTNAM JACOBI presented a specimen of pericarditis in a child aged eight years. Two years previous to death the patient had an attack of chorea which lasted two weeks, but never any rheumatism. When first seen on Sept. 21, a diagnosis could be made very easily. There was great hypertrophy of the heart, dulness extending from the second to the seventh ribs and to the right of the sternum. The condition of mitral insufficiency was very marked, there being a loud blowing murmur at the apex, prolonged at the back. There was also found pneumonia of the middle lobe of the right lung.

The child improved somewhat under the treatment of digitaline and iodide of iron, but a relapse occurred on the 26th of Oct. The symptoms at that time were bronchial respiration on left side, dyspnœa, and the other physical rational evidences of pneumonia. The temperature ranged from 101° F. to 91° F., remaining

at the latter for some days previous to death. The patient soon became very much prostrated. On auscultation no exocardial murmuring could be discovered. The endocardial murmur was the same as before, except that during the height of the acute attack it was somewhat muffled. The area of former dulness was also somewhat increased.

During the last three or four days the face became œdematous, the dyspnœa increased, and the child finally died with symptoms of pulmonary œdema.

The heart, lungs, liver and spleen were presented for examination. The pericardial surface of the left ventricle was adherent throughout, and the other surfaces were covered with recent lymph. At the posterior surface over the right ventricle there were evidences of hemorrhagic extravasation. The mitral valve was insufficient, one-half being completely destroyed, and the other much thickened. The other valves were healthy. The presence of the recent lymph, with the absence of exocardial murmurs, entirely coincided with the fact so often noticed by authorities when an acute and secondary attack of pericarditis occurs.

The pericardial effusion was quite sanguinolent, the lungs were both very œdematous, and the middle lobe of the right lung was quite hepatized. Both the kidneys showed marked venous congestion of the pyramids. The liver was markedly fatty.

The points of interest in the specimen of pericarditis were: First, its rarity in a child—occurring, according to one observer, only once in seven hundred cases, and according to another once in one hundred and fifty. Secondly, the absence of rheumatism as the cause, the first symptom showing itself in chorea. Thirdly, the absence of exocardial murmurs in consequence of the secondary acute attack of pericarditis.

Dr. Loomis remarked that the absence of exocardial murmurs in these cases depended more upon the extent and locality of the adhesions than upon the fact of its being a secondary attack. If there were no extensive adhesions on the posterior surface, so that the motions of the heart are not interfered with, exocardial murmurs would be present even in the third attack; when these murmurs could not be heard anywhere else on account of adhesions, the friction sound could be distinctly made out over that portion of pericardium which covers the aorta. The specimen of Dr. Putnam was a very interesting one in other points of view, especially in reference to the increased size of the organ.

(To be continued.)

Correspondence.

THE INVENTION OF TUNNELLED URETHRAL INSTRUMENTS.

A SECOND LETTER FROM

PROFESSOR J. W. S. GOULEY, M.D.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I have given the aggressors two months' grace to reply to my communication to THE MEDICAL RECORD of October 1, 1873, concerning the invention of tunnelled urethral instruments, and can no longer withhold from the profession the additional evidence,—a part of which I omitted in my first communication, in the hope that some acknowledgment would be made of the wrong done me.

Ample time and opportunity have thus been accorded the alleged principal complainant to deny (in writing, and not merely orally), that he had ever made, to his anonymous champion, the assertions, unsupported by a vestige of proof, in which he indulged,—and which would tend greatly to injure my personal and professional character, unless I should refute them all;—or to sustain "Honor to whom Honor is Due."

His silence may be regarded as an acknowledgment of responsibility for what "Honor to whom Honor is Due" says. I therefore think I am warranted in holding him accountable for it all,—"*qui facit per alium facit per se*"—and shall apply my remarks to him as well as to his champions.

In law, when the plaintiff fails to establish the *guilt* of the defendant, judgment is given in *favor* of the defendant. The burden of proof is always upon the *accuser's* side, and the accused is considered *innocent* until proved guilty.

In this case, however, I, the accused, fortified by truth, come forward to establish my innocence and vindicate my rightful claim.

Had I remained silent any longer under the accusation of claiming another's invention, my professional brethren would have little faith in statements which, in future, I might make upon any subject. Much as I regret to be obliged, in defence of my assailed character, to arraign before the profession a person for whom I had entertained great respect and whom I had always regarded as a sincere friend, I am compelled to do so in self-justification. His charges against me are too serious to be borne in silence. If he is right, my claim to the invention implies falsehood on my part, and I will not rest under any such imputation. Consequently I must prove him wrong; and to do this, I am obliged to place him under impeachment. Here the principles of truth and justice, as much as men's rights, are to be vindicated. If the aggressors suffer in consequence of the long-delayed investigation, it is a fault of their own, for I have not sought to injure them, but to defend myself against their gratuitous attacks—"*Veritas visu et mora, falsa festinatione et invertis valescunt.*"

It is proper now that I should clearly define my position, and thus leave no room for misconception in the mind of the reader. I claim:

1. That mine is a new *method* of catheterism upon a conductor, that is, a new *manner* of carrying out the *principle* of catheterism upon a conductor, which principle was originated and established, in the last century, by Pierre Joseph Desault.

2. That my method is an improvement on all the other modes of catheterism—in difficult cases—of which I have any knowledge.

3. That my instruments—tunnelled catheters and sounds—are different from all catheters and sounds previously known to me; that they do not bear any resemblance to the sliding tubes employed by Desault and by other, more modern, surgeons; and that they are used in an entirely different manner from the latter.

4. That the tunnel has been adapted by me to the vesical end of all urethral instruments which have been susceptible of this alteration,—hence the name tunnelled urethral instruments.

It will be perceived that it is A *method*, and not THE *principle*, of catheterism upon a conductor that I claim to have originated; and to carry this out, I claim to have invented special instruments—tunnelled sounds and catheters—the description of which shows that they are very different from those of Desault, of Doctor Buchanan of Glasgow, of Doctor Hutton of Dublin, of Mr. Maisonneuve and of Mr. Wakley.

Should it be urged that, inasmuch as I had so often

been in the company of Doctor Van Buren, he might possibly have suggested to me the idea of the tunnelled sound; I would say that the person who might offer this lame apology would surely depart from the text, beg the question, fail to understand it, or forget that the Doctor never claimed that he had made any such suggestion to me, but that I had robbed him of an invention which he had made many years ago before he knew me.

Another weak attempt at extenuation, worthy of the individual who might make the above, would be the misinterpretation of the statement, in my letter of November 19th, 1870, to Dr. Van Buren, that, "had I not made my claim public, I would most cheerfully yield to you:" which means that, rather than to have had a dispute about the matter, I would have permitted him (Dr. V. B.) to appropriate to himself what I knew belonged to me, if he had only requested it before I had made my claim public, and in print too. No one however but a partisan would interpret my ingenuous expression of a generous impulse as an acknowledgment of copartnership in the invention. Any one knowing me as well as Dr. Van Buren does, will readily recognize the fact that I have been, and am, too *self-reliant* to have accepted or ever to accept a copartnership in anything. The invention is wholly mine or it is not at all. The evidence will establish the one or the other.

If Dr. Van Buren had had the conviction that he was the author of the method I labored so hard and so constantly to establish, would he not have given the categorical answer required by my letter to him of November 19th, 1870, in which I say, "*Had I borrowed the idea from you, I should have been happy to acknowledge it.*" . . . "*I have asserted, and do now maintain, that they are mine, and no facts have been adduced to disprove my claim.*" . . . "*Your denial of any right to the invention will settle the point*". . . and which ended with, "*Now, my dear Doctor, that I have stated what I believe to be the truth in this matter; will you be so good as to set it right before the profession?*" Instead of answering the letter as it demanded to be answered, he said that it contained points the meaning of which he "could not get at." There is not a point in this letter which a medical Freshman could not thoroughly comprehend. If the Doctor was sincere in his affirmation that he could not understand the letter, so much the worse for his understanding. I wrote it with all the clearness and simplicity of which I was capable, in order to elicit from him an answer claiming or disclaiming the invention. His very failure to reply shows him to be in the wrong. But he does worse by making the claim covertly. He has not, himself, come out in print, but has induced others to do so, who evidently required little persuasion to attempt to "filch from me my good name," which is dearer to me than life. Whatever may have been their motive, they have shown a very bad animus, and are guilty of a breach of justice and of ethics. As they have failed to examine both sides of the question, which they were bound to do, they should be considered *particeps criminis*, for, to sustain wrong is to do wrong.

Every writer of a medical or surgical work, who undertakes to investigate a disputed question of priority in an invention, or in the establishment of some device tending to advance the cause of science or to relieve suffering humanity, is bound in conscience, courtesy, justice, and ethics to examine thoroughly all sides; that is, after having heard the contestants, and obtained from them in writing a clear definition of their respective positions and claims, to inquire whether all, or any part of what they claim, was previously known at home or abroad. Having done this, and weighed the whole evidence,—setting aside prejudice, partiality, or preconceived notions,—he is prepared to say: I have fairly investigated the question, and, in my opinion, the credit belongs to this or that one; or the method and instruments they both claim have long been known and used (stating where, when, and by whom), and both claimants are wrong.

The writer who does this will always have the respect and approval of the profession for his honesty and independence.

On the other hand, the investigating writer who has failed to hear *both* contestants in a question of priority of invention—whether he give credit to the right or to the wrong person—will surely forfeit the confidence of the whole profession, who will have good cause to discredit his future statements upon any topic.

The medical profession, in our days, will accept no magisterial statement, no dogmatism, however high may be the source. It requires that everything man advances, does, or claims to have done, in medical science, shall be founded upon reason, truth, and well-sustained argument, or absolutely demonstrated, before it can be received as correct.

In support of my argument against the probability of Dr. Van Buren's having *made* or used tunnelled urethral instruments many years ago, before he knew me, I have the honor to submit statements from the prominent surgical cutlers of New York City, who declare that, prior to 1864, they had no knowledge of such instruments, and that they consider me the rightful claimant of the invention: —

NEW YORK, September 1, 1873.

I, Edward Pfarre, at present partner in the establishment known as George Tiemann & Co., manufacturers of, and dealers in, surgical instruments, have, since 1837, been familiar with the workings of both the factory and the store, having served in the capacity of apprentice, workman, and foreman. I further declare that, prior to 1864, no instrument answering the description of tunnelled sound, given by Dr. Gouley in his recent work, had ever been manufactured or sold in our establishment, and that I consider Dr. J. W. S. Gouley as the inventor of the tunnelled sound.

(Signed) EDWARD PFARRE.

NEW YORK, September 25, 1773.

I, F. A. Stohlmann, senior partner of the firms known as Geo. Tiemann & Co. and Stohlman, Pfarre & Co., manufacturers of surgical instruments, beg leave to state that I have been connected with the house of Geo. Tiemann & Co. since 1840; that no instruments bearing any resemblance to tunnelled urethral instruments had ever, until 1864, been made or sold in the establishment; and that I consider Dr. J. W. S. Gouley as the inventor of tunnelled urethral instruments.

(Signed) F. A. STOHLMANN.

NEW YORK, September 2, 1873.

I have been a surgical instrument maker since 1844, having been in this capacity practically employed in Amsterdam (Holland) first; later in the establishment of A. Luther (Berlin), M. Goerck (Heidelberg), and others in Germany, up to 1850; from 1850 to 1853, at Mr. A. Lüer's, in Paris. In the last city I had, from daily visits to the principal hospitals, occasion to come in communication with the first physicians treating urinary diseases. In America I was engaged, from 1853 to 1860, in the establishments of Mr. Frederick Liese and the late Mr. Geo. Tiemann; since which

time I have had an establishment of my own, under the firm of Otto & Reynders, No. 64 Chatham Street, New York.

I have never known of tunnelled urethral instruments to bear any other name than that of Dr. J. W. S. Gouley, whom I believe to be the inventor.

I made his first tunnelled urethrotome in the Spring of 1866, and have always sold it as Gouley's urethrotome. Prior to 1864, neither in Europe nor in the United States have I seen or sold any instruments like Dr. Gouley's tunnelled urethral instruments.

(Signed) JOHN REYNDERS.

NEW YORK, September 2, 1873.

I am a surgical instrument maker, and have been engaged in this business for the past thirty-seven years, partly in Europe, and for the last twenty-seven years in this city. Up to the year 1866 I had no knowledge of an instrument called tunnelled urethrotome, in which year our firm, Otto & Reynders, made an instrument of this kind for Dr. J. W. S. Gouley, and I have never known them to go under any other name but that of Dr. J. W. S. Gouley, whom I believe to be the inventor.

(Signed) FERDINAND G. OTTO.

NEW YORK, September 4th, 1873.

I, William R. Leonard, have been salesman at Wade & Ford's, afterwards W. F. Ford & Co., manufacturers of surgical instruments in the city of New York, from 1859 to 1865. I am now principal salesman in the house of Shepard & Dudley, and have occupied this position ever since the organization of their surgical instrument department. During my connection with these establishments I have frequently sold tunnelled urethral instruments, which have always borne the name of Dr. Gouley. I know of no one else in connection with these instruments. I have always considered, and now regard, Dr. J. W. S. Gouley as the inventor of tunnelled urethral instruments.

(Signed) WILLIAM R. LEONARD.

NEW YORK, September 9th, 1873.

I have been a surgical instrument maker in England and the United States for the last thirty-eight years, and had never heard of, made, nor seen the instruments described as tunnelled urethral instruments, until they were shown to me by Dr. J. W. S. Gouley, whom I regard as their inventor.

(Signed) W. F. FORD.

In Tiemann's "Armamentarium Chirurgicum" (1872) my tunnelled urethral instruments are figured and duly credited to me. The firm Geo. Tiemann & Co., like our other cutlers, are too shrewd business men not to attribute to the right surgeon an invention which they know belongs to him. Even a mistake might be fatal to them commercially, for in that case they would probably forfeit the good-will of the wronged man, and lose the confidence and the patronage of a large proportion of the profession.

The cutlers who have made the above statements were surely not the manufacturers of the instruments which Dr. Van Buren alleges to have invented and used many years ago, before he knew me. Who, then, was their maker?

There are, in the country, ingenious surgeons who, much to their credit, have sometimes been obliged to be their own cutlers; but in large cities inventors of surgical instruments generally have them made by some responsible surgical cutler. If, however, Dr. Van Buren is able to show that he has ever been his own surgical cutler, and to exhibit a tunnelled sound which he can prove that he himself "made many years ago, and before he knew me," or if he can produce even a wooden model of the instrument, and prove that he made it many years ago, etc., I shall then say that I have unwittingly done him great injustice and shall do my best to repair the wrong. Nevertheless, my invention was made independently of anything of the sort which might before have existed. It suggested itself to me after I had read a description of Mr. Wakley's instruments, made after the plan of Desault's.

In my first communication I argued that, if Dr. Van Buren had made the invention he alleges to have made and used before 1851, it "would have been noticed and tried by his contemporaries, who would doubtless have given him due credit." But now I have the declaration of some of his former colleagues and of other surgeons of the highest repute who have practised for many years in New York. All these gentlemen declare that, prior to 1864, they had never seen, read nor heard of, any such instruments as I describe, under the name of tunnelled urethral instruments, and that they consider me the rightful claimant of the invention.

Among these surgeons are, Alfred C. Post, M.D., Professor of Surgery, Medical Department of the University of New York, since 1851, attending surgeon from 1836 to 1853, and consulting surgeon since 1853, to the New York Hospital; John O. Stone, M.D., attending surgeon to Bellevue Hospital from 1849 to 1855, and thirty-five years in practice in New York City; John J. Crane, M.D., surgeon to Bellevue Hospital since 1851, house-surgeon to the New York Hospital from 1842 to 1846; Ernst Krackowizer, M.D., surgeon to the New York and Mount Sinai Hospitals.

I might have added to this list a great number of names, but it will be sufficient for me to show that representative men in the profession, and prominent teachers of surgery, had no knowledge of these instruments until I made them known.

I shall next offer the testimony of two of Dr. Van Buren's house-surgeons who served with him, in Bellevue Hospital, many years ago. Dr. John Moore, now a Surgeon in the United States Army, and Dr. Stephen Smith, Surgeon to Bellevue Hospital, were both house-surgeons in Bellevue Hospital (1850 and 1851) in Doctor Van Buren's service, and they declare that they had never seen him use, nor heard him speak of, any urethral instruments similar to those I describe under the name of tunnelled urethral instruments.

Professor S. D. Gross, M.D., now of Philadelphia, was, in 1850 and 1851, professor of surgery in the Medical Department of the University of New York. He was then preparing his "Practical Treatise on the Diseases and Injuries of the Urinary Bladder, the Prostate Gland, and the Urethra," and was gathering facts from the experiences of the New York surgeons, whom he quotes largely. But he makes no mention, in either edition of this elaborate work, of any instruments bearing the slightest resemblance to tunnelled urethral instruments. Had they then existed—and in habitual use in the practice of a single surgeon, who had not, in violation of medical ethics, possessed a secret remedy or appliance—he would surely have noticed them; if not in the first, certainly in the second edition of his book.

In his paper on "Strictures of the Urethra of Extreme Calibre," Professor F. N. Otis, M.D., of New York,—who was aware that my claim to the invention

had been disputed on behalf of Dr. Van Buren, but who had sufficient reason to consider me the rightful claimant,—takes occasion to speak favorably of tunnelled urethral instruments, and to credit them to me.

So far, then, the evidence goes to prove that Dr. Van Buren had never made tunnelled instruments, nor employed the method of treating urethral strictures claimed for him, many years ago, before he knew me.

To the question, Were these instruments known *abroad* prior to 1864? the answer is, that none such were ever described in the British, French, or German works or periodicals prior to 1864. Sir Henry Thompson's excellent book on stricture, etc. (even to the third edition), contains nothing resembling my method or instruments. Mr. Teevan, of London, who is one of the best-informed Englishmen in urological literature, says, in his paper published in *The Lancet* of July 5, 1873: "The Americans would seem to be ahead of us on this point, for they have for some time possessed a most beautiful and useful instrument, designed, I believe, by Professor Gouley, of New York." In Ireland and Scotland the method and instruments are considered both good and new. Nothing like tunnelled urethral instruments is to be found in Civiale's voluminous writings. In Mr. Auguste Mercier's works (the most exhaustive on urinary diseases in any language), there is no mention of instruments in any way like mine. Among the inaugural dissertations for the doctorate in medicine, published in Paris, is the thesis of Dr. Bourgain (No. 88, 1870): "*De l'uréthrotomie externe sur conducteur, Procédé du Docteur Gouley.*" Dr. Bourgain was induced to write this essay from seeing one of his professors, Dr. Verneuil, perform my operation with my tunnelled catheter staff, which is not only considered good, but new in France. In Germany and Austria the instruments and method have been approved in the medical periodicals and by the best surgeons, and their claim to novelty has not been disputed.

The above facts and other evidence I have, together with the most careful search made in many ancient as well as modern works on surgery and in medical periodicals, lead me to conclude that the method and instruments which I claim to have devised were not known at home nor abroad before the year 1864.

Now comes a point of no mean import. The subject of priority of invention and of the method in question are treated by the opposition as a small matter, too trivial to merit any reply or notice on their part. Too insignificant, now that it is clearly proved to whom belongs the invention, but really of sufficient consequence to have induced them to claim it. I do not consider it a trivial matter to be accused of theft and falsehood. Neither do I think the accusation unworthy of refutation. Proving myself in the right, I prove the others in the wrong. Do *they* think it a trivial matter now to occupy the position in which their acts have placed them? Can they blame me for defending myself against an *anonymous* and gratuitous attack made by one with the sanction of the other? Has "Honor to whom Honor is Due" done himself *honor* by stabbing in the dark the reputation of a professional brother, residing in the same city? Is conduct of this kind in accord with medical ethics? If such a course be permitted to continue, no member of the profession will ever be protected from like attacks; anybody may come at any time and claim with impunity what is not his. The offence is to the whole profession as well as to myself, and the most ample apology is due.

Having established, as I think, that the invention is mine, I asked myself whether, after all, it is such a small matter as the aggressors wish to make it appear? In the latter part of a century so noted as this is for progress, great inventions, and advances in every department of science, it might, at first sight, appear a very small thing. But is any device to be considered trivial that tends to relieve human suffering, and to prolong and save life? The smallest and simplest invention with these aims is, in my belief, not unimportant. I think I made an advance in surgery when I devised instruments and a method of using them by which a great principle can be safely carried out; and many of the profession think as I do. But I shall now let others speak who are familiar with my instruments.

UNIVERSITY OF VIRGINIA, Nov. 4, 1873.

". . . . . I have just received yours of the 3d, and hasten to say that in my opinion you have defined your position with extreme accuracy and precision, in laying down very clearly the distinction between a *principle* and a *method* of carrying out a principle. You have at the same time abundantly established the justice of your claim to the invention of tunnelled urethral instruments and the method of catheterism by their instrumentality.

I can truly say that prior to 1864, I had never seen, read, nor heard of this method or these instruments. . . . . ."

(Signed) J. L. CABELL, M.D.,
Professor of Surgery, etc., University of Virginia.

PHILADELPHIA, Nov. 12, 1873.

". . . . . My visits (to New York) have been extremely brief. . . . . but I have often thought of calling on you and expressing my continued appreciation of the advances you have made in a special direction. I have long practised your method of treating urethral stricture, and consider it preferable to all others in reference to safety, facility in performance, and efficiency; and I think the tunnelled staff and filiform guide are now essentials of the surgery of the urethra. . . . . It gives me pleasure to endorse the merits of your improvements in the surgery of the urethra and your claims to their originality."

(Signed) R. J. LEVIS, M.D.,
Surgeon to the Pennsylvania Hospital, etc.

UNIVERSITY OF VIRGINIA, Nov. 13th, 1873.

". . . . . I have no hesitation in expressing my sense of the value of the whalebone guides and bridged bougies . . . . . they have already been of inestimable service to me, and when they attain that general recognition which I am confident awaits them, unskilful hands will no longer force false passages, and many lives will be prolonged. . . . ."

(Signed) J. S. DAVIS, M.D.,
Professor of Anatomy, etc., University of Virginia.

Professor A. Vanderveer, M.D., of Albany, writes me as follows:—

". . . . . Permit me just here to express my own feelings of gratitude for the advance you have made in urethral surgery. With the use of your tunnelled instruments I can now approach a case of stricture with a confidence and an ease of mind—as to the good results that will follow—that I never experienced before using them. . . . . ."

(Signed) A. VANDERVEER.
ALBANY, N. Y., Nov. 14th, 1873.

Nov. 20th, 1873.

To J. W. S. Gouley, M.D.

My dear Sir:—I have used your tunnelled sound in several instances when making external perineal urethrotomy. I do not say it is indispensable for the operation to succeed, but of all methods it is without doubt the easiest and safest one, furnishing an unerring guide from the entrance of the stricture all the way into the bladder.

Let me add that, before I read your letter in The Medical Record of Oct. 1st, 1873, I had not been aware that your claim as the inventor of the tunnelled catheter and sound had been called in question.

The principle and its embodiment form so important and so original a step in the treatment of urethral strictures, that, if you were laboring under the delusion of being the inventor, friendly correction right at the outset should have spared you the mortification of being mentioned now as appropriating another's claim to priority.

With such facts as are known to me, I hold you entitled to the honor of being the inventor of the tunnelled urethral instruments. At the same time, I doubt not that all those who now think Dr. Wm. H. Van Buren the inventor, by canvassing the subject with this gentleman again, may soon get aware that they have been laboring under a misapprehension, and that in consequence they will correct their mistake as publicly as they have stated it.

Yours respectfully,

(Signed) E. Krackowizer, M.D.,

Surgeon to Mount Sinai Hospital, and to the New York Hospital until its closure.

I have letters from Drs. Erskine Mason and Robert F. Weir, of New York, and John H. Brinton and John H. Packard, of Philadelphia, and similar testimony from many other quarters.

There are three others who are fully committed regarding these instruments. One is Dr. Van Buren, who has not always thought them so trivial, but has given them his most unqualified approval, which he cannot well take back. The second is Dr. Bumstead, who is quite as deeply committed, but in the opposite direction. He first claims the invention, in his book published in 1870, for his friend Dr. Van Buren, and then dogmatically condemns it. *Sic. . . !* The third is "Honor to whom Honor is Due," who is a little mixed and uncertain, and says, "*whatever may be* the value of tunnelling the end of urethral instruments." He does not say whether he has ever tried to learn how to use them. However, he thinks there is honor due to the inventor. Is he not a little inconsistent? If there is honor due to the inventor, the invention must be worth something. Perhaps "Honor to whom Honor is Due" is open to conviction, and may after a while see some good in the method and instruments, then repent and become a zealous convert to their use.

In concluding this communication I must quote Dr. Van Buren, who, through a champion, has made such grave charges against me, to show what he said on March 25th, 1873.

Tuesday, March 25

"Dear Gouley:—I have been absent for some days, ... and am thus late in thanking you for your book—of which the only opinion I have formed so far is that it is characteristic of its author in accuracy and self-reliance. I thank you for it, and shall use it with pleasure and profit. . . . . ."

"Sincerely,

(Signed) "Wm. H. Van Buren."

Dr. Van Buren received my book—which contains correct accounts of my tunnelled urethral instruments—early in March, 1873, and had sufficient time to examine it and see that I still persisted in claiming the invention. He had probably read as far as page 53, where the tunnelled sound is described and figured. If he had not done so before writing the above letter, surely, like all careful readers, he could not have failed to look at the table of contents and list of illustrations, where the author's tunnelled urethral instruments are mentioned. The opinion, he says, he has so far formed ("sincerely") of the book is, that it is "characteristic of its author in accuracy and self-reliance," which means that it is in "exact conformity to truth, free from mistakes, correct, precise, just, and nice." But it is "characteristic of its author," that is, the author himself exactly conforms to the truth, has made no mistakes, is correct, precise, just, and nice. The author, in the Doctor's opinion, is also self-reliant. Therefore the author "trusts to his own powers" for what he does and says, and not to those of any one else.

Could the Doctor have made a more plain admission that what I claim is really my own, and that in the invention I have trusted to my own powers and not to another's?

Had Dr. Van Buren been the inventor of the tunnelled sound, or had he even suggested it to me, would he not then have written me to say: In your several publications, and more recently in your book, you have not dealt fairly with me, for I invented and used this instrument long ago, before I knew you, or I suggested the idea to you? But the Doctor has never made any such complaint to me. I think I have been fair with him, for I have given him ample time and opportunity to claim or disclaim the invention. I say disclaim, because his champion (not himself) has publicly claimed it for the Doctor. But unfortunately for him, this very zealous friend has overshot his mark by causing to be printed the assertion (still uncontradicted by Dr. Van Buren), which he affirms came directly to him from Dr. Van Buren, that he (Dr. V. B.) "had *made*, and was in the *habit of employing*, instruments constructed upon this principle *many years ago*, and prior to the time when I became a student of medicine," or before I knew Dr. Van Buren, which is practically all the same.

In my defence, which I respectfully place in the hands of the profession, I have made statements in which I have observed "a regularity of account, a precision in points of fact, and a punctual reference to dates." That they "form a strong presumption of integrity," Dr. Van Buren tacitly admits in his letter of March 25, 1873, by saying that my "book is characteristic of its *author* in accuracy and self-reliance."

A little recapitulation here may not be out of place. In January, 1870, Dr. Bumstead claimed my invention for Dr. Van Buren, who then told me, orally, that this was not done on his authority and that he had never claimed it. In the third edition of Dr. Bumstead's book, the supposed error was not corrected. On March 25, 1873, Dr. Van Buren admitted, in a letter to me, that what I claimed was my own. On July 12, 1873, a champion, under an assumed name, reasserted what Dr. Bumstead had said, and more besides, and affirmed that he did so on the authority of Dr. Van Buren, who has given assent to this by preserving the most profound silence. His statement that I am *accurate* (a very high compliment, for which I thank him), is certainly at variance with the allegations of his champion. I must again call attention to the fact that, though these instruments were invented, and used by

me in public, since 1864, my claim was not disputed until 1870, some time after it had been discovered that the profession approved them. Also that Dr. Van Buren has never published a word about such a method or instruments, in any of his printed clinical lectures, or anywhere else; not even in his paper which appeared in the *New York Medical Journal*, December 1, 1868. In this paper, which was read before the Medical Society of the County of New York, November 2, 1868, the Doctor's object was to lay before his hearers the most advanced views and the most recent improvements in the treatment of urethral strictures. But he gave no account of the very useful method of treating difficult cases, which it is alleged that he introduced. I made some remarks to the Society (see *New York Medical Journal*, December 1, 1868, p. 296), after the reading of this paper, and spoke of my tunnelled urethrotome, and no question was then raised about authorship, though this was an excellent opportunity for it. The Doctor had then probably given little if any thought to this "small matter," about which, as he afterwards said, it "made little difference" whether it was attributed to him or to me! . . .

I think I have established the following points, to wit:—

1. That I never was a "student of medicine in Dr. Van Buren's office."

2. That tunnelled urethral instruments were not known at home nor abroad before 1864.

3. That Dr. Van Buren is not the inventor of tunnelled urethral instruments.

4. That I am the inventor of tunnelled urethral instruments, and that I am not indebted to Dr. Van Buren for a single suggestion in their invention or construction.

5. That the invention of tunnelled urethral instruments is not a trivial matter, but a decided advance in the surgery of the urinary organs, tending to relieve suffering and to prolong and save life.

6. That the allegations made against me are without foundation, and that they are consequently libellous.

56 West Thirty-eighth Street, New York.
December 1, 1873.

THE PROPER MODE OF PREPARING CAOUTCHOUC ELECTUARY.

To the Editor of The Medical Record.

Sir:—Having originally prepared for Dr. Theodore R. Varick, of this city, the electuary caoutchouc spoken of by him in The Medical Record, Nov. 15th, at his request I give a more detailed account of its preparation for the use of physicians who may desire to prescribe it in the exact form used by its author.

The caoutchouc should be in the crude state as imported, with no admixture of sulphur, lead, etc., and when cut showing a semi-transparent reddish-brown surface. ℥ i. of this in very thin slices is macerated in ℥ ii. ol. terebinth. pur. for one week, the mass being frequently stirred. It is then heated gently in a water-bath until solution is effected, and strained, care being taken to add sufficient ol. terebinth. to replace that evaporated. Two drachms (by weight) of this are next rubbed thoroughly with ℥ iss. pulv. sacch. alb., and ℥ iiss. mel. purificat. gradually added.

It will be necessary, in dispensing the electuary, to stir it thoroughly, as a granular deposit of sugar is gradually formed by standing.

James R. Mercein,
Graduate in Pharmacy.

Jersey City, N. J.

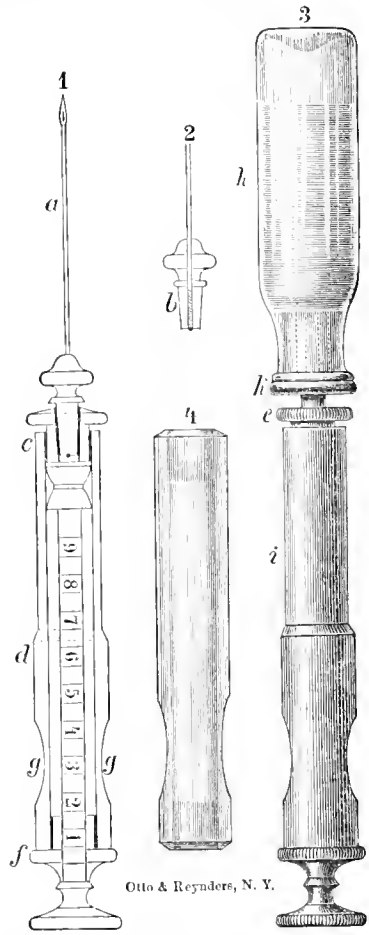
New Instruments.

A NEW HYPODERMIC SYRINGE.

Not many instruments are used as often as the Hypodermic Syringe, and are consequently so easily liable to be injured.

The Hypodermic Syringe formerly improved by Otto & Reynders, instrument-makers, of this city, had advantages which met with the full approbation of the interested parties, and which were very much imitated: the old steel canula was substituted by a golden one, and the mounting made of hard rubber instead of metal.

Experience has proved that there were other conditions to be fulfilled before the instrument could overcome many of the objections to its use. Many, if not all, the difficulties in construction, have now been overcome by the invention of Mr. Joseph Leiter, of Vienna, the description of whose instrument we present to our readers.



The canula of this new Hypodermic Syringe is made of steel, either gilt or nickel-plated outside and lined with platinum inside, avoiding thus oxidation entirely; at the same time it is so tempered that it can always be repointed by grinding only.

To facilitate the cleaning of the instrument, screwing and cementing are with only one exception entirely avoided. A mouthpiece, of conical form, in which the canula is screwed (so that when taken out both ends can be easily approached with a wire for clean-

ing purposes) is inserted in a conical ring, and both in the front part of the cylinder; by gently pressing together, the different parts will then fit air-tight.

The other end, through which the piston-rod passes, is closed in the same way; its opening is also conical, growing wider towards the end, by which the reinsertion of the cuff-shaped piston, after oiling, is made very easy. This is also an essential improvement; the attention only needs to be directed to the numerous troubles encountered when doing this with the old syringes, to fully appreciate its high value.

The syringe is made of hard rubber; near the piston end its body is ground out so that it can be held firmer. Its contents is one gramme, and corresponds with the scale on the piston rod, on which each mark denotes five centigrammes.

The method of filling the opaque cylinder is peculiar, and is one of the particular recommendations of the instrument, viz., pouring in the liquid when the piston is drawn back. The syringe is attached to a small vial (Fig. 3) containing the liquid, both reversed (the vial to be uppermost), and the piston drawn back; should the cylinder still contain any air, the same can be expelled by moving the piston several times in and out.

The stopple (*k*) used for this bottle consists of a tube whose one end fits in the ring (*c*), and whose other end is surrounded with rubber, so that it closes air-tight; it may remain on the vial when the latter is not in use, a small cap fastened on the same keeping the liquid from flowing out (as shown in Fig. 5).

Nevertheless, any vial with a cork may be used for filling the syringe in the manner described by putting a tube through the cork which fits in the ring (*c*), or the canula itself may be pierced through the cork, but only up to its end.

To meet all requirements the hard rubber cylinder can be replaced by one of the same size made of glass (whose walls are 2–2½ mm. thick). However, in regard to durability and exactness of finish the hard rubber cylinders are to be preferred.

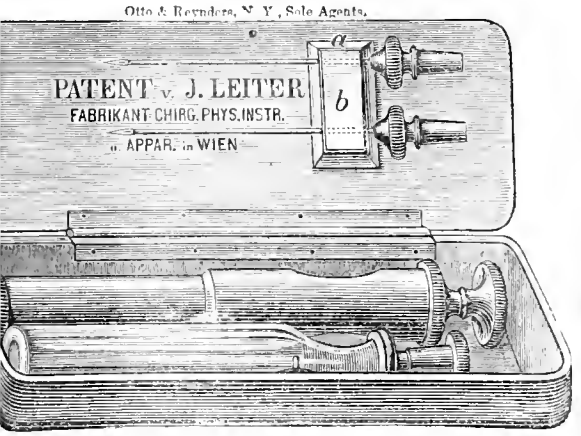


Fig. 5.

For this syringe we have constructed a neat case of hard rubber (Fig. 5); the lower part holds the syringe, and the vial containing five grammes; the needles are placed in the cover, and are held in position by springs.

The advantages of this syringe over others may be briefly enumerated as follows:—

(1) The platinum-lined steel canulas.

(2) The manner in which the canulas are attached to the fitting *b* (Fig. 2).

(3) The construction of the cylinder of hard rubber or glass without screws, and the simple manner in which the different parts are made to adhere.

(4) The construction of the stopple and the method of filling.

(5) The manner in which the canulas are held in the case.

Messrs. Otto & Reynders are the agents of this instrument for the United States, and Mr. Leiter has assigned his patent to them.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from November 19, 1873, to December 4, 1873.

ABADIE, E. H., Surgeon.—To report by letter to the Commanding General, Military Division of the Atlantic, for assignment to duty. S. O. 230, A. G. O., November 18, 1873.

BILL, J. H., Surgeon.—Granted leave of absence for 3 months on surgeon's certificate of disability. S. O. 231, A. G. O., November 19, 1873.

ALDEN, C. H., Surgeon.—Assigned to duty at Fort Walla Walla, W. T. S. O. 157, Department of the Columbia, Nov. 6, 1873.

WEBSTER, WARREN, Surgeon.—Assigned to duty at Angel Island, California. S. O. 133, Department of California, Nov. 4.

WOLVERTON, W. D., Assistant Surgeon.—Assigned to duty at Nashville, Tennessee. S. O. 202, Department of the South, Nov. 21, 1873.

GREENLEAF, C. R., Assistant Surgeon.—Assigned to duty at Huntsville, Alabama. S. O. 202, C. S., Department of the South.

HUNTINGTON, D. L., Assistant Surgeon.—Assigned to duty at Fort Stevens, Oregon. S. O. 157, Department of the Columbia, Nov. 6, 1873.

CALDWELL, D. G., Assistant Surgeon.—When relieved by Assistant Surgeon Wolverton, to comply with War Department orders in his case. S. O. 202, C. S., Department of the South.

TAYLOR, M. K., Assistant Surgeon.—When relieved by Assistant Surgeon Greenleaf, to comply with War Department orders in his case. S. O. 202, C. S., Department of the South.

KOERPER, E. H., Assistant Surgeon.—To report by letter to Commanding General, Military Division of the Atlantic, for assignment to duty. S. O. 230, A. G. O., Nov. 18, 1873.

VICKERY, R. S., Assistant Surgeon.—Assigned to duty at Jackson Barracks, New Orleans, Louisiana. S. O. 188, Department of the Gulf, Nov. 28, 1873.

STYER, CHAS., Assistant Surgeon.—Granted leave of absence for 30 days, with permission to leave limits of Department, and apply at Division Headquarters for 30 days' extension. S. O. 200, Department of the South, Nov. 19, 1873.

WIGGIN, A. W., Assistant Surgeon.—Assigned to duty at Fort Vancouver, W. T. S. O. 157, Department of the Columbia, Nov. 6, 1873.

KING, W. H., Assistant Surgeon.—Granted leave of absence for 30 days, with permission to leave limits of Department and apply at Division Headquarters for an extension of ten days. S. O. 204, Department of the South, Nov. 26, 1873.

Medical Items and News.

Dr. Lyon Playfair has been appointed Postmaster-General of Great Britain and Ireland.

The Danger of Storing Wet Coal.—People who prefer wetting the winter's store of coal to lay the dust, on putting it into their cellars, do not generally know that they are laying up for themselves a store of sore throats and other evils consequent upon the practice. Even the fire-damp, says an exchange, which escapes from the coal mines, arises from the slow decomposition of coal at temperatures of but little above that of the atmosphere, but under augmented pressure. By wetting a mass of freshly broken coal and putting it into a cellar, the mass is heated to such a degree that carburetted and sulphuretted hydrogen are given off for long periods of time and pervade the whole house. The liability of wet coal to mischievous results under such circumstances may be appreciated from the fact that there are several instances on record of spontaneous combustion of coal when stowed into the bunkers or holds of vessels. And from this cause, doubtless, many missing coal vessels have perished.

Death from Ether.—The wife of the cashier of the Freight Department of the Old Colony Railway, died in a dentist's office, in Boston, on the 10th of last month, while under the influence of ether. Only a small quantity had been administered when she was seized with a convulsion and soon died.

Diminution in the Attendance at the Vienna School of Medicine.—*The British Med. Jour.* says: "The number of students in the Vienna Medical Faculty diminishes sadly from year to year. Since Oppolzer's and Skoda's death the diminution is very marked. Where one could with difficulty get within ear-shot in days gone by, on account of the number attending, the wards now, it is stated, are almost empty. In Prag and Gratz, however, the attendance is unusually good.

Dr. B. W. McCready has resigned his position as Visiting Physician to Bellevue Hospital.

University of New York—Medical Department.—We learn that Professor Henry Draper has resigned the Chair of Physiology in the Medical Department of the University of the City of New York, and that Professor J. W. S. Arnold will give the lectures on that subject during the remainder of this session.

New York Society for the Relief of Widows and Orphans of Medical Men.—The 31st Annual Meeting of the Society was held at the College of Physicians and Surgeons, Nov. 26, 1873.

Officers for the ensuing year, who were elected, or whose terms of office had not expired:—

President—John O. Stone, M.D. *Vice-Presidents*—John R. Van Kleek, M.D.; Samuel T. Hubbard, M.D.; John G. Adams, M.D. *Treasurer*—J. W. G. Clements, M.D. *Secretary*—Gouverneur M. Smith, M.D.

Managers.—Term (1874, '75, '76), O. White, I. E. Taylor, E. Krackowizer, C. D. Smith, E. Delafield, R. Watts, R. A. Barry. Term (1873, '74, '75), Jared Linsley, A. Underhill, J. O. Smith, Edw. L. Beadle, Gouverneur M. Smith, Joel Foster, Thos. F. Cock. Term (1872, '73, '74), Willard Parker, Jas. Anderson, Gurdon Buck, J. L. Banks, Jas. H. Anderson, William Detmold, Wm. C. Roberts.

Medical Library and Journal Association of New York.—The annual meeting of this Association took place on the 2d of December last. The election for officers resulted in the choice of—

For *President*, Dr. John C. Peters; *1st Vice-President*, Dr. A. Jacobi; *2d Vice-President*, Dr. H. P. Farnham; *Recording Secretary*, Dr. A. H. Smith; *Corresponding Secretary*, Dr. George Bayles; *Treasurer*, Dr. J. H. Emerson; *Librarian*, Dr. A. E. M. Purdy.

As Trustees for Three Years: Drs. J. H. Leaming, F. A. Burrall, J. S. Banks, Ellsworth Eliot, T. M. Cheesman.

This Association continues to flourish, and were all the back dues of members paid, there would be not only a considerable sum for binding journals, but also a balance in the treasury.

The District Medical Society of the County of Hudson, N. J.—The officers chosen for the ensuing year are:—

President, J. D. McGill, M.D.; *Vice-President*, H. H. Abernethy, M.D.; *Secretary*, J. T. Field, M.D.; *Treasurer*, L. A. McBride, M.D.; *Reporter*, T. R. Varick, M.D.

Delegates to New Jersey Medical Society.—Drs. Payn, Chabert, Watson, Culver, Benson, Field, McGill, and Abernethy.

Alternates.—Drs. Miller, McBride, Bock, Gilman, Finn, McLaughlin, Talson, and Rau.

Committee on Ethics.—Drs. Chabert, Miller, Watson, Field, Benson, and Culver.

Errata.—Dr. Rose writes: In No. 191 of your valuable paper, where you give a report of a meeting of the Journal and Library Association I find some errors:—

In answer to a question raised by Dr. Sell, I suggested that immersion (*not the water dressing*) prevented the occurrence of certain ferments (not foments) which would cause a great deal of reaction. The hot poultice is ordinarily constituted of material which would contribute largely to the production of *fermentation*, hence the great disadvantage attending its use.

Statistics of Deaths from Anæsthetics.—In the returns recently published by Dr. Morgan, it is shown that the ratio of mortality from the different anæsthetics is as follows:

One death in 23,204 from administration of ether; one in 5,588 from ether and chloroform; one in 5,000 from the bichloride of methyl, and 0 in 2,873 from chloroform.

New Publications.

Medical Department of Life Insurance.

THE BEARING OF INEBRIETY ON LIFE INSURANCE.

By WILLIAM C. WEY, M.D.,

ELMIRA, NEW YORK.

It must be admitted that the principal safeguard against loss in life insurance consists in the care and discrimination with which medical examinations are conducted. It is not enough to learn, by demonstration in our presence, that the applicant is apparently in perfect health. As the victim of Bright's disease may suddenly perish without manifesting indications of his malady; in the same way, only more slowly and by visible tokens, the inebriate by inheritance or by acquired habit may lose the appearance of health, and put on the positive sign and seal of degeneracy and decay. In one case the undermining disease betrayed its presence by no recognizable symptoms; it was not suspected by the patient, it formed no part of his family history, and could not therefore be anticipated or averted. It came with explosive violence, like a railway shock, and an insurance company is called upon to adjust damages sustained by reason of the death. In the other case the family history, if accurately given, may or may not throw light upon the prospective development of inebriety. If the habit of alcoholic indulgence comes by inheritance, a careful analysis of the causes of death in the family for two or three generations will assuredly set forth the fact that the tendency to "repeat itself" is as prominently stamped on inebriety as on insanity, cancer, or other well-known transmitted disorder. The death of a parent or other near relative in consequence of "apoplexy," should be as carefully investigated as death by suicide. "Apoplexy," when examined, may be found to mean the abrupt termination of prolonged alcoholic indulgence, called by this term to mitigate the nature of the victim's habit or to soothe the feelings of friends and relations. In the same way "pneumonia," if interrogated, may reveal that form of subacute disease which, in a person fortified by abstemiousness of life, would not occur, or, taking place, would quickly resolve itself in recovery, without leaving trace of its existence. In an inebriate, on the contrary, with vital powers greatly depressed by continued indulgence, inflammation of an important organ would stop only with the life of the patient, in obedience to a law which proclaims that the "elimination of disease is effected by and is proportionate to the vigor of the remaining healthy functions, and not to the extent of diseased actions."*

Faithful scrutiny of many other causes of death among ancestors, near and remote, would exhibit, perhaps, a permeating inebriate tendency, whose mischievous influence would be everywhere witnessed, as inclining to shorten life, especially in the male line of descent.

In confirmation of this view, and to illustrate the unreliability of mortuary returns, I am enabled to present the following statistical facts, kindly furnished by an insurance company with which I have the honor to be connected:—

Total number of deaths in 23 years	981
From delirium tremens	10
" intemperance, terminating otherwise than in delirium tremens	19
	— 29

Nearly 3 per cent.

* Samuel Henry Dickson, M.D.

Average number of years the 29 were insured	6½
" " " " 981 "	not yet calculated.
Average age at insurance	37 1-9 years.
Average age at death	43 3-5 years.
Average height of 20 of the number at time of insurance	5 ft. 7½ in.
Average weight of 20 of the number at time of insurance	160 pounds.

Occupations.—1 lawyer; 2 bankers; 6 merchants; 3 clerks; 5 cattle brokers and butchers; 2 liquor merchants; 2 tailors; 4 shop-keepers; 1 plumber; 1 auctioneer; 1 printer; 1 unknown.

Nationalities.—19 Native Americans; 1 German; 4 Irishmen; 1 Scotchman; 1 Canadian; 3 unknown.

Hereditary.—In two cases the father had died of intemperance, and in two others a brother had died from the same cause.

Married or Single.—21 married; 5 single; 3 unknown.

Mode of Death.—By delirium tremens, 10; apoplexy, 3; epilepsy, 1; insanity, 3; pneumonia, 2; inflammation of brain, 1; gastritis, 1; falling from carriage, 1; heart disease, 1; and the remainder from a complication of diseases.

The above statement is interesting and instructive, as showing a weak side of human nature, in which a habit of exaggeration is stronger than a disposition to tell the truth. It cannot be believed that in nine hundred and eighty-one deaths only twenty-nine, or about three per cent., took place from the effects of alcoholism. Nearly one thousand insured men indicate a state or condition in society favorable to the production of inebriety to a greater extent than three per cent., for the reason that they represent a period of business activity which is subject to successes and reverses, involving the most severe mental, moral, and physical strain and effort to which they can be subjected,—a period and condition inclining, above all other causes except inheritance, to the production of intemperate habits. It may be inferred, also, that more than three per cent. of the insured partake of inebriety by transmission, which leaves a large number to lapse into alcoholism by the force of circumstances alone.

A glance at the occupation of twenty-two out of the twenty-nine persons mentioned in the list, will suggest the moral bearing of financial embarrassment on this subject, with its consequent reduction of compensation, loss of employment, diminished sales, scanty collections, general distrust, and individual disappointment, despondency, and suffering.

Additional statistics, made to reach to the marrow of the question, and covering a larger area of observation, are needed to demonstrate the relations existing between acquired or inherited alcoholism and increased death-rate among the insured.

In the table before us we do not see the expansion of alcoholic consequences as they are observed in every-day life. We see as little of the certain effects of drunkenness, except in the item of delirium tremens, as will subserve the purpose of individuals in procuring specific amounts of insurance on the lives of deceased friends. Death, as a direct or remote penalty of intemperance, is concealed to the extent of the tact and ingenuity of interested persons to keep the facts of each case from the knowledge of insurance officials. Cunning as are the devices employed to admit inebriates to the benefits of insurance, equally unwarrantable are the arts practised to obtain the payment of policies in case of death, as one or two examples will show.

It was the duty of the writer on one occasion to meet in consultation a physician who had charge of a case of delirium tremens. The disease appeared as a sequel of acute rheumatism, in a hard-drinking young man, by occupation a saloon-keeper. After several days and nights of vigilance, he was made to sleep, his delirium subsided, and he partook of food. In the midst of slumber a procession passed his door, led by a band of music. The sound of drums and brass instruments suddenly striking on his ear aroused him to excitement. The full force of delirium returned, remedies proved unavailing, and he died. A policy

of insurance had been effected on his life a short time before, in which it was stipulated that in case death was produced or ascertained to be dependent upon habits of intemperance, his heirs should waive all claim against the insurance company for the amount of the policy. Several weeks later a representative of an insurance company, sent to investigate the case, presented full proof, in the usual way, of the death and burial of the party, including a certificate from the attending physician, which gave rheumatism as the cause of the fatal issue. Rebutting testimony being promised to show the actual cause of death, the family of the deceased wisely abandoned the claim.

An inebriate, whose long-continued habit was understood in the community, and whose impaired physical condition threatened speedy death, was taken by an unscrupulous agent to a medical examiner, with a request that he be accepted as a good risk, adding, when the shocking condition of the infirm man was pointed out, that he was as likely to live as many he had previously examined. The agent relied too implicitly upon the amiability of the physician, and was sent from his office with a stern rebuke for his insolence. In less than three months the nearly demented drunkard tottered into his grave.

A man whose daily custom was known universally, for he was a "publican," was rejected by a medical examiner, to be immediately caught up by the agent of another company and accepted as an unexceptional risk.

Like instances of fraud in connection with inebriety and life insurance might be multiplied from personal experience; but enough has been furnished to show the systematic design on the part of agents, the applicant, and the friends and relatives of the latter, to deceive for purposes of profit to be immediately or prospectively realized from the company. Occasionally medical officers become parties in these transactions; and it has been observed that a tripartite agreement of a physician, an agent, and a sick person seeking insurance, may reveal a degree of criminal boldness and audacity in keeping with the deliberate proceedings of incendiaries and highwaymen. Brief allusion will be made to two such instances of nefarious compact.

A consumptive, whose mother and sister had died of tuberculosis, was offered by an agent and accepted by the regular medical examiner of an insurance company, in the stage of softening of the disease, and a policy was obtained upon his life. He died in seven months, and the certificate furnished by the medical examiner, who continued in attendance, showed that death was occasioned by "inflammation of the lungs;" duration of disease, "three weeks." Examination by a special agent of the insurance company brought all the details of the transaction to light, and resulted simply *in the discovery of the fraud*. The guilty officials escaped even the publicity of their crime, much less adequate punishment.

The wife of a middle-aged man, who had lain four or five years in bed with inflammation of the spinal cord, resulting in hemiplegia, with the aid of the agent and a medical examiner, both of whom visited the applicant, secured insurance upon his life. Soon after the payment of the first premium, the home office learned the nature of the case and cancelled the policy, but no effort was made to bring the offending parties to justice. In three months the hemiplegic died.

A brief but interesting paper on "Personal Habits," by Dr. Edward W. Lambert, of New York, appeared in this department of THE MEDICAL RECORD on the 15th May, 1873, in which the difficulty of procuring satisfactory information concerning the daily life of applicants for insurance is made the subject of comment. The position of the author of the paper, as chief medical officer in an extensive company, renders his testimony on this subject exceptionally valuable; and the following extracts indicate the delicate and responsible nature of his duties, as well as his conviction of the necessity for more explicit information in respect to the manner of life of persons who desire the benefits of insurance: "No question presents more difficulties than that relating to the personal habits of the applicant. As a rule, this question is answered more indefinitely than any other in the application; yet this is *the question*, of all others, which will give the most information as to the probable longevity of the individual, and it ought to be answered so definitely and clearly, that he who reads may correctly understand the manner of the daily life of the applicant."

Added to the inebriate disposition, and so immediately dependent upon it as to prove unity of causation, may be mentioned syphilis and epilepsy, which are connecting links, from whose combination or inter-communication an endless variety of morbid phenomena are engrafted on otherwise sound family stock. In this association the question of insanity naturally occurs. Intemperance is recognized as the chief factor in the production of mental alienation. It has taken a long time to sift the maze of statistics on this subject, and arrive at a just conclusion, in accordance with the inevitable laws of transmitted mental and physical defect or unsoundness. Individual instances of inebriate transmission, with insane development interwoven in the family line, have been frequently presented to us, and we have been taught to accord more than ordinary significance to striking illustrations of physical traits and deficiencies, whose origin and expansion into confirmed habits of life have contaminated or impressed many families, through exhaustless forms of implication.

We have seen the power of inebriate transmission exerted on the males in each succeeding generation, through a long history, acquiring rather than losing intensity, because of the assimilating leaven of intermarriage with stock in which the same fault of inheritance is perceived to exist. Interruption of the inebriate, the insane, or the epileptic element, for one or two generations, may or may not be explained to our satisfaction. The admixture of blood from a source not contaminated by these evils lessens the degree and violence of their manifestation, and may in time, if marriage continues to be fortunate and eradicable, altogether remove the family tendency to such disorders. On the contrary, with a proclivity to inebriety, insanity, and crime still in existence, and with no apparent causes in operation to arrest their development, it not unfrequently occurs that for one, or two, or three generations the moral or physical taint is not produced, and it seems as if its power in the system had actually ceased to be productive of evil results. In accordance with a "determinate law," however, the sin of the father is visited upon the children, and sooner or later, with greater or less intensity, the physical condition of inherited inebriety is again revealed in the family.

Thus, it will be observed, the extent of inebriety as an agent of physical impairment in the prospective issues of life insurance is almost limitless. It is impossible, in the space of this paper, even to allude to all the prominent features of the subject, which crowd upon the mind, in connection with longevity and expectancy of life, as measured by charts and tables.

It is apparent that life-insurance companies have not shown that degree of sagacity in dealing with this

complex question which its importance demands. They have adopted such a course as admits to privileges, not the descendant of the inebriate alone, but the inebriate himself, and this, too, with his family history open and plain, in one sense, for the inspection and edification of company officials; and in another sense, as thoroughly closed against scrutiny as the pages of a sealed book.

The pertinent fact that something more than mere examination of an applicant for insurance is to be canvassed and considered does not appear to be taken into account. While questions are put to elicit information respecting an inherited tendency to "insanity, pulmonary, scrofulous, or any other constitutional disease," which contemplates a survey of the family history, the whole subject of inebriety is summed up by one company, at least, in the following, answered by the applicant: "Is the party addicted to the habitual use of spirituous liquors or opium?" and to the additional query by the medical examiner: "Do you believe the party to be sober and temperate in all the habits of life?"

To aid discussion in this inquiry, and for the purpose of keeping within the bounds of a physical estimate of inebriety, it will at once appear that the answer of the first question relates absolutely to the habit of the individual at the time of examination. The question is put to ascertain if the disease of alcoholism is already established, just as similar inquiries are propounded, and many tests used, to determine if the party is laboring under cardiac, pulmonary, or other organic disease. Acknowledgment of a vital law by which "characteristics cling to families," mental as well as physical, is disregarded in this instance, to be accepted in matters less significant, because more open to inspection and review. For instance, the family history may be clearly and impartially told, and a record of tuberculous fatality revealed, which stamps with suspicion the entire blood or race, in direct or collateral descent. In case the applicant is received as not habitually or even occasionally addicted to the use of spirituous liquors, and the family history is not critically interrogated in respect to proneness to inebriety, the insurance company incurs a risk in accepting such a person, that a latent physical degeneracy will in time break forth with as much intensity as stamped its manifestation in former generations.

The question should be asked in such a manner as to include the rules of hereditary descent; and to accomplish this end, it should be divided, the first portion taking in a survey of the family history, carefully and truthfully prepared, while the remainder, based upon the former, deals with the individual himself.

Very cursory inspection of the family history might show the outcropping of inebriety at an *early age* in every generation in which it appeared, or it might indicate *sudden* development of the habit, using the word in its ordinary sense, at the age of thirty or thirty-five years. The case under review might prove an exception to the rule, in which event, all other circumstances being weighed and appreciated, the insurance company might in one instance accept the risk as denoting the non-appearance of the infirmity of drunkenness in the person and generation before them, while in another contingency, reaching a result by the only process at their command, which would be sound, physiological and determinate, the hazard would also be taken, simply because the party had passed that period in life at which his forefathers, as if smitten by withering disease, had fallen victims to intemperate habits.

Examined critically, by such tests as vital science insists on imposing, the occurrence of inebriety in a family line at a specific age is not indicative of rapid causation or of sudden development. It should be regarded as the production or generation of physical phenomena, under circumstances favorable to their elimination, irrespective of mental and moral convictions and the highest scale of enlightenment. Subject to causes already mentioned, which interrupt the force of the inborn tendency, such as marriage with non-inebriate stock, the infirmity rises or falls in successive generations like the tides or fluctuations which govern the tuberculous habit, the insane disposition, or the marked and distinctive family lineaments or general physical configuration.

If we had access to minute details of pedigree in this particular, we could arrive at the starting or engrafting point of inebriety, and trace its growth and culmination along the line of descent, by repetition of the habit here and there, by the manifestation of insanity instead of drunkenness, in general or specific form, by the development of mania as an immediate product of intemperance, by that peculiar condition of the nervous system allied to aberration of mind, "which will necessarily be transmitted, under various forms and with increasing fatality, to his descendants."* and by the interminable catalogue of results which proceed directly and remotely from imbecility, vagrancy, and crime.

It is difficult, indeed quite impossible, to analyze a family history through many generations, setting down in their appropriate order inebriety, insanity, nervous disorganization, imbecility, criminal instincts, and eccentricity; weaving them in connected and interchangeable dependence, and demonstrating the fact that their occurrence is in accordance with fixed and unalterable rules which govern and control the race. This difficulty arises solely from the hopelessness of tracing the family history with such particularity as to make these elements appear in the order of succession, or as cause and effect. Marking the consequences of drunkenness in all its details for two, three, and four generations, we are rarely able to go farther back in family history to the origin of the habit. For the sake of precision it would be desirable to procure such explicit information; but for purposes of illustration, our knowledge is sufficiently specific and reliable. It has been derived chiefly from the wide field of observation open to the physician, whose opportunities for the study of psychical and physical phenomena are constant and absorbing. It is such knowledge as embraces the parent stock, the origin of observation, whose physical and moral traits, with varying degree of force and circumstance, enter into and mould and fashion the lives, character, and diseases of the progeny. It is such knowledge also as suggests to insurance companies the danger of taking risk in lives which are liable to terminate in some of the immediate or consecutive forms of alcoholism before the usual period of expectancy. It is such knowledge, too, as opens a vast extent of inquiry in a direction but little cultivated. A careful study of inebriety, prompted first by observation of patent facts, and next by the grouping of such facts in laws of morbid phenomena, has been the means of transforming what was believed to be "*a vice*" into the domain of diseases, whereby the question of individual responsibility is being settled, and with it the vital problems of prevention and rational treatment, and the duty of the State towards the hapless subjects of alcoholism.†

* Anstie.—In Sheppard's "Lectures on Madness."

† The "Symptoms of Inebriety" will be discussed in a later number of the RECORD.

ON THE SELECTION OF MEDICAL EXAMINERS.

BY A MEDICAL DIRECTOR.

In the report of the Hon. Orlow W. Chapman, Superintendent of Life Insurance of the State of New York, we find these words: "What plan can be adopted that will give the most perfect security to a company in its selection of Medical Examiners? . . . . . The desirability of having the best medical examiners possible will be universally conceded. But the question here presented is: What plan can be adopted that will the most certainly secure such? If this inquiry be of no importance to old, it may be vital to new, companies."

At the recent National Insurance Convention, held in the City of Boston in the month of September last, Dr. T. S. Lambert, of this city, having been invited to address the Convention, quoted these words of Superintendent Chapman, and followed them by some practical and, in the main, sound remarks upon the general question of medical examinations. The only words in the printed report * which seem to convey an answer to this important question of our State Superintendent are the following: "But a matter of still greater importance is this: Can a sufficient number of examiners be found everywhere to conduct examinations, and determine upon the reliability and insurability of the proposed persons? That certainly cannot be done.

"But if the question is, Can a sufficient number of persons be found who can make such a complete medical examination as will, with the other blanks properly filled, permit an expert at the home office to judge of the reliability and insurability of the proposed person, the answer is, Yes, in regard to most places.

"To ask a medical man to give a correct physical description of a person, in answer to numerous and detailed questions, is a very different thing from asking him to give answers to a few indefinite questions, and a judgment upon the vitally important question of the insurability of the person.

"Almost any ordinary or average physician can do the former duty well; very few, and none without special study and practice, can do the latter.

"The ordinary mode of conducting medical examinations not only, but the intent in having them done, is therefore wrong.

"The wrong way is also difficult as well as subversive of the object—the security of the company.

"The right way is easy, and confirms the security of a company, since it is the *sine qua non*. By the right way, also, the ability and capacity of the examiner for his duty is at once determined by the very manner in which he does it."

While in these words we do not by any means find an answer to the important question at issue, nevertheless we are led to infer from them that the safest course to pursue is to allow any physician to act as a medical examiner, and then to judge from the nature of his report whether the person examined is a first, second, or third class risk, and also whether the examiner himself is a first, second, or third class doctor.

We have already, in a previous number of THE RECORD (July 15), described as clearly as we could the plan which seemed to us most likely to afford the life companies the greatest security in the selection of their medical examiners. This plan has been thoroughly tested by one of the companies for a number of years past, and has more recently been adopted by two or three others. Its principal feature is to entrust to physicians of well-known ability and integrity the selection of those who shall act as medical examiners in their respective States or Counties. It involves not a little expense, but if worth having, it certainly is worth paying for, though we are sure that the ultimate saving in death-losses will more than compensate for the original outlay. That it is safer than the plan which Dr. Lambert's words at least imply, seem to us hardly to require discussion. If we could believe in the proposition that all doctors are strictly conscientious and truthful, we should be disposed to say that Dr. L.'s plan of guarding against professional ignorance and incompetency, by requiring the examiner to fill out a very complicated blank, was perhaps the easiest and cheapest way of protecting the company's interests. We do not believe, however, that a blank can be invented which will throw light upon the question of an examiner's truthfulness and willingness to do his full duty toward the company employing him. Nothing can be easier for the dishonest or careless examiner than to fill out any and all blanks now in use among the life companies in such a manner as to make the "worse appear the better cause" to the most astute of medical directors. Such being the case, is it not clear that the characteristic most to be insisted upon in an examiner is honesty? And is it not equally plain that a physician's professional brethren are in a better position to judge of his moral as well as professional standing than any agent or other non-professional person?

We hope that the day is not far distant when all life-insurance companies will see the necessity of enlisting the best elements of the medical profession in their service, and when the position of medical examiner to a life-insurance company will be considered as an honor to be sought for, and to be obtained only by the best men in the profession. It is a question well worthy of thoughtful consideration whether this desired object could not be obtained by something like united action among the companies. But the discussion of this question would lead us too far from our immediate theme.

* Report of the Proceedings of the National Insurance Convention of the United States. Compiled by Oliver Pillsbury, Secretary of the Convention. Boston, Mass., 1873.

MORTALITY EXPERIENCE OF AMERICAN MISSIONARIES.*

BY NATHAN WILLEY.

THE following tables † comprise a record of the mortality experience of over 1,000 missionaries of the A. B. C. F. M., including more than 13,000 years' service, mostly in foreign lands. The original data from which these tables were compiled were prepared by Rev. John A. Vinton, of Winchester, Massachusetts. Mr. Vinton has spent several years in preparing statistical information of this kind for the Board, and but few men ever lived more competent to execute such a task.

These tables embrace all the missions established by the Board since its organization. In some cases, missions have been transferred to other Boards, as the Presbyterian and Reformed Dutch, and from that time the A. B. C. F. M. has had no further control over them. Missions have also been discontinued, as in the Sandwich Islands and Borneo. In these cases the data fur-

* From the *Insurance Monitor*, November, 1873.

† Only the Recapitulation table has been introduced here.—Editor RECORD.

nished do not generally extend beyond the period of transfer or discontinuance.

In preparing these tables, the compiler was furnished with cards containing the name, place and date of birth, date of embarkation, of death, release, or return to this country, and the field of labor of each missionary. In a very few instances the date of birth was not given, but the number of years of exposure was always ascertained. In such cases the average expected mortality of the known ages exposed in each locality was found, and the additional mortality from the unknown ages, found by a simple proportion, was added to it.

It will be noticed that there is a great difference in the mortality in different parts of the globe. In Western Africa, Southern India, Southern China, and the Indian Archipelago, the mortality has been from three to nearly seven times as great as the American Experience Tables indicate, while in the Sandwich Islands and in Southern Africa the aggregate mortality has been less. In the Sandwich Islands, though lying within the tropics, the mountainous nature of the country enables foreigners to select places of residence where the air is as mild as in the mountains of Tennessee; and in South Africa, the mission stations are on an elevated plateau, where the climate is as healthy and salubrious as in West Virginia.

But in all that belt of country commencing with Turkey, and extending eastward and southward through Syria, Persia, India, and Southern China, and especially in the Indian Ocean, the mortality of American missionaries has been excessive, as a glance at the RECAPITULATION TABLE will show. In these countries, fevers and the cholera have caused a large ratio of the deaths, while only a very small number have died by violence.

One important and instructive feature in these tables is the comparative mortality of males and females. In all the unhealthy countries, with the singular exception of Persia, the mortality among women is much greater than among men. This may be partly accounted for by the younger age of embarkation and the less previous exposure to hardship. Among the missionaries to Turkey, the mortality among females who embarked under the age of twenty-five has been about two-and-a-half times as great as among those who were older at the time of leaving home. Among the female lives in the Sandwich Islands, we find eleven deaths between the ages of twenty-five and thirty-nine inclusive, while the tabular mortality calls for a fraction over six.

We find also a good illustration of the influence of climatic differences upon Northern men and women living in the Southern States. In the missions among the Cherokee and Choctaw Indians, in the States of Georgia, Mississippi, Arkansas, and the Indian Territory, the mortality of males is about 44 per cent. and of females 46 per cent. greater than the tabular rate.

Another circumstance which will make these tables of great practical value to our life-insurance companies, is the fact that nearly all these lives are from the Northern States, not more than one or two per cent. being from the South or foreign countries.

We cannot assert that these tables give the total mortality of the American missionaries arising from their foreign residence. In many cases, finding that health and usefulness were ruined, the missionary bade farewell to his chosen field and returned to die in his native land. If his recovery was deemed impossible, he severed his connection from the Board, and his subsequent record does not appear in this table. Neither have we any account of those whose health, though permanently injured, was just sufficient to enable them to linger for a few years till prematurely cut off by death, after they had left the Board and engaged in other pursuits. To obtain the total mortality which has resulted, directly and indirectly, from missionary life, would require more elaborate data.

RECAPITULATION.

MORTALITY STATISTICS—MISSIONARIES A. B. C. F. M.

	Males.					Females.				
	Number of lives.	Years of exposure.	Expected mortality.	Actual mortality.	Ratio of actual to expected mortality.	Number of lives.	Years of exposure.	Expected mortality.	Actual mortality.	Ratio of actual to expected mortality.

Total	496	6957.3	85.5510	140	1.6365	523	6360.	71.4624	146	2.0488

In preparing the foregoing tables, it has occurred to the writer that it might be of great importance to the cause of Foreign Missions, as well as for the information of the public at large, that careful and accurate statistics of the health, exposure, and mortality of the foreign missionaries should be prepared. When we take into consideration the years of constant study and the initial expense of fitting one for this field of labor; the difficulty in finding the right class of men, who are willing to peril their lives and health in this cause, at a time when wealthy congregations are willing to pay liberally for their services at home; and

especially the fact that the majority of them return with impaired health after a few years' exposure—the value of a single life rises to an importance which it is impossible for us to estimate in money, and the subject of knowing their sanitary and mortality experience, and of discovering such methods as will enable them to prolong their lives and usefulness, becomes a matter which ought to concern all who take an interest in the cause.

These tables also suggest the question whether some investigation should not be made, or statistical information obtained, to lessen the great excess of mortality among the female lives. In nearly all the mission fields the female mortality is from thirty to fifty per cent. greater than among males, which is far greater than the corresponding mortality among the sexes in the United States. It seems as if it would be but an act of justice towards that sex which makes the greatest sacrifices, who lead silent and uncomplaining lives among so much that is repugnant and disgusting to their finer sensibilities, that the causes which have produced this excess of mortality should be thoroughly investigated, and, if possible, measures taken to avoid it in the future.

SEPARATE MEDICAL EXAMINERS' REPORT.

If separating the medical examiners' report from the applications, and having it sent directly to the home office, without its coming into the hands of the agent, or its contents being known to the applicant himself, would secure the very desirable objects claimed for it by those who urge a separation, then of course mere considerations of convenience, either to the agent or to those whose duty it is to pass on the application, should not be allowed to prevent such separation.

By the course suggested it is urged that medical examiners will be more free and unrestrained, and therefore more candid and independent in their statements to the home office, and especially that they will be relieved from the embarrassment, and oftentimes from the injurious consequences, of being known as the cause of depriving the chagrined and disappointed applicant, who may be his friend or patron, of the benefits of life insurance. But would such results necessarily follow? I am persuaded that they would not.

Let us suppose a case. An application is made in regular form,—all the questions addressed to the applicant are answered in the most favorable manner,—the agent witnesses the signature, attests the regularity of the whole procedure, and forwards the application. The applicant is then taken to the regular appointee of the company, who, after making his examination, likewise forwards his report directly to the home office. In due time the agent is informed by the proper officer of the company that the application has been declined without assigning any reason therefor. Now under such circumstances, will either agent or applicant have any difficulty whatever in accounting for the rejection? Of course it will be attributed to the unfavorable report of the medical examiner—more especially as his was a "secret" report. Even in cases where he recommends the risk, if from any cause whatever the application is rejected, the secret medical report will be sure to be blamed for it. So far, therefore, from protecting medical examiners by the course indicated, their difficulties will be the rather increased.

As to the hope of securing a more candid and truthful report, that also, it is believed, will prove delusive. If the physician has not honesty and manliness enough; if professional honor and obligation are not motives sufficiently strong to induce him to faithfully perform his duty to the company which employs him, and which looks to him for an impartial report, it is useless to expect to obtain this in any other way.

The medical officer whose duty it is to pass on risks is, after all, governed far more in his decision by the facts stated in the application, and in the certificate of examination, than by the opinion of the risk expressed by the examiner; and if medical examiners were at all times careful and candid in stating all the necessary facts, their recommendation in the case would be of comparatively little importance.

There would seem, therefore, to be no sufficient reason for a separate medical report, especially where there are obvious advantages in keeping together all the papers relating to the same case.

It is true, however, that cases do occasionally arise in which the peculiar relations of the examiner to the party examined may be such as to render an unfavorable report in his case exceedingly embarrassing; but such contingencies are amply provided for in the directions laid down in our books of instruction for the guidance of medical examiners, where it is said: "If at any time it should become desirable to communicate to the company privately any fact or opinion, which it might not be proper to state in the certificate of examination, or if the relation of the examiner to the applicant should be such as to render an unfavorable report in any case prejudicial to his business, a private note addressed to the company, who will assume the responsibility of declining the risk, would effectually obviate all such difficulties; and it is to be hoped that medical examiners will not hesitate to pursue this course."

A Medical Director.

St. Louis, Nov. 26, 1873.

ON THE IMPORTANCE OF AN EXAMINATION OF THE URINE OF APPLICANTS FOR LIFE ASSURANCE.

BY A CANADIAN EXAMINER.

It has occurred to the writer that the importance of an examination of the urine of applicants for life assurance has to a certain extent been overlooked by assurance companies, and perhaps by some of their medical officers. No examiner would recommend a risk, no matter how robust the appearance of the individual or free from flaw his family history, without placing his ear over the heart and directing his attention more or less to the state of the lungs; but the kidneys, although equally subject to disease with the former, speaking generally, and of equal importance in the economy, are allowed to escape scrutiny, unless, indeed, the attention be arrested by some prominent symptom.

The prevalence of chronic structural renal diseases, and the tendency of many of them to terminate fatally; the obscurity of the early symptoms, and the comparative ease with which they may be concealed, indicate the necessity of an examination in the great majority of cases. It is not uncommon to meet with persons who have always enjoyed good health, but who latterly have suffered in a slight degree from flatulence and indigestion, which they ascribe to change of habits, or error in diet, or to temporary anxiety, which has also to account for the frequent headaches and neuralgic pains, and perhaps paleness of countenance. These

derangements may be so slight that the sufferer attaches little importance to them,—so little that he does not consider it necessary to consult his ordinary medical attendant, but either takes some simple domestic remedy, or trusts entirely to nature to right herself. It is almost needless to say, in this place, that the ailments mentioned above are frequently the only indications of the commencement of serious mischief in the kidney. In some important morbid states of that organ, there is little or no local pain to direct attention to the seat of disease. At length a puffiness about the eyelids or swelling of the feet startles the patient and his friends, and the cause of his previous indisposition is soon but too apparent. But there are other cases in which the symptoms are still more obscure and so trifling that the patient has ignored them altogether, and an attack of convulsions or the approach of coma, or the sudden appearance and rapid advance of dropsy, reveals the presence of a disease which in most instances tends to a fatal issue.

If the foregoing remarks be correct in a general way; if renal diseases be comparatively common, and sometimes without marked symptoms in the early stages, and if many of them tend to terminate fatally, then the necessity for testing the urine of persons applying for life assurance is as great as that of an examination of the heart by means of the stethoscope. It has been assumed that the managers of life companies are of a different opinion. In proof of this, it may be mentioned that some companies have an established rule that when the applicant desires a policy for over a certain fixed sum the urine shall be examined, implying, to some extent, that in ordinary cases this examination is superfluous. Most companies, however, have no rule in this respect, leaving the matter entirely in the hands of their examiners; and if their examiners were to insist on testing the urine of even a considerable proportion of the persons presented for examination, the probability is—as life assurance business is now conducted—that many of them would soon find their occupation, as such, gone.

Dr. Purdon, of Belfast, whose paper upon Medical Examination for Life Assurance appeared in the last number of the RECORD, since the above was written, is of opinion that "in all cases the specific gravity of the urine ought to be taken, and the urine tested, at least, for albumen."

Correspondence.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I have been a careful reader, from the first, of your Medical Department of Life Insurance, and I am much gratified in noticing the interest which is taken in the questions to whose discussion you have loaned your columns. But I am afraid this discussion has not always taken a very practical direction, and, at the risk of being tiresome in following a path already pretty well worn, I offer you a few suggestions as the result of some personal acquaintance with the subject-matter. I feel the more at liberty to do this since it seems quite clear to me that the topic will bear further investigation, and because I conceive that no one has as yet hit the nail just on the head. The question is, in fact, much broader than it is the custom to regard it, reaching as it does through every branch of the business of Life Insurance, and it appears quite as improbable that any very marked improvement is to result from an overhauling of medical examiners without, at the same time, correcting abuses which exist at the fountain-head whence all medical examiners may be said to flow, as it might be to attempt to straighten the course of the Mississippi by dredging some of the smaller streams which contribute to form the Missouri.

The medical examiner is only one of the factors—and one of the simplest ones—composing a very complex problem with many other factors, all more or less antagonistic, from whose combination the medical examiner's work, in greater or less perfection, is the resultant; and it is a curious thing that while life underwriters have universally acknowledged that a selection of lives is imperative, they have used the very means, in securing this selection, to render it as barren as possible of any good results. I have only to point you, sir, to the fact that, with few exceptions, medical examiners are selected, directly or indirectly, by the agents for whom their services are desired; and to what I believe is the greatest of all the evils enshrouding this whole business—that the agents' remuneration is made commensurate with the number of applicants accepted by his medical examiner. A premium is thus distinctly offered for dishonesty. What wonder, then, that it is gravely announced that the benefits of medical selection do not appreciably extend beyond two or three years, and, following the old doctrine of hebdomadal cycles, are entirely imperceptible after seven. The secretary of a life company, writing in one of the earlier numbers of the RECORD, has said that it is not so much incompetence of medical examiners which he fears, as the lack of a certain "moral qualification" to do justice to the companies. I suppose this is only an elegant way of saying that it is not incompetency but dishonesty which his company stands in dread of. If he will add, now, to his indictment: "and a great lack of care,"—a moral delinquency of another sort—I am ready to believe that he has come nearer to stating the whole case in a nutshell than any writer I have known.

But there is a point bearing upon this subject of life examinations which I have not seen touched upon at all, and it is one, I think, of very obvious import: Not every very good general practitioner may be qualified to make a thoroughly competent examination; for the problem of longevity is not to be decided upon exclusively by the methods of physical diagnosis, nor from any catalogue of general inquiries. Many suggestions as to the probable longevity of an assurant will present themselves to the mind of an examiner who has made the subject a careful study, which might not be thought of by another. With the one, the decision will be based upon broad principles, with due regard to all the concomitant events entering into the judgment; for the other, the whole investigation may be one of mere routine answering of certain printed questions. So that I imagine, Mr. Editor, that when, by and by, the millennium of life insurance is come, your medical examiner will be a specialist—at least in those districts sufficiently large to afford him an adequate support.

As a further objection to the employment of general practitioners—in large cities, let us say—it might be urged that the demands of practice leave insufficient time for the full discharge of the duties of the medical examiner. Every physician who has had much experience in life-insurance matters—and a good many who are not physicians, as I know—can hardly have failed to notice the insufficiency of the vast majority of medical examinations.

An applicant is brought to your office, having suffered perhaps for a fortnight the importunities of an

agent, who has at last brought him "up to the scratch" by wild promises of "dividends," and all the other "inestimable advantages" forming his stock in trade, and very possibly after having partaken on the way of certain diluted drinks, "to get his courage up;" he knows a medical examination is a formidable thing—to speak of—and so he is ushered into your presence

> "Like one who, on a lonesome road,
> Doth walk in fear and dread,"

You stand him up against the wall, take his height, measure his chest, percuss, auscultate, palpate, possibly look if he has a hernia, or poke your fingers under his ribs to see if he have an enlarged spleen or liver—and *presto!* the thing is done. It has occupied you, perhaps, twenty minutes. If you suggest to the agent that such an examination as this is not likely to elicit the fullest truth as to an applicant's condition, he will easily find other more complaisant medical examiners who will trouble him less than you. To such an extent reaches this desire to save time, and annoyance, and inconvenience to agents, that I have known certain medical men grown so astute through long experience that they can tell if an applicant is a good risk by simply looking him in the face and feeling his pulse, as men, they say, who have been kicked sufficiently immediately know if a boot is of calf-skin or of kip.

One other thing is worth a brief mention here: the manifest unfairness of the present system of classifying risks, which assumes the quite ridiculous proposition that one insurable life at a given age is equally good with any other insurable life of the same age. It can hardly be doubted, I think, that any just classification of lives should recognize differences similar to those made by the fire underwriters in their classifications. A fire-proof structure is insured at a certain rate, a wooden one at a certain other, and no one questions the custom which awards to the latter a higher rate than to the former. See now this curious contrast: Smith, who is a hearty, vigorous man, of good habits and healthful occupation, in whose family there is no suspicion of hereditary taint, and who is in every possible aspect an unexceptionable risk, is insured at the same rate as Brown, who is of less vigorous constitution and family, whose occupation is not so conducive to healthfulness, and who, in a word, may be of doubtful insurability at all. And this is what we facetiously call securing the benefits of medical selection!

I ask your indulgence, sir, for having taken up so much of your valuable space, but I feel more than a passing interest in your efforts to raise the standard of medical examinations, and I wish you in the heartiest manner good-speed. The task is one of no small difficulty, but with a proper co-operation on the part of the companies, its accomplishment may not be very remote. I am sorry, for the success of the undertaking, that one may not say of all medical examiners, as old Sangrado did of his pupil: *Tu étais savant, Gil Blas, avant que d'être médecin.*

San Francisco, November 10, 1873.

Miscellaneous.

A Centenarian.—There is now living at the Lye, Worcestershire, an old woman, who, on well-established evidence, has reached the age of 103. Her name is Sarah Hill, and she lives with a married daughter. For a number of years past she has been receiving 2s. a week from the parish, and she has all along asserted her age to be in accordance with the years given above, but her statement was doubted. She said she was baptized at Old Swinford Church in 1772, and that she well remembered walking there on the occasion, being at the time a little trot of between two and three years. Her friends, piqued apparently at the doubt entertained on the subject, have lately obtained a certificated extract from the parish register at Old Swinford, showing that she was baptized on December 15, 1772. Up to last year she was tolerably active, but she has now taken to her bed. At the last meeting of the Stourbridge Board of Guardians, it was resolved, on the recommendation of the relieving officer, to allow her an extra 6d. per week.—*Insurance Gazette, London.*

Mortality from Yellow Fever.—Several of our eastern life-insurance companies have suffered unexpected losses among their policy-holders by the recent epidemic of yellow fever at Shreveport and Memphis. We have searched in vain for any facts bearing upon the question of the influence of epidemics upon the mortality of insured lives, and would be glad to receive any communications that might enlighten our readers upon this topic.

By referring to the records of one company, we find that in 1852 the mortality was unexpectedly large, owing to the prevalence, in San Francisco more particularly, of a severe type of dysentery or diarrhœa. Out of 38 deaths, as many as 14 were due to these causes.

The institution of life insurance has not been long enough in existence to enable us to safely predict whether or not it could stand the strain of a severe epidemic such as even this city, for instance, has once or twice witnessed during the present century. With good sanitary laws, however, it is not likely that any of our Northern cities will again be visited with scourges of similar fatality.

Physical Aspects of Primogeniture.—Dr. Hough's promised article on "Physical Aspects of Primogeniture," is again postponed till the January 15th number of the Record.

Have you ever been Intoxicated? If so, when Last?—This question, in the new blanks spoken of in the last insurance number of the Record, meets, at the very outset, with strong opposition,—not from the agents, but from the persons to whom the question has to be put. They prefer not to have their social transgressions thus explicitly recorded.

The Variables Affecting Life.—Dr. T. S. Lambert brings the variables affecting life under eight heads:—

"First variable: *The Nature of Life.*—There is associated with life a lifetime, to wit: to all living things there is a natural lifetime which cannot be exceeded. Not only this, but the different parts or organs of a living thing may and usually do have different lifetimes. . . . . A man may be long-lived in regard to all his organs but one, and therefore appear generally well, hearty, and long-lived; but the discerning eye will read the truth. Second variable: *Ancestry.* Third variable: *Constitution.* Fourth variable: *Habits.*—The person's answers should be particular and definite, and when made again through the examiner are confirmatory or detective. Fifth variable: *Vocation.* Sixth variable: *Residence.* Seventh variable: *Intelligence* in regard to taking care of health. Eighth variable: *Instincts.*"
